1 Abstract

The rapid growth of economy makes China the largest energy consumer and sulfur 2 dioxide (SO₂) emitter in the world. In this study, we estimated the trends and step 3 changes in the planetary boundary layer (PBL) vertical column density (VCD) of SO₂ 4 from 2005 to 2015 over China measured by the Ozone Monitoring Instrument (OMI). We show that these trends and step change years coincide with the effective date and 6 period of the national strategy for energy development and relocation in northwestern 7 China and the regulations in the reduction of SO₂ emissions. Under the national 8 regulations in the SO₂ emissions reduction in eastern and southern China, SO₂ VCD 9 in the Pearl River Delta (PRD) of southern China exhibited the largest decline during 10 2005-2015 at a rate of -7% yr⁻¹, followed by the North China Plain (NCP) (-6.7% yr⁻¹), 11 Sichuan Basin (-6.3% yr⁻¹), and Yangtze River Delta (YRD) (-6% yr⁻¹), respectively. 12 The Mann-Kendall (MK) test reveals the step change points of declining SO₂ VCD in 13 2009 for the PRD and 2012-2013 for eastern China responding to the implementation 14 of SO₂ control regulation in these regions. In contrast, the MK test and regression 15 analysis also revealed increasing trends of SO₂ VCD in northwestern China, 16 particularly for several "hot spots" featured by growing SO₂ VCD in those large-scale 17 energy industry bases in northwestern China. The enhanced SO₂ VCD is potentially 18 attributable to increasing SO₂ emissions due to the development of large-scale energy 19 industry bases in energy-abundant northwestern China under the national strategy for 20 the energy safety of China in the 21st century. We show that these large-scale energy 21 industry bases could overwhelm the trends and changes in provincial total SO₂ 22

emissions in northwestern China and contributed increasingly to the national total SO₂ emission in China. Given that northwestern China is more ecologically fragile and uniquely susceptible to atmospheric pollution as compared with the rest of China, increasing SO₂ emissions in this part of China should not be overlooked and merit scientific research.

1. Introduction

Sulfur dioxide (SO₂) is one of the criteria air pollutants emitted from both anthropogenic and natural sources. The combustions of sulfur-containing fuels, such as coal and oil, are the primary anthropogenic emitters, which contributed to the half of total SO₂ emissions (Smith et al., 2011; Lu et al., 2010; Stevenson et al., 2003; Whelpdale et al., 1996). With the rapid economic growth in the past decades, China has become the world's largest energy consumer accounting for 23% of global energy consumption in 2015 (BIEE, 2016). Coal has been a dominating energy source in China and accounted for 70% of total energy consumption in 2010 (Kanada et al., 2013). The huge demand for coal and its high sulfur content make China the largest SO₂ emission source in the world (Krotkov et al., 2016; Su et al., 2011), which also accounted for two-third of Asia's total SO₂ emission (Ohara et al., 2007). From 2000 to 2006, the total SO₂ emission in China increased by 53% at an annual growth rate of 7.3% (Lu et al., 2010). To reduce SO₂ emission, from 2005 onward the Chinese government has issued and implemented a series of regulations, strategies, and SO₂ control measures, leading to a drastic decrease of SO₂ emission, particularly in eastern

and southern China (Lu et al., 2011; Li et al., 2010).

Recently, two research groups led by NASA (National Aeronautics and Space Administration) and Lanzhou University of China published almost simultaneously the temporal and spatial trends of SO₂ in China from 2005 to 2015 using the OMI retrieved SO₂ PBL column density after the OMI is launched for 11 years (Krotkov et al., 2016; Shen et al., 2016). The results reported by the two groups revealed the widespread decline of SO₂ in eastern China for the past decade. Shen et al. noticed, however, that, in contrast to dramatic decreasing SO₂ emissions in densely populated and industrialized eastern and southern China, the OMI measured SO₂ in northwestern China appeared not showing a decreasing trend. This is likely resulted from the energy industry relocation and development in energy-abundant northwestern China in the past decades under the national strategy for China's energy development and safety during the 21st century. Concern is raised about the potential impact of SO₂ emissions on the ecological environment and health risk in northwestern China because high SO₂ emissions could otherwise damage the rigorous ecological environment in this part of China, featured by very low precipitation and sparse vegetation coverage which reduce considerably the atmospheric removal of air pollutants (Ma and Xu, 2017). To assess and evaluate the risks of the ecological environment and public to the growing SO₂ emissions in northwestern China, it is necessary to investigate the spatiotemporal distributions of SO₂ concentrations and emissions. However, the

ground measurements of ambient SO₂ are scarce temporally and spatially in China,

and often subject to significant errors and uncertainties. Owing to the rapid progress in the remote sensing techniques, satellite retrieval of air pollutants has become a powerful tool for the assessment of emissions and spatiotemporal distributions of air pollutants. In recent several years, OMI (Dutch Space, Leiden, The Netherlands, embedded on Aura satellite) retrieved SO₂ column concentrations have been increasingly applied to elucidate the spatiotemporal variation of global and regional SO₂ levels and its emissions from large point sources, and evaluate the effectiveness of SO₂ control policies and measures (Krotkov et al., 2016; McLinden et al., 2015, 2016; Ialongo et al., 2015; Fioletov et al., 2015, 2016; Wang et al., 2015; Li et al., 2010). The decadal operation of the OMI provides the relatively long-term SO₂ time series data with a high spatial resolution which are particularly useful for assessing the changes and trends in SO₂ emissions induced by national regulations and strategies. The present study aims to (1) determine the spatiotemporal variations of SO_2 and its trend under the national plan for energy industry development in northwestern China by making use of the OMI-measured SO₂ data during 2005-2015; (2) to identify leading causes contributing to the enhanced SO₂ emission in northwestern China.

2 Data and methods

2.1 Satellite data

The OMI Ozone Monitoring Instrument (OMI) was launched on July 15, 2004, on the EOS Aura satellite, which is in a sun-synchronous ascending polar orbit with 1:45 pm local equator crossing time. It is an ultraviolet/visible (UV/VIS) nadir solar

backscatter spectrometer, which provides nearly global coverage in one day, with a spatial resolution of 13 km×24 km (Levelt et al. 2006a, 2006b). It provides global measurements of ozone (O₃), SO₂, NO₂, HCHO and other pollutants on a daily basis. The OMI uses spectral measurements between 310.5 and 340 nm in the UV-2 to detect anthropogenic SO₂ pollution in the lowest part of the atmosphere (Li et al., 2013). The instrument is sensitive enough to detect the near-surface SO₂. Previously, the OMI PBL SO₂ data were produced using the Band Residual Difference (BRD) algorithm (Krotkov et al., 2006), which have large noise and unphysical biases particularly at high latitudes (Krotkov et al., 2008). Subsequently, a principal component analysis (PCA) algorithm was applied to retrieve SO₂ column densities. This approach greatly reduces biases and decreases the noise by a factor of 2, providing greater sensitivity to anthropogenic emissions (Li et al., 2013). In the present study, we collected the level 3 OMI daily planetary boundary layer (PBL) SO₂ vertical column density (VCD) data in Dobson units (1 DU=2.69×10¹⁶ molecules cm⁻²) produced by the PCA algorithm (Li et al., 2013). The spatial resolution is 0.25°×0.25° latitude/ longitude, available at Goddard Earth Sciences Data and Information Services Center (http://disc.sci.gsfc.nasa.gov/Aura/data-holdings/OMI/omso2 v003.shtml). The systematic bias of PCA retrievals is estimated as ~0.5 DU for regions between 30°S and 30°N. The bias increases to \sim 0.7-0.9 DU for high latitude areas with large slant column O_3 but is still a factor of two smaller than that from **BRD** retrievals (https://disc.gsfc.nasa.gov/Aura/data-holdings/OMI/documents/v003/omso2readme-v120-2

107

108

109

0140926.pdf). As a result, the PCA algorithm may yield systematic errors for anthropogenic emission sources located in different latitudes and under complex topographic and underlying surface conditions. The air mass factors (AMFs) used to convert SO₂ slant column density (SCD) into VCD are also subject to uncertainties. Fioletov et al. (2016) revealed an overall AMF uncertainty of 28% which was created by surface reflectivity, surface pressure, ozone column, and cloud fraction. As Fioletov et al. (2016) noted, the PCA retrieved SO₂ VCD was virtually derived by using an AMF of 0.36 which is best applicable in the summertime in the eastern United States (US). Wang (2014) suggested adopting AMF≈0.57 in the estimate of SO₂ VCD distribution in eastern China. In the present study, we have taken the AMFs values in China provided by Fioletov et al. (2016) to adjust OMI measured VCD in the estimation of the SO₂ emission of the main point sources in northwestern China.

To evaluate and verify the spatial SO₂ VCD from OMI, ground SO₂ monitoring data of 2014 through 2015 at 188 sampling sites (cities) across China (Fig. 1), operated by the National Environmental Monitoring Center, available at http://www.aqistudy.cn/historydata. Annually averaged SO₂ air concentrations from 2005 to 2015 in 6 capital cities in Urumqi (Xinjiang), Yinchuan (Ningxia), Beijing (BTH and NCP), Shanghai (YRD), Guangzhou (PRD), and Chongqing (Sichuan Basin) were collected from provincial environmental bulletin published by the Ministry of Environmental Protection of China (MEPC) (http://www.zhb.gov.cn/hjzl/zghjzkgb/gshjzkgb. SO_2 anthropogenic emission inventory in China with a 0.25° longitude by 0.25° latitude resolution for every two years from 2008 to 2012 was adopted from Multi resolution Emission Inventory for China (MEIC) (Li et al., 2017, available at http://www.meicmodel.org).

The socioeconomic data in China were collected from the China Statistical Yearbooks and China Energy Statistical Yearbook, published by National Bureau of **Statistics** of China (NBSC), (http://www.stats.gov.cn/tjsj/ndsj/;http://tongji.cnki.net/kns55/Navi/HomePage.aspx? id=N2010080088&name=YCXME&floor=1), as well as China **National** Environmental Protection Plan in the Eleventh Five-Years (2006-2010) and Twelfth Five-Years (2011-2015) released by MEPC (http://www.zhb.gov.cn). These data include industrial GDP, coal consumption, thermal power generation, steel production, and SO₂ emission reduction plan, and they are presented in Table 1.

147

148

149

150

151

152

153

154

The long-term trends of SO₂ VCD were estimated by linear regressions of the gridded annually SO₂ VCD against their time sequence of 2005 through 2015. The gridded slopes (trends) of the linear regressions denote the increasing (positive) or decreasing (negative) rates of SO₂ VCD (Wang et al., 2016; Huang et al., 2015; Zhang et al., 2015, 2016).

The Mann-Kendall (MK) test was also employed in the assessments of the temporal trend and step change point year of SO₂ VCD time series. The MK test is a nonparametric statistical test (Mann,1945; Kendall, 1975), which is useful for assessing the significance of trends in time series data (Waked et al., 2016; Fathian et

al., 2016). The MK test is often used to detect a step change point in the long term trend of a time series dataset (Moraes et al., 1998; Li et al., 2016; Zhao et al., 2015). It is suitable for non-normally distributed data and censored data which are not influenced by abnormal values (Yue and Pilon, 2004; Sharma et al. 2016; Yue and Wang., 2004; Gao et al. 2016; Zhao et al., 2015). Recently, MK-test has also been used in trend analysis for the time series of atmospheric chemicals, such as persistent organic pollutants, surface ozone (O₃), and non-methane hydrocarbon (Zhao et al., 2015; Assareh et al.,2016; Waked et al.,2016; Sicard et al., 2016). Here the MK test was used to identify the temporal variability and step change point of SO₂ VCD for 2005-2015 which may be associated with the implementation of the national strategy and regulation in energy industry development and emission control during this period. Under the null hypothesis (no trend), the test statistic was determined using the following formula:

168
$$S_k = \sum_{i=1}^k r_i (k=2, 3, ..., n)$$
 (1)

where S_k is a statistic of the MK test, and

$$r_i = \begin{cases} +1, (x_i > x_j) \\ 0, (x_i \le x_j) \end{cases}$$
 (j=1,2, ...,i-1) (2)

where x_i is the variable in time series $x_1, x_2, ..., x_i, r_i$ is the cumulative number for $x_i > x_j$. The test statistic is normally distributed with a mean and variance is given by:

173
$$E(S_k) = k(k-1)/4$$
 (3)

174
$$Var(S_k) = \frac{k(k-1)(2k+5)}{72}$$
 (4)

From these two equations, one can derive a normalized S_i , defined by

176
$$UF_{k} = \frac{S_{k} - E(S_{k})}{\sqrt{Var(S_{k})}} \quad (k=1, 2, ..., n)$$
 (5)

- where UF_k is the forward sequence, the backward sequence UB_k is calculated using the same function but with the reverse data series such that UB_k =- UF_k .
 - In a two-sided trend test, a null hypothesis is accepted at the significance level if $|(UF_k)| \le (UF_k)_{1-\alpha/2}$, where $(UF_k)_{1-\alpha/2}$ is the critical value of the standard normal distribution, with a probability of a. When the null hypothesis is rejected (i.e., when any of the points in UF_k exceeds the confidence interval ± 1.96 ; P=0.05), a significantly increasing or decreasing trend is determined. $UF_k > 0$ often indicates an increasing trend and vice versa. The test statistic used in the present study enables us to discriminate the approximate time of trend and step change by locating the intersection of the UF_k and UB_k curves. The intersection occurring within the confidence interval (-1.96, 1.96) indicates the beginning of a step change point (Moraes et al., 1998; Zhang et al., 2011; Zhao et al., 2015).

2.4 Estimate of SO₂ emission from OMI measurements

To assess the connections between the major point sources in large-scale energy industrial bases in northwestern China and provincial emissions, we made use of OMI measured SO₂ VCD to inversely simulate the SO₂ emission from Ningdong Energy Chemical Industrial Base (NECIB) in Ningxia and Midong Energy Industrial Base (MEIB) in Xinjiang. McLinden et al. (2016) and Fioletov et al. (2015, 2016) have developed a source detection algorithm which fits OMI-measured SO₂ vertical

column densities to a three-dimensional parameterization function of the horizontal coordinates and wind speed. This algorithm was employed in the present study to estimate the SO_2 source strength in the two industrial bases and its contribution to the provincial total SO_2 emissions. The details of this algorithm are referred to Fioletov et al (2015). Briefly, the source detection algorithm uses a Gaussian function f(x, y) multiplied by an exponentially modified Gaussian function g(y, s) to fit the OMI SO_2 measurements (Fioletov et al., 2015) $OMI_{SO_2} = a \cdot f(x, y) \cdot g(y, s)$, defined by

$$f(x,y) = \frac{1}{\sigma_1 \sqrt{2\pi}} \exp(-\frac{x^2}{2\sigma_1^2});$$

$$g(y,s) = \frac{\lambda_1}{2} \exp(\frac{\lambda_1(\lambda_1 \sigma^2 + 2y)}{2}) \cdot \operatorname{erfc}(\frac{\lambda_1 \sigma^2 + y}{\sqrt{2}\sigma});$$

$$203 \qquad \sigma_1 = \begin{cases} \sqrt{\sigma^2 - 1.5y}, y < 0, \\ \sigma, y \ge 0 \end{cases};$$

$$(6)$$

$$\lambda_1 = \lambda/s;$$

$$\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^{\infty} e^{-t^2} dt$$

where x and y indicate the coordinates of the OMI pixel center (km); s is the wind speed (km h⁻¹) at the pixel center; a represents the total number of SO₂ molecules (or SO₂ burden) observed by OMI in a target emission source $\lambda = 1/\tau$, where τ is a decay time of SO₂, and σ describes the width or spread of SO₂.

The f(x, y) function represents the Gaussian distribution across the wind direction line. The function g(y, s) represents an exponential decay along the y-axis smoothed by a Gaussian function. Once σ and τ are determined, the SO₂ burden as a function of x, y, and s (OMI SO₂ (x, y, s)) can be reconstructed. SO₂ emission strength from a large point source can be estimated by $E=a/\tau$. In the present study, following Fioletov

(2016) we choose a mean value of σ =20 km and τ =6 h in the calculation of SO₂ emission large point sources of interested. Wind speed and direction on a 1°×1° latitude/longitude spatial resolution were collected from NCEP (National Centers for Environmental Prediction) Final Operational Global Analysis (http://dss.ucar.edu/datasets/ds083.2/). These data were interpolated to the location of each OMI pixel center on a 1/4°×1/4° latitude/longitude spacing.

There are several potential sources of errors which need to be taken into account when determining the overall uncertainty of the SO_2 emission estimation. Fioletov et al. (2016) have highlighted three primary sources of errors in the OMI-based emission estimates, including AMF, the estimation of the total SO_2 mass as determined from a linear regression, and the selection of σ and τ used to fit OMI measurements. Based on the coefficients of variation (CV, %) in these three error categories (McLinden et al., 2014, 2016; Fioletov et al.; 2016) listed in **Table S1** of Supplement, we estimated uncertainties in the SO_2 emissions derived from OMI measurements in the two major point sources in northwestern China by running the source detection model repeatedly for 10,000 times using Monte Carlo method. Results show the standard deviation of -35 to 122 kt/yr for SO_2 emissions in NECIB and -29 to 95 kt/yr for SO_2 emissions in MEIB from 2005 to 2015, respectively.

2.5 Satellite data validation

The OMI retrieved SO₂ PBL VCDs were evaluated by comparing with ambient air concentration data of SO₂ from routine measurements by local official operational air quality monitoring stations. The statistics between OMI retrieved SO₂

VCD and monitored annually averaged SO₂ air concentrations during 2014-2015 at 188 operational air quality monitoring stations across China are presented in Table S2 of Supplement. Figure S1 is the correlation diagram between SO₂ VCD and sampled data. As shown in Table S2 and Fig. S1, the OMI measured SO₂ VCDs agree well with the monitored ambient SO₂ concentrations across China at the correlation coefficient of 0.85 (p<0.05) (Table S2). Figure 2 further compares annually averaged SO₂ VCD and SO₂ air concentrations from 2005 to 2015 in 6 capital cities. These are Urumqi, Yinchuan, Beijing, Shanghai, Guangzhou, and Chongqing, respectively. The mean SO₂ concentration data were collected from provincial environmental bulletin published by the Ministry of Environmental Protection of China (MEPC) (http://www.zhb.gov.cn/hjzl/zghjzkgb/gshjzkgb). Results show that the annual variation of mean SO₂ VCD are higher than the measured SO₂ concentrations from 2010 to 2015, but SO₂ VCD match well with the monitored data except for Urumqi, the capital of Xinjiang Uygur Autonomous Region. The OMI retrieved SO₂ VCDs in Shanghai and Chongqing are higher than the measured concentrations in these two regions show consistent temporal fluctuation and trend. The measured SO₂ concentrations peaked in 2013 in Yinchuan whereas the SO₂ VCD reached the peak in 2012 and decreased thereafter. OMI measured SO₂ VCD in Urumqi shows different yearly fluctuations compared with its annual concentrations. The measured SO₂ concentrations in Urumqi decreased from 2011 to 2015 whereas the OMI measured SO₂ VCD did not illustrate obvious changes. In particular, the monitored mean SO₂ concentration from 2013 to 2015

250

251

252

253

254

255

decreased by 75% compared with that from 2005 to 2012. This is partly attributed to the change in air quality monitoring sites in Urumqi city. Before 2013, there were only three operational air quality sites in Urumqi City, all located in the heavily polluted downtown region. Since 2013, the air monitoring sites increased from 3 to 7. The four new sites are located in less polluted suburbs of the city. As a result, the spatially averaged SO₂ concentrations over 3 downtown air quality monitoring sites before 2013 were higher than the mean concentrations averaged over 7 monitoring sites (http://xjny.ts.cn/content/2012-06/05/content 6899388.htm). It is worth noting that the measured SO₂ concentration in Urumqi is the highest among all cities as shown in Fig. 2 whereas the OMI VCD value in Urumqi was lower than other selected cities. This may be due to systematic biases in OMI-retrieved SO₂ VCD. In the present study, the level 3 OMI PBL SO₂ VCD data produced by the PCA retrievals were used to estimate the spatiotemporal variation in SO₂ pollution in China. The PCA retrievals have a negative bias over some highly reflective surfaces in arid and semi-arid lands, such as many some places in the Sahara (up to about -0.5 DU in monthly **VCD** mean) (https://disc.gsfc.nasa.gov/Aura/data-holdings/OMI/documents/v003/omso2readmev120-20140926.pdf). Also, PCA retrievals is subject to the systematic bias of 0.7-0.9 DU in relatively high latitude regions. Located at a relatively high latitude in northwestern China with a large surrounding area covered by Gobi desert, the PCA algorithm might yield lower SO₂ VCD value in Urumqi than other cities shown in Fig. 2.

274

275

276

277

SO₂ emissions data were further collected to compare with annual OMI SO₂ VCD in selected regions. The results are presented in Fig. 3. As shown, the annual variation in SO₂ VCD agrees reasonably well with SO₂ emission data except for Urumqi-Midong region. The OMI measured SO₂ VCD in the PRD and Sichuan Basin decreased from 2008 to 2012, but SO₂ emission changed little. Compared with the other five marked regions (Fig. 1), the satellite measured SO₂ VCD in Urumqi-Midong declined in 2010 and inclined in 2012. However, SO₂ emissions in Urumqi-Midong 2012 are factors of 11 and 8 higher than that in 2008 and 2010, respectively. It should be noted that air pollutants released in the atmosphere are affected by physical and chemical processes. They may be transported over large distances by atmospheric motions, transformed into other compounds by chemical or photochemical processes, and "washed out" or deposited at the Earth's surface (Zhao et al., 2017; Brasseur et al., 1998). The atmospheric removal and advection processes may also contribute to the inconsistency between monitored and satellite observations. In addition, the MEIC SO₂ emission inventory from the bottom-up approach might be subject to large uncertainties due to data manipulation, and the lack of sufficient knowledge in human activities and emissions from different sources (Li et al., 2017; Zhao et al., 2011; Lu et al., 2011; Kurokawa et al., 2013). The uncertainties in the MEIC estimated SO₂ emissions used in the present study are up to $\pm 12\%$ (Li et al., 2017). As shown in Fig. 3, the OMI measured SO₂ VCD from 2008 to 2012 in Urumqi-Midong was about 0.2 DU which was comparable with that in the EGT. However, the reported SO₂ emission in Urumqi-Midong was only 4% of the SO₂

emission in the EGT in 2012 and 0.5% of that in the EGT from 2008 to 2010. It might be subject to that part large SO₂ emission sources were not included in emission inventory. From this perspective, the satellite remote sensing provides a very useful tool in monitoring SO₂ emissions from large point sources and in the verification of emission inventories (Fioletov et al., 2015, 2016; McLinden et al., 2016; Wang et al., 2015;).

3 Results and discussion

3.1. OMI measured SO₂ in China

Given higher population density and stronger industrial activities, eastern and southern China are traditionally industrialized and heavily contaminated regions by air pollutions and acid rains caused by SO₂ emissions. **Figure 4a** shows annually averaged OMI SO₂ VCD over China on a 0.25° × 0.25° latitude/longitude resolution averaged from 2005 to 2015. SO₂ VCD was higher considerably in eastern and central China, and Sichuan Basin than that in northwestern China. The highest SO₂ VCD was found in the NCP, including Beijing-Tianjin-Hebei (BTH), Shandong, and Henan province. The annually averaged SO₂ VCD between 2005-2015 in this region reached 1.36 DU. This result is in line with previous satellite remote sensing retrieved SO₂ emissions in eastern China (Krotkov et al 2016; Lu et al., 2010; Bauduin et al., 2016; Jiang et al 2012; Yan et al., 2014). However, in contrast to the spatial distribution of decadal mean SO₂ VCD (**Fig. 4a**), the slopes of the linear regression relationship between annual average OMI-retrieved SO₂ VCD and the

time sequence from 2005 to 2015 over China show that the negative trends overwhelmed industrialized eastern and southern China, particularly in the NCP, Sichuan Basin, the YRD, and PRD, manifesting significant decline of SO₂ emissions in these regions. SO₂ VCD in the PRD exhibited the largest decline at a rate of 7% yr⁻¹, followed by the NCP (6.7% yr⁻¹), Sichuan Basin (6.3% yr⁻¹), and the YRD (6% yr⁻¹), respectively. Annual average SO₂ VCD in the PRD, NCP, Sichuan Basin, and YRD decreased by 52%, 50%, 48%, and 46% in 2015 compared to 2005 (Fig. 5), though the annual fluctuation of SO₂ VCD shows rebounds in 2007 and 2011 which are potentially associated with the economic resurgence stimulated by the central government of China (He et al., 2009; Diao et al., 2012). The reduction of SO₂ VCD after 2011 in these regions reflects virtually the response of SO₂ emissions to the regulations in the reduction of SO₂ release, the mandatory application of the flue-gas desulfurization (FGD) on coal-fired power plants and heavy industries, and the slowdown in the growth rate of the Chinese economy (CSC, 2011a; Wang et al., 2015, Chen et al., 2016).

342

343

344

Since in the MK test the signs and fluctuations of UF_k are often used to predict the trend of a time series, this approach is further applied to quantify the trends and step changes in annually SO_2 VCD time series in those highlighted regions (a-f) in **Fig. 4b** from 2005 to 2015. Results are illustrated in **Fig. 6**. As shown, the forward and backward sequences UF_k and UB_k intersect at least once from 2005 to 2015. These intersections are all well within the confidence levels between -1.96 and 1.96 at the statistical significance α =0.01. A common feature of the forward sequence UF_k in

eastern and southern China provinces is that UF_k has been declining and become negative from 2007 to 2009 onward (Fig. 6a-d), confirming the downturn of SO₂ atmospheric emissions and levels in these industrialized and well-developed regions in China. The step change points of OMI measured SO₂ VCDs in the NCP, YRD and Sichuan Basin occurred between 2012 and 2013. These step change points coincide with the implementation of the new Ambient Air Quality Standard in 2012, which set a lower ambient SO₂ concentration limit in the air (MEPC, 2012), and the Air Pollution Prevention and Control Action Plan in 2013 by the State Council of China (CSC, 2013a). This Action Plan requests to take immediate actions to control and reduce air pollution in China, including cutting down industrial and mobile emission sources, adjusting industrial and energy structures, and promoting the application of clean energy in the BTH, YRD, PRD and Sichuan Basin. The step change in SO₂ VCD over the PRD occurred in the earlier year of 2009-2010 and from this period onward the decline of SO_2 VCD speeded up, as shown by the forward sequence UF_k which became negative since 2007 and was below the confidence level of -1.96 after 2009, suggesting significant decreasing VCD from 2009 (Fig. 6c). In April 2002, the Hong Kong Special Administrative Region (HKSAR) Government and the Guangdong Provincial Government reached a consensus to reduce, on a best endeavor basis, the anthropogenic emissions of SO₂ by 40% in the PRD by 2010, using 1997 as the base year (http://www.epd.gov.hk/epd/english/action blue sky/files/exsummary e.pdf). By the end of 2010, all thermal power units producing more than 0.125 million kilowatts

365

electricity in the PRD were equipped with the FGD. During the 11th Five-Year Plan (2006-2010), the thermal power units with 1.2 million kilowatts capacity have been shut down. SO₂ emission was reduced by 18% in 2010 compared to that in 2005 (NBSC, 2006, 2011). This likely caused the occurrence of the step change in SO₂ VCD over 2009-2010.

383

384

385

386

387

388

As also shown in Fig. 4b, in contrast to widespread decline of SO₂ VCD, there are two "hot spots" featured by moderate increasing trends of SO₂ VCD, located in the China's Energy Golden Triangle (EGT, Shen et al., 2016, Ma and Xu, 2017) and Urumqi-Midong region in northwestern China. The annual growth rate of SO₂ VCD from 2005 to 2015 are 3.4% yr⁻¹ in the EGT and 1.8% yr⁻¹ in Urumqi-Midong, respectively (Fig. 4b). SO₂ VCD in these two regions peaked in 2011 and 2013 which were 1.6 and 1.7 times of that in 2005 (Fig. 5). The raising SO₂ VCD in the part of the EGT have been reported by Shen et al. (2016). The second hot spot is located in Urumqi-Midong region including MEIB that is about 40 km away from Urumqi. The both EGT and MEIB are featured by extensive coal mining, thermal power generation, coal chemical, and coal liquefaction industries. The reserve of coal, oil and natural gas in the EGT is approximately 1.05×10¹² ton of standard coal equivalent, accounting for 24% of the national total energy reserve in China (CRGECR, 2015). It has been estimated that there are deposits of 20.86 billion tons of oil, 1.03 billion cubic meters of natural gas, and 2.19 trillion tons of coal in Xinjiang, accounting for 30%, 34% and 40% of the national total (Dou, 2009). Over

the past decades, a large number of energy-related industries have been constructed in northwestern China, such as the EGT and MEIB to enhance China's energy security in the 21st century and speed up the local economy. The rapid development of energy and coal chemical industries in Ningxia Hui Autonomous Region and Xinjiang of northwestern China alone resulted in the significant demands to coal mining and coal products. The coal consumption, thermal power generation, and the gross industrial output increased by 2.7, 3.5, and 6.6 times in Ningxia from 2005 to 2015, and by 2.7, 4.2 and 6.6 times in Xinjiang during the same period (NBSC, 2005, 2015). As a result, SO₂ emissions increased markedly in these regions, as shown by the increasing trends of SO₂ VCD in the EGT and Urumqi-Midong region (Fig. 4b). The MK forward sequence further confirms the increasing SO₂ VCD in the EGT and Urumqi-Midong. As seen in Fig. 6e and 6f, the UF_k values for SO₂ VCD are positive and growing, illustrating clear upward trends of SO₂ VCD over these two large-scale energy industry bases, revealing the response of SO₂ emissions to the energy industry relocation and development in northwestern China. To guarantee the national energy security and to promote the regional economy, the EGT energy program has been accelerating since 2003 under the national energy development and relocation plan (Zhu and Ruth, 2015; Chen et al., 2016), characterized by the rapid expansion of the NECIB which is located about 40 km away from Yinchuan, the capital of Ningxia (Shen et al., 2016). By the end of 2010, a large number of coal chemical industries, including the world largest coal liquefaction and thermal power

plants, have been built and operated, and the total installed capacity of thermal power

403

404

405

406

407

408

409

generating units has reached 1.47 million kilowatts (Zhao, 2016). Under the same national plan, the MEIB in Xinjiang started to construction and operation from the early to mid-2000s which have almost the same industrial structures as those in the EGT, featured by coal-fired power generation, coal chemical industry, and coal liquefaction.

The statistical significant step change points of SO₂ VCD in the EGT and Urumqi-Midong took place in 2006 and 2009 (**Fig. 6e** and **6f**), differing from those regions with decreasing trends of SO₂ VCD in eastern and southern China. The first step change point in 2006-2007 corresponds to the increasing SO₂ emissions in these two large-scale energy bases till their respective peak emissions in EGT (2007) and Urumqi-Midong (2008). The second step change point in 2009 coincides with the global financial crisis in 2008 which slowed down considerably the economic growth in 2009 in China, leading to raw material surplus and the remarkable reduction in the demand for coal products.

3.3 OMI SO₂ time series and step change point year in northwestern China

The clearly visible "hot spots" featured by increasing OMI measured SO₂ VCD in the EGT/NECIB and MEIB raise a question: to what extent could these large-scale energy industrial bases affect the trend and fluctuations of SO₂ emissions in northwestern China? **Figure 7** illustrates the fractions of OMI measured annual SO₂ VCD and SO₂ emissions averaged over the 6 provinces of northwestern China in the annual national total VCD (**Fig. 7a**) and emissions (**Fig. 7b**) from 2005 to 2015. The both SO₂ VCD and emission fractions in northwestern China in the

national total increased over the past decade. By 2015, the mean SO₂ VCD fraction in 6 northwestern provinces has reached 38% in the national total. The mean emission fraction was about 20% in the national total. It should be noted that there were large uncertainties in provincial SO₂ emission data which often underestimated SO₂ emissions from major point sources (Li et al., 2017; Han et al., 2007). In this sense, OMI retrieved SO₂ VCD fraction provides a more reliable estimate to the contribution of SO₂ emission in northwestern China to the national total.

The annual percentage changes in SO₂ VCD from 2005 onward are consistent well with the per capita SO₂ emissions in China (**Fig. 8**). As aforementioned, while the annual total SO₂ emissions in the well-developed BTH, YRD, and PRD were higher than that in northwestern provinces, the per capita emissions in all provinces of northwestern China, especially in Ningxia and Xinjiang where the NECIB and MEIB are located, were about factors of 1 to 6 higher than that in the BTH, YRD, and PRD, as shown in **Fig. 8**. In contrast to declining annual emissions from the BTH, YRD, and PRD, the per capita SO₂ emissions in almost all western provinces have been growing from 2005 onward.

Since almost all large-scale coal chemical, thermal power generation, and coal liquefaction industries were built in energy-abundant and sparsely populated northwestern China over the past two decades, particularly since the early 2000s, those large-scale industrial bases in this part of China likely play an important role in the growing SO₂ emissions in northwestern provinces. We further examine the OMI retrieved SO₂ VCD to confirm and evaluate the changes in SO₂ emissions in

northwestern China which should otherwise respond to these large-scale energy programs under the national plan for energy relocation and expansion. **Figure 9** displays the MK test statistics for SO_2 VCD in the 6 provinces in northwestern China from 2005-2015. The forward sequence UF_k suggests decreasing trends in Shaanxi and Gansu provinces and a moderate increase in Qinghai province. In Xinjiang and Ningxia where the most energy industries were relocated and developed for the last decade (2005-2015), as aforementioned, UF_k time series estimated using SO_2 VCD data illustrate clear upward trends. Compared with those well-developed regions in eastern and southern China, the UF_k values of SO_2 VCD in these northwestern provinces are almost all positive, except for Shaanxi province where the UF_k turned to negative from 2008, and Gansu province where the UF_k value become negative during 2012-2013.

The step change points identified by the MK test for SO_2 VCD in northwestern China appear associated strongly with the development and use of coal energy. As shown in **Fig. 9**, the intersection of the forward and backward sequences UF_k and UB_k within the confidence levels of -1.96 (straight green line) to 1.96 (straight purple line) can be identified in 2006 and 2007 in Ningxia and Xinjiang, respectively, corresponding well to the expansion of two largest energy industry bases from 2003 onward in Ningxia (NECIB) and Xinjiang (MEIB). The step change point of SO_2 VCD in 2012 in Gansu province coincides with fuel-switching from coal to gas in the capital city (Lanzhou) and many other places of the province initiated from 2012 (CSC, 2013b). The MK derived step change point in Shaanxi province occurred in

2010 which was a clear signal of marked decline of fossil fuel products in northern Shaanxi where, as the part of the EGT (Ma and Xu, 2017) of China, the largest energy industry base in the province is located, right after the global financial crisis.

492

493

494

495

496

497

498

It is interesting to note that the forward sequences UF_k of SO_2 VCD (**Fig. 9e** and f) in Ningxia and Xinjiang exhibit the similar fluctuations as that in Ningdong (NECIB) and Urumqi-Midong (MEIB) (Fig. 9e and f), manifesting the potential associations between the SO₂ emissions in these two large-scale energy industrial bases (major point sources) and provincial emissions in Ningxia and Xinjiang, respectively. This suggests that large-scale energy industrial bases might likely overwhelm or play an important role in the SO₂ emissions in those energy-abundant provinces in northwestern China. Figure 10 illustrates mean SO₂ VCD from 2005 to 2015 in northern Xinjiang (Fig. 10a) and Ningxia (Fig. 10b). The largest concentrations can be seen clearly in the MEIB and the NECIB in these two minority autonomous regions of China. Lower SO2 concentrations are illustrated in mountainous areas of northern Xinjiang. Based on inverse modeling of SO₂ burdens $(a, 10^{26} \text{ molecules})$ in the source detection model (section 2.4), we estimated SO₂ emission (E, kt yr⁻¹) in the NECIB and MEIB from 2005 to 2015, defined by $E=a/\tau$, where τ is a decay time of SO₂ (section 2.4). The results are illustrated in Fig. 11. As shown, the SO₂ emission increased from 2005 and reached the maximum in 2011 in the NECIB and declined thereafter, in line with the annual SO₂ VCD fluctuations in this energy industry base which is, as aforementioned, attributable to the economic rebound in 2011 in China. Of particular interest is the large fractions of the estimated

SO₂ emission in the NECIB in Ningxia Province (Fig. 11a) from 2005 to 2015. These large fractions suggest that this energy industry park alone contributed up to more than 50% emission to the provincial total SO₂ emission. Likewise, the OMI SO₂ VCD derived SO₂ emissions in the MEIB also made an appreciable contribution (15-20%) to the provincial total SO₂ emission in Xinjiang. Covered by a large area of Gobi desert (Junngar Basin), there are only a few of SO₂ emission sources in vast northern Xinjiang region (total area of Xinjiang is 1.66×10^6 km²). This likely leads to the small fractions of SO₂ emissions in the MEIB in the total SO₂ emission in Xinjiang. Figure 11c and 11d show SO₂ VCDs (the left y-axis) and the ratios (the right y-axis) of the mean VCDs in NECIB and MEIB to the provincial mean VCDs in Ningxia and Xinjiang from 2005 to 2015, respectively. It can be seen that the maximum mean SO₂ VCD over the MEIB is about a factor of 4.5 greater than the mean SO₂ VCD over Xinjiang province (Fig. 11d), This ratio is larger than the ratio (2.9) of the SO₂ VCD in the NECIB to the SO₂ VCD averaged over Ningxia province (Fig. 11c). Nevertheless, overall our results manifest that, although there were only a small number of SO₂ point sources in these two energy industrial bases, the SO₂ emissions from the NECIB and MEIB made significant contributions to provincial total emissions. Given that the national strategy for China's energy expansion and safety during the 21st century is, to a large extent, to develop large-scale energy industry bases in northwestern China, particularly in Xinjiang and Ningxia (Zhu and Ruth, 2015; Chen et al., 2016) where the energy resources are most abundant in China, we would expect that the rising SO₂ emissions in northwestern China would

499

increasingly be attributed to those large-scale energy industry bases and contributed to the national total SO_2 emission in China.

Table 1 presents the annual average growth rates of SO₂ VCD, industrial (second) Gross Domestic Product (GDP), and major coal-consuming industries in northwestern China and three developed areas (BTH, YRD, PRD) in eastern and southern China. The positive growth rates of SO₂ VCD can be observed in the three provinces and autonomous regions (Qinghai, Ningxia, and Xinjiang) of northwestern China. Although the growth rates of SO₂ VCD in other two provinces (Gansu and Shaanxi) are negative, the magnitudes of the negative growth rates are smaller than those in the BTH, YRD, and PRD, except for Zhejiang province in the YRD. This regional contrast reflects both their economic and energy development activities and the SO₂ emission control measures implemented by the local and central governments of China. Although China has set a national target of 10% SO₂ emission reduction (relative to 2005) during 2006-2010 and 8% (relative to 2010) during 2011-2015 (CSC, 2007; CSC, 2011b), under the Grand Western Development Program of China, the regulation for SO₂ emission control was waived in those energy-abundant provinces of northwestern China in order to speed up the large-scale energy industrial bases and local economic development, and improve local personal income. Also, although FGDs were widely installed in coal-fired power plants and other industrial sectors since the 1990s, by 2010 as much as 57% of these systems were installed in eastern and southern China (Zhao et al., 2013). The capacity of small power generators which were shut-down in western China was merely about 10808 MW, only accounting for about 19% of the capacity of total small power plants which were eliminated in China (55630 MW) during the 11th Five-Year Plan period (2006-2010) (Cui et al., 2016). As shown in **Table 1**, the SO₂ emission reduction plans virtually specified the zero percentage of SO₂ emission reductions in Qinghai, Gansu, and Xinjiang and lower reduction percentage in the emission reduction in Ningxia and Inner Mongolia as compared to eastern and southern China during the 11th (2006-2010) and 12th (2011-2015) Five-Year Plan. As a result, the average growth rate for thermal power generation, steel production, and coal consumption from 2005 to 2015 in northwestern China reached 14.1% yr⁻¹, 35.7% yr⁻¹, and 11.9% yr⁻¹, considerably higher than the averaged growth rates over eastern and southern China (5.9% yr⁻¹ in the BTH, 0.8% yr⁻¹ in the YRD, and 2.3% yr⁻¹ in the PRD).

4 Conclusions

The spatiotemporal variation in SO₂ concentration during 2005-2015 over China was investigated by making use of the PBL SO₂ column concentrations measured by the OMI. The highest SO₂ VCD was found in the NCP, the most heavily polluted area by SO₂ in China, including Beijing-Tianjin-Hebei, Shandong, and Henan province. Under the national regulation for SO₂ control and emission reduction, the SO₂ VCD in eastern and southern China underwent widespread decline during this period. However, the OMI measured SO₂ VCD detected two "hot spots" in the EGT (Ningxia-Shaanxi-Inner Mongolia) and Midong (Xinjiang) energy industrial bases, in contrast to the declining SO₂ emissions in eastern and southern

China, displaying an increasing trend with the annual growth rate of 3.4% yr⁻¹ in the EGT and 1.8% yr⁻¹ in Midong, respectively. The trend analysis further revealed enhanced SO₂ emissions in most provinces of northwestern China likely due to the national strategy for energy industry expansion and relocation in energy-abundant northwestern China. As a result, per capita SO₂ emission in northwestern China has exceeded industrialized and populated eastern and southern China, making increasing contributions to the national total SO₂ emission. The estimated SO₂ emissions in the Ningdong (Ningxia) and Midong (Xinjiang) energy industrial bases from OMI measured SO₂ VCD showed that the SO₂ emissions in these two industrial bases made significant contributions to the total provincial emissions. This indicates, on one side, that the growing SO₂ emissions in northwestern China would increasingly come from those large scale energy industrial bases under the national energy development and relocation plan. On the other side, this fact also suggests that it is likely more straightforward to control and reduce SO₂ emissions in northwestern China because the SO₂ control measures could be readily implemented and authorized in those state-owned large-scale energy industrial bases.

848

851 Table 1 Annual growth rate for OMI SO₂ VCD and economic activities for

individual provinces and municipality during 2005-2014 (% yr⁻¹), and SO₂ emission reduction plan during the 11th and 12th Five-Year Plan period (%).

Region		OMI SO ₂ VCD	coal consumption	Industrial GDP	Thermal power generation	steel production	SO ₂ emission reduction plan (%)	
							2006-2010 ^a	2011-2015 ^b
Northwest ern	Inner Mongolia	0.94	11.29	20.48	14.07	8.38	-3.8	-3.8
	Shaanxi	-3.41	13.14	19.96	13.01	14.48	-12	-7.9
	Gansu	-0.09	6.69	14.19	8.89	9.92	0	2.0
	Qinghai	0.69	11.20	18.70	9.88	12.37	0	16.7
	Ningxia	0.95	11.79	17.44	15.04	152.71	-9.3	-3.6
	Xinjiang	1.57	17.21	14.21	23.39	16.27	0	0
ВТН	Beijing	-3.59	-6.13	9.13	5.99	-48.52	-20.4	-13.4
	Tianjin	-4.63	3.15	15.84	6.01	10.19	-9.4	-9.4
	Hebei	-5.05	4.16	12.37	6.22	10.70	-15	-12.7
YRD	Shanghai	-7.65	-0.93	6.64	0.86	-0.92	-26.9	-13.7
	Jiangsu	-5.93	5.39	12.51	7.49	13.35	-18.0	-14.8
	Zhejiang	-2.07	4.04	11.40	8.68	13.94	-15.0	-13.3
PRD	Guangdong	-4.55	6.15	12.03	5.92	6.87	-15.0	-14.8

a and b represents proposed reduction in SO₂ emission in 2010 relative to 2005, and 2015 relative to 2010, respectively. The value for PRD refers to the proposed target for Guangdong Province.

Figure Captions

Figure 1 Provinces, autonomous regions, and selected regions in China in this investigation. Northwestern China, defined by pink slash, includes Inner Mongolia, Shaanxi, Gansu, Oinghai, Ningxia, and Xinjiang province. Light green shadings with cross highlight Beijing-Tianjin-Hebei (BTH) and the light green color stands for the North China Plain (NCP, including BTH), including BTH, Shandong, and Henan province. The Sichuan Basin, Yangtze River Delta (YRD), and Pearl River Delta (PRD) is defined by yellow, pink, and blue color. The Urumqi-Midong region including Midong energy industrial base (MEIB) is defined by brick red. The Energy Golden Triangle (EGT), defined by purple color, including Ningdong energy chemical industrial base (NECIB) in Ningxia, Yulin in Shaanxi, and Erdos in Inner Mongonia. Red triangles indicate 188 monitoring sites across China. Blue solid circles indicate 6 selected cities in Fig. 2.

Figure 2 Annually averaged SO_2 VCD (DU), scaled on the right-hand-side y-axis and measured annual SO_2 air concentration ($\mu g/m^3$), scaled on the left-hand-side y-axis, in Beijing, Shanghai, Chongqing, Guangzhou, Yinchuan, and Urumqi.

Figure 3 Annually averaged SO₂ VCD (DU), scaled on the right-hand-side y-axis and annual emissions (thousand ton/yr) of SO₂ on the left-hand-side y-axis in the NCP, YRD, PRD, Sichuan Basin, EGT, and Urumqi-Midong.

Figure 4 Annual averaging OMI-retrieved vertical column densities of SO_2 (DU) and their trends from 2005 to 2015 on $0.25^{\circ} \times 0.25^{\circ}$ latitude/longitude resolution in China. (a). Annual mean SO_2 vertical column densities; (b). slope (trend) of linear regression relationship between annual average OMI-retrieved SO_2 VCD and the time sequence from 2005 to 2015 over China. The positive values indicate an increasing trend of SO_2 VCD from 2005 to 2015, and vice versa. The blue circle highlights the six selected regions where SO_2 VCD displayed dramatic change for further assessment of the long term trends and step change points in SO_2 VCD. These six regions are NCP (a), YRD (b), PRD (c), Sichuan Basin (d), Energy Golden Triangle (EGT, e), and Urumqi-Midong region (f).

Figure 5 Percentage changes in annual mean OMI SO₂ VCD in the four highlighted regions in eastern and southern China and two large-scale energy industry bases in the EGT and Urumqi-Midong region in **Figure 4b** (relative to 2005).

Figure 6 Mann-Kendall (MK) test statistics for annually SO_2 VCD in those highlighted regions (**Figs. 1** and **4b**) from 2005-2015. The blue solid line is the forward sequence UF_k and the red solid line is the backward sequence UB_k defined by Eq (5). The positive values for UF_k indicate an increasing trend of SO_2 VCD, and vice versa. Two straight solid lines stand for confidence interval between -1.96 (straight green line) and 1.96 (straight purple line) in the MK test. The bold black line in the middle highlights zero value of UF_k and UB_k . The bold black line in the

middle highlights zero value of UF_k and UB_k . The intersection of UF_k and UB_k sequences within the intervals between two confidence levels indicates a step change point.

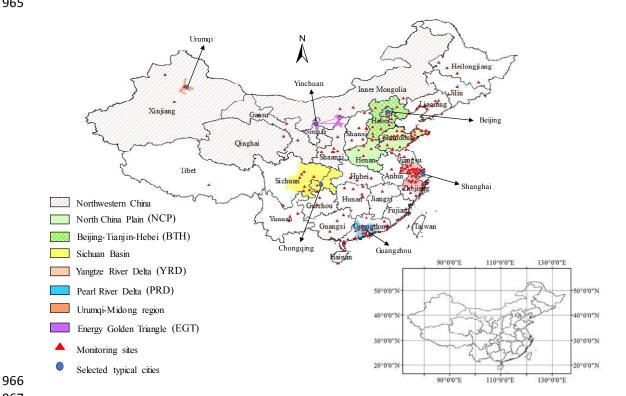

Figure 7 Annual fractions of OMI retrieved SO_2 VCD and emissions averaged over 6 northwestern provinces in the national total SO_2 VCD from 2005 to 2015 and emission from 2005 to 2014. (a) fraction of annual mean SO_2 VCD; (b) fraction of annual mean emission. Fractions of SO_2 VCD are calculated as the ratio of the sum of annually averaged SO_2 VCD in northwestern China to the sum of annually averaged SO_2 VCD in the national total from 2005 to 2015 (%).

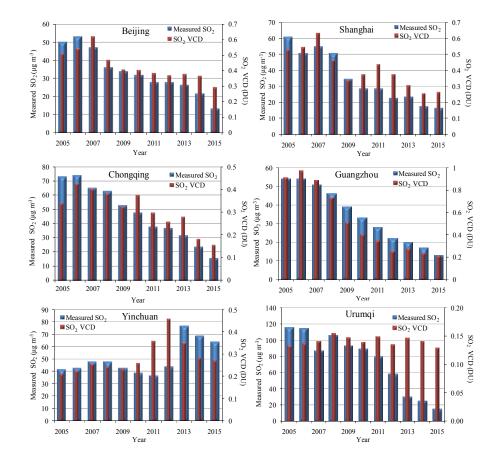

Figure 8 Per capita SO₂ emission in six provinces of northwestern China and three key eastern regions (tons/person). The value for PRD refers to the per capita SO₂ emission for Guangdong province.

Figure 9 Mann-Kendall (MK) test statistics for annually averaged SO₂ VCD in six provinces in northwestern China from 2005-2015. The blue solid line is the forward sequence UF_k and the red solid line is the backward sequence UB_k defined by Eq (5). The positive values of UF_k indicate an increasing trend of SO₂ VCD, and vice versa. Two straight solid lines stand for confidence interval between -1.96 (straight green line) and 1.96 (straight purple line) in the MK test. The intersection of UF_k and UB_k sequences within intervals between two confidence levels indicates a step change point.

Figure 10 Annually averaging OMI-retrieved vertical column densities of SO₂ (DU) in two major point sources, the MEIB in Xinjiang (a), and the NECIB in Ningxia (b).

Figure 11 Annually averaged SO₂ emissions (kt yr⁻¹) and SO₂ VCD (DU) in the NECIB and MEIB, and their fractions in provincial total SO₂ emission and ratios between SO₂ VCD in these two regions and that in province. (a). SO₂ emission (blue bar) in the NECIB and its fraction (red solid line) in the total provincial SO₂ emission in Ningxia; (b). SO₂ emission (blue bar) in the MEIB and its fraction (red solid line) in the total provincial SO₂ emission in Xinjiang. (c). SO₂ VCD (blue bar) in the NECIB and the ratio (red solid line) between SO₂ VCD in the NECIB and that in Ningxia; (d). SO₂ VCD (blue bar) in the MEIB and the ratio (red solid line) between SO₂ VCD in the MEIB and that in Xinjiang; The left y-axis stands for SO₂ emission and the right y-axis denotes the fraction (%) at the upper panel. The left y-axis stands for SO₂ VCD (DU) and the right y-axis denotes the ratio at the lower panel. The error bars denotes the standard deviations of Source Detection Algorithm estimated SO₂ emission in two major point sources.
