Abstract. Interactions between absorbing aerosols and the planetary boundary layer (PBL) play an important role in enhancing air pollution near the surface. In this study, a unique feature of the interaction is found that has important implications in monitoring and combating air pollution. Opposite trends in aerosol loading between the lower and upper PBL are found on a wide range of time scales and from different types of data acquired by various platforms: from a short-term field experiment to decadal satellite observations, and multi-decadal ground observations in China. A novel method is proposed to obtain the vertical profiles of aerosol loading from passive sensors by virtue of varying elevations. Trend analyses of three particulate variables having different temporal scales, namely, visibility, aerosol optical depth, and extinction, all exhibit the same trend: increasing at the lower atmosphere, but decreasing in the upper. Column-integrated quantities are much less variable. The reversal trend is consistent with the strong vertical gradients in the aerosol-induced atmospheric heating rate that unevenly modifies the atmospheric temperature profile and alters the stability differently. These findings have multiple implications in understanding and combating air pollution, especially in many developing countries producing large amounts of black and brown carbon aerosols.

1 Introduction

Air pollution induced by rapid industrialization and urbanization over the past decades has become a critical constraint for sustainable development in China. Aerosol particulate pollutants, or aerosols in general, can also alter weather and climate due to their radiative and microphysical effects. Heavy aerosol loading over China as revealed by both ground and satellite observations has a significant influence on a wide range of meteorological variables and may play significant roles in the climate change of China (Wu et al., 2016) and the Asian monsoon system (Li et al., 2016).

The frequent occurrence of hazy weather in China has severely undermined people's lives. Average concentrations of particulate matter (PM) with aerodynamic diameters < 10 μm (PM10) and < 2.5 μm (PM2.5) at urban/suburban sites in

China from 2006 to 2014 are 83.6 and 56.3 µg m^{-3}, respectively, while values at rural stations are 54.8 and 30.8 µg m^{-3}, respectively (Y. Wang et al., 2015). Mean ground-level PM2.5 concentrations observed over the North China Plain and the Guan-Zhong Plain (GZP) exceed the latest air quality standards of China by about several times (Y. Wang et al., 2015). Long-term exposure to ambient PM may have led to significant increases in cardiorespiratory mortality in China (Chen et al., 2013; Yin et al., 2015). The mean aerosol optical depth (AOD) observed by sun photometers in rural and urban sites over China was 0.34 and 0.74, respectively (Lee et al., 2007; Che et al., 2015), which is well above the global average of 0.17 (Lee and Chung, 2013).

Economic development plays an important role in dictating air quality in China. The spatial and temporal distributions of AOD and PM2.5 are also affected by urbanization and topography (Li and Wang, 2014). Through the study of extreme air pollution events, the interaction between absorbing aerosols and the planetary boundary layer (PBL) height (PBLH) was recognized as an important contributor to the accumulation of PM in the near-surface atmosphere (Wendisch et al., 2008; Ding et al., 2013). A broad theoretical perspective of the impact of absorbing aerosols on the PBL was hypothesized by Wang et al. (2013), suggesting that a feedback between the PBLH and absorbing aerosols may play a key role in the aggravation of surface pollution during heavy pollution episodes.

In this study, we strive to obtain unique observational evidence that the aerosol-PBL feedback plays a special role in the long-term trend in air pollution, especially at the ground level, using both ground-based and historical satellite measurements.

2 Data

We used three types of measurements: long-term surface visibility measurements, medium-term satellite retrievals, and short-term field experiment measurements to take advantage of the merits of each product.

Visibility data obtained by China Meteorological Administration (CMA) stations located on the GZP are used here as a proxy for air quality at the surface, while AOD retrieved from the Moderate Resolution Imaging Spectroradiometer (MODIS) and the Multi-angle Imaging Spectro-Radiometer (MISR) are used to denote total aerosol loading in the atmospheric column.

The GZP is a key economic zone in western-central China, located along the lower valley of the Wei River (Fig. 1a). As one of the most densely populated regions of China, the GZP covers an area of 34000 km^2 and has a population of about 25 million people. The average altitude of the plain is around 500 meters. Xi'an is the largest and most developed city in the plain. As shown in Fig. 1, the spatial distribution of AOD follows the topography closely, i.e., higher over the basin than over the surrounding hilly mountain area.

The Qinling Atmospheric Environment Observation Experiment was conducted at the Changan meteorological station in the southern suburb of Xi'an (34.150°N, 108.917°E, 433 m above sea level) and at the nearby Qinling Mountains. Measurements of aerosols and atmospheric radiation have been made since May 2013 at Changan. Its goal is to investigate

5   the impact of heavy aerosol loading on radiation, clouds, and climate in central China. A multi-filter rotating shadowband radiometer (MFRSR) and a set of broadband radiometers were operated side by side. A micro-pulse lidar (MPL) manufactured by the Sigma Space Corporation was used to obtain aerosol profiles. Based on solar radiation measurements from the MFRSR, the Langley technique was used to retrieve AODs in the visible and near-infrared spectral bands.

3 Trend analyses

10 ### 3.1 Trends in visibility and AOD

The very rapid urbanization and economic development in China from the 1980s until the present has resulted in serious pollution problems in this region, as shown by the trend in visibility measurements made at stations located at altitudes less than 1 km (Fig. 2a). Note that the two are anti-correlated: poor visibility corresponds to high AOD (Fig. 2b). From 1980 to about 2008, visibility over the lowland of the GZP had been declining. A turnaround has occurred since then with a more

15 dramatic improvement in visibility occurring over the past few years when Chinese central and local governments began to take action toward curbing air pollution. This increase in visibility was accompanied by a decrease in AOD, which is seen in both ground and satellite observations. However, a different trend in visibility measured at the high mountain stations (altitudes over 1 km) is seen, i.e., a general increasing trend since 1980, suggesting that air quality over the mountains has been improving.

20

Note that visibility is often influenced by local emissions and fog whose long-term trends may contribute to visibility trends. To overcome this limitation, we also analyzed trends in AOD clustered according to topography so that each set of AODs represents the aerosol loading at some level above ground. By varying the ground elevation, we can derive profiles of AOD trends at different altitudes as shown in Fig. 3 using both MODIS and MISR data. AOD retrievals from both satellite

25 products show that the trend in AOD varies with height, i.e., increasing at low altitudes but decreasing at higher altitudes. We hypothesize that this switch in trend with height results from the feedback between absorbing aerosols and the PBLH.

3. 2 Variation of the trend with height

The proportion of light-scattering aerosol components, e.g., nitrate and sulphate, to the total PM2.5 in Xi'an is much lower than that in other big cities such as Beijing, Shanghai, and Guangzhou, while the proportion of light-absorbing aerosol

30 components, e.g., black carbon and dust, is much higher (Huang et al., 2014). The single scattering albedo (SSA) over this

region is well below 0.85, while the mean SSA in China is ~0.9 and high in southeast China, as derived by Lee et al. (2007) from a combination of satellite and ground observations across China. Absorbing aerosols trap solar radiation in the atmosphere with much more intensive heating in the upper PBL than in the lower atmosphere. This could lead to a significant decrease in the PBLH, which tends to increase near-surface particulate concentrations.

However, the aforementioned process is complex and difficult to evaluate by direct observations due to the influence of other factors, such as the large-scale circulation, local pollutant emissions, and atmospheric transport. Therefore, the study of the interaction between aerosols and the PBLH has thus far been mainly achieved through model simulations or by studying short-term extreme pollution cases. The complex terrain of the GZP hinders the advective diffusion of pollution (Zhao et al.,

10 2015a) and thus provides a unique opportunity to study the interaction between aerosols and the PBLH. Here we attempt to illustrate the impact of aerosols on the evolution of the PBL and the feedback between them by using long-term observations from the GZP.

3.3 Comparison of profiles of aerosol extinction from satellite and lidar

Profiles of aerosol extinction were derived from MPL backscattering measurements in conjunction with MFRSR AOD data

15 following the method of Welton et al. (2000). Data collected at the Changan station during the summers of 2013 and 2014 were used in this study to characterize the aerosol vertical distribution.

Due to a lack of long-term MPL observations, we propose a novel approach of obtaining profiles of aerosol extinction from AOD measurements at different altitudes by assuming that aerosols are homogeneously distributed across the basin

20 surrounded by the Qinling Mountains and the Loess Plateau. Data from the summers of 2002-2014 extracted from the Collection 6 MODIS-Aqua AOD product is used. Unlike other plains, the GZP is rarely influenced by large-scale circulations because airflow is blocked by the 1500-km long Qinling mountain range. Also, the regional prevailing winds over the GZP are unfavorable for the horizontal transport of PM (Zhao et al., 2015b). As a result, particles are mostly confined to their source region and tend to accumulate in the lowlands (Zhao et al., 2015a). In this case, aerosols may be

25 well-mixed over the valley. The AOD at a given location and at an elevation of z (in m), denoted as AOD_z, is defined as the integrated extinction coefficient over the vertical path from the surface to the top of atmosphere (TOA):

$$AOD_z = \int_z^{TOA} \beta_{z'} dz' \qquad (1)$$

where $\beta_{z'}$ is the extinction coefficient at a height of z'.

30 If the hypothesis is true, the observed AODs at the same elevation over the GZP should be similar. To test this, comparisons were made between the MODIS AOD at different altitudes and the integrated extinction coefficient obtained from the MPL.

As shown in Fig. 4, the AOD at different altitudes (green dots) and MPL data (black dots) are generally consistent. Note that the MPL detects vertical profiles of aerosols directly above the observation site in the GZP, while MODIS AOD retrievals are spatially distributed over the rugged terrain surrounding the plain. The distance between MODIS AOD pixels at varying altitudes and the MPL site at the Changan station increases with altitude. Consequently, profiles derived from MODIS AOD at different locations having different altitudes represent basin-wide (including the perimeters of the surrounding mountains) profiles. Profiles from the MPL were obtained at a fixed site. As such, the agreement between the AODs at varying altitudes from the MPL and MODIS attests to the validity of our assumption that the vertical mixing is uniform across the basin.

Thus, AOD with respect to any vertical path segment going from z0 to z1, denoted as $AOD_{z0\text{-}z1}$, can be computed by integrating the extinction coefficient β_Z' over the corresponding altitude range or by subtracting the AOD observed at z0 from that observed at z1:

$$AOD_{z0-z1} = \int_{z0}^{z1} \beta_{z'} dz' = \int_{z0}^{TOA} \beta_{z'} dz' - \int_{z1}^{TOA} \beta_{z'} dz' = AOD_{z0} - AOD_{z1} \quad (2)$$

In this way, any portion of AOD at a given altitude range can be obtained from a combination of MODIS AOD data and Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) global digital elevation model (GDEM) standard data products at a 30-m spatial resolution (http://reverb.echo.nasa.gov/reverb). Gridded mean summertime AODs are first created by gridding the high-quality (Quality Assurance Confidence Flag = 3) granule-level MODIS AOD retrievals onto a daily 0.1°-longitude × 0. 1°-latitude grid for the period 2002–2014. The mean AOD is then calculated by taking the average of the daily AOD in each grid cell. Grid boxes over the GZP having elevations from the GDEM with high relative standard deviations (> 10%) are not included in the analysis because the AOD in those boxes can vary considerably due to the elevation inhomogeneity.

To illustrate the impact of aerosols on the vertical temperature structure, the Santa Barbara DISORT Atmospheric Radiative Transfer (SBDART) model (Ricchiazzi et al., 1998) was used in this study to simulate the atmospheric heating rate induced by absorbing aerosols. The aerosol inputs to the SBDART model are AODs, Ångström exponents retrieved from MFRSR measurements, SSAs taken from Lee et al. (2007), and aerosol extinction profiles at 532 nm obtained from the MPL. The mid-latitude summer atmospheric profile adopted in the SBDART model was used in simulations. Additional input parameters include MODIS surface reflectance (http://ladsweb.nascom.nasa.gov/data/search.html), ozone column amounts from the Ozone Monitoring Instrument (https://ozoneaq.gsfc.nasa.gov/data/ozone/), and precipitable water vapor from the MFRSR.

3.4 Coupling between the PBL and aerosol absorption

The aerosol extinction profiles obtained from co-located MFRSR and MPL measurements were classified into three categories based on the quartiles of the aerosol loading in the lowest 270–870 m of the atmosphere:

1) clean condition: in the first quartile,

2) moderate pollution: between the second and third quartile,

3) severe pollution: the fourth quartile.

An altitude of 270 m was chosen as the lower limit because of missing data in the blind zone of the MPL (0–270 m). The upper limit of 870 m is a value established by Song et al. (2013) who found that ~50% of aerosols were confined to the lowest 600 m of the atmosphere over Lanzhou, a city surrounded by mountains.

Aerosol profiles corresponding to the three pollution levels in the summers of 2013 and 2014 are shown in Fig. 5a and 5b. The column-integrated AODs for the clean, moderate pollution, and severe pollution categories are 0.23, 0.38, and 0.50 in Fig. 5a, respectively, and 0.24, 0.33, and 0.41 in Fig. 5b, respectively. The PBLH for the clean, moderate, and severe pollution cases in the summer of 2013 are 2.9, 2.4, and 1.2 km, respectively. Those values in the summer of 2014 are 2.2, 2.0, and 0.8 km, respectively. As shown in Fig. 5a and 5b, the shapes of the aerosol profiles in both years are similar for all three pollution conditions, suggesting that these profiles are characteristic of the region. The relative changes in the level of pollution in the lower and upper PBL are generally out of phase. For the case of severe pollution (orange curve), pollution decreases most dramatically presumably at the top of a shallow PBL, whereas extinction increases with height for the clean and moderate pollution cases. Extinction coefficients above 1500 m for the severe pollution case are smaller than those in the moderate pollution case. Our finding suggests that a strong correlation exists between absorbing aerosols and the PBL over the GZP. However, causality cannot be established by such an analysis because the PBL strongly affects aerosols and vice versa.

Several simulation studies have demonstrated the coupling between absorbing aerosols and the PBL in China. Absorbing aerosols heat up the lower atmosphere due to aerosol absorption of solar radiation and cool down the lower PBL by reducing the amount of solar radiation reaching the earth's surface (Wendisch et al., 2008; Ding et al., 2013). Ding et al. (2016) found that the PM2.5 mass concentration was significantly underestimated near the surface and overestimated around the top of the PBL when the impact of absorbing aerosols was neglected. Aerosols trapped in the basin increase atmospheric stability and suppress convection locally (Fan et al., 2015).

Aerosol heating rates computed during the course of the day (0800–1800 Beijing Time) in the summer are shown in Fig. 5c and 5d. The maximum heating rate occurs at ~1 km. In the relatively clean and moderate pollution scenarios, maximum heating rates are seen at higher altitudes. This suggests that the stability inside the PBL was strengthened while the instability above the PBL was enhanced, causing a "heat pump" effect (Lau and Kim, 2006) that favors the vertical diffusion of aerosol

5   particles in the upper atmosphere. As a result, aerosol extinction coefficients observed at altitudes above 1500 m in the most polluted scenario are lower than in the moderately polluted scenario.

The visibility at ground level has significantly decreased in northern China from 2000 to 2012 (Chen and Wang, 2015) and the number of hazy days has increased noticeably (H. Wang et al., 2015). However, the column-integrated AOD has shown a

10   much weaker trend as shown in Fig. 3 and in Lin et al. (2013). The disproportionate changes in surface visibility and column aerosol loading could be due to the rapid accumulation of particles near the surface in combination with a reduction in aerosol particles in the upper PBL due to the inefficient vertical transport of aerosol particles.

To test this conjecture, we used the MODIS AOD product to derive aerosol loading in the lower PBL (400-800 m, AOD_{400-}

15    $_{800m}$) and the upper PBL (1500-1900 m, $AOD_{1500-1900m}$) using the aforementioned method for each summer from 2002 to 2014. The aerosol scale height was calculated using an exponential curve fitting of MODIS AOD and ASTER GDEM data (Dong et al., 2013). The aerosol scale height is used as a proxy of the PBLH because it is related to the height of the boundary layer (Gerasopoulos et al., 2003). The scatterplots of $AOD_{400-800m}$ and $AOD_{1500-1900m}$ as a function of aerosol scale height in Fig. 6 shows the difference in the response of the aerosol loading at different altitudes to the scale height. As the

20   AOD near the surface increases from 0.2 to 0.6, the aerosol scale height drops from ~1100 m to 670 m. In response to the decrease in scale height, the aerosol loading above the PBL decreases. The correlation coefficients of the linear relationships between $AOD_{400-800m}$ and $AOD_{1500-1900m}$, and the aerosol scale height are 0.71 and 0.55, respectively. The correlations are statistically significant at the 95% confidence level. However, the correlation coefficient of the linear relationship between $AOD_{1500-1900m}$ and $AOD_{400-800m}$ does not reach the 0.05 significance level, suggesting that the amount of aerosol particles near

25   the surface has an indirect impact on the aerosol concentration in the upper PBL through its effect on the PBLH.

During the period of MODIS observations, the trend in AOD over China has a turning point around 2008: an upward trend pre-2008 followed by a downward trend post-2008, as reported by He et al. (2016). We examined the summertime trends in AOD at different altitudes during the period 2002–2008 (red line in Fig. 7a) and 2008–2014 (blue line in Fig. 7a). AOD over

30   the lowlands (< 800 m) increased dramatically during the period 2002–2008. However, the AOD at higher altitudes (1.7–2.3 km) decreased at a rate of -0.0075 per year. It is worth emphasizing that the magnitude of this negative AOD tendency at high altitudes exceeds that of the ascending tendency over the entirety of China (+0.0003) during the same period (He et al., 2016), suggesting that the changes in AOD at higher altitudes over the GZP are different from the changes in other regions.

For the period 2008–2014, the trends in AOD at different altitudes are opposite to those from the 2002–2008 period. The AOD over the lowlands with altitudes < 700 m dramatically decreased while AOD at altitudes from 800 to 1200 m increased. To further illustrate this phenomenon, the variation in aerosol extinction coefficient derived from d(AOD)/dz using MODIS AOD retrievals in conjunction with the GDEM is shown in Fig. 7b. Concurrent with the increase in aerosol concentration in the lower PBL during the period 2002–2008, aerosol extinction coefficients at altitudes above 1850 m decreased with a maximum value occurring near 2300 m. The opposite is seen during the period 2008–2014. A notable downward tendency in the aerosol extinction coefficient in the lower PBL is found, while at the same time, a positive trend with a maximum magnitude of 0.04 km^{-1} yr^{-1} is seen at altitudes between 900 and 1300 m. The vertical distribution of trends in AOD and aerosol extinction coefficient during the two periods show that changes in aerosol loading near the surface were opposite to those above the PBLH over the GZP, which is solid evidence that the aerosol-PBL feedback plays a significant role in the long-term trend in air pollution, and especially in the opposite trends between the lower and upper PBL.

To further investigate the role of aerosol absorption in the opposite trends, we expanded our satellite analyses to over large areas in China. The SSA in northern China is generally lower than in southern China (Lee et al., 2007). It was thus hypothesized that the reversal trends would be more significant than in southern China, which is confirmed from the trend analyses at different altitudes over the entire period of MODIS observations, as shown in Fig. 8.

4 Summary and conclusions

While an aerosol and PBL interaction has been conjectured, chiefly based on an inverse correlation between air pollution (both gas and particulate pollutants) and PBL height. This may not be construed as an evidence of the interaction because they may co-vary with meteorological conditions. A low PBL is favorable for the accumulation of any pollutant, but this does not imply that they interact with each other. For aerosols to interact with the PBL, the atmospheric thermodynamic status must be modified.

To obtain more direct evidence and to gain further insight into the interaction on both air pollution and PBL dynamics, we took advantage of rich measurements made from an intensive field experiment, long-term routine surface visibility observations, and satellite aerosol retrievals. A unique region in central China was chosen: the GZP and the Qinling mountain range composed of mountains having a wide range of heights. The GZP is one of the most heavily polluted regions in China due to coal-burning industries and has the lowest aerosol SSA measured in China. Next to the GZP lies the Qinling mountain range, which offers an opportunity to examine vertical profiles of aerosol loading through a novel method proposed here.

Using both the inferred and observed profiles of aerosol extinction together with computations of aerosol-induced radiative heating, a unique "signature" of the interaction between absorbing aerosols and the PBL is discovered, namely, the opposite trends in aerosol extinction, visibility, and aerosol optical depth as measured in the lower and upper PBL. Visibility data collected at meteorological stations located at altitudes below and above 1 km showed generally downward and upward trends, respectively, since 1980. The same opposite trends are also seen from retrievals of AOD from both MODIS and MISR since ~2000 over regions with altitudes below and above 1 km. Two years of lidar measurements showed that the vertical structure of the aerosol extinction coefficient varied systematically with the aerosol concentration in the lower atmosphere, i.e., a cleaner surface corresponded to a higher peak in aerosol extinction and vice versa. As near-surface pollutants accumulate, they are confined to the lower PBL due to enhanced atmospheric stability, whereas pollutants in the upper PBL are dispersed more efficiently as the atmosphere becomes more unstable, thanks to heating in the lower PBL.

To further verify if it indeed stems from aerosol-PBL interactions, similar analyses were done in regions with distinctly different values of single scattering albedo. In low SSA regions, the reversal trends are much more pronounced than in high SSA regions, which attests to the critical role of aerosol absorption.

The findings presented in this study have numerous important implications. First, it signifies the importance of aerosol-PBL interactions in dictating ground-level pollution. In particular, it implies that particulate pollution at the ground level can be much heavier than what is denoted by a column-integrated AOD. The latter is relatively readily and widely available and has been used as a proxy for indices representing air pollution on the ground such as PM2.5 and PM10. In regions/periods dominated by absorbing aerosols, changes in AOD may be totally decoupled from ground-level PM concentrations. Second, it suggests that one may not be able to use ground-based measurements of pollutants to assess the effect of any emission controls. Taking China as an example, drastic measures have been taken to reduce emissions but they seem to have little impact on heavy haze episodes because a significant part of the real reduction may have occurred in the upper PBL at the expense of worsening air quality at the surface or lower atmosphere. Finally, it points to a more efficient means of reducing air pollution: reducing/removing absorbing aerosols such as soot or black carbon, which can cause far more serious pollution than non-absorbing aerosols such as sulfates.

Data availability

The ASTER GDEM and MODIS AOD data are available from http://reverb.echo.nasa.gov/reverb and https://ladsweb.nascom.nasa.gov/, respectively. The MPL-derived aerosol profiles and other relevant data will be made available upon request (contact: Zipeng Dong, dzp2003@126.com).

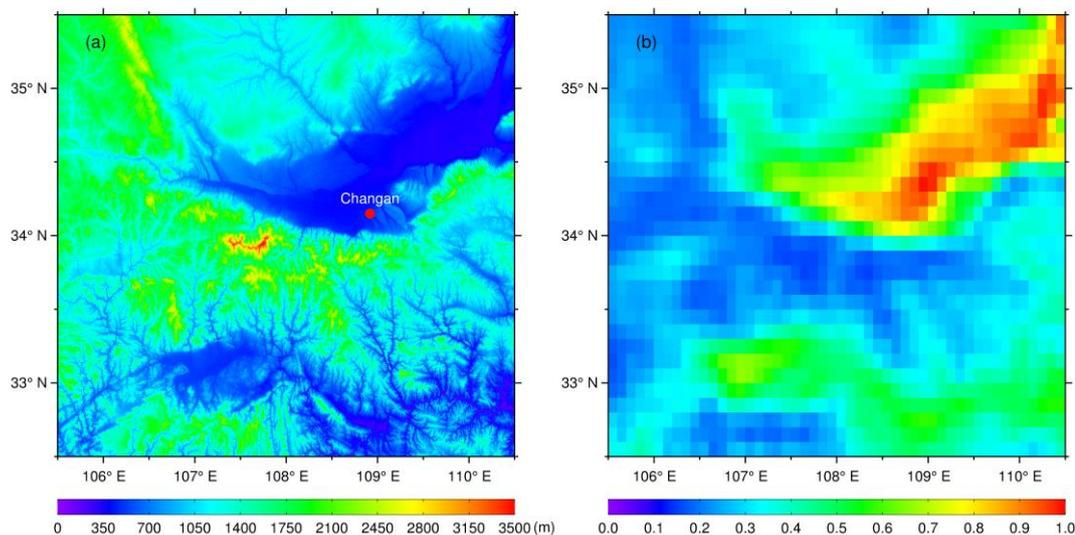

Fig. 1. (a) A topographic map of the Guanzhong Plain and (b) the spatial distribution of AOD over the basin. The red solid dot in (a) shows the location of the Qinling experimental site in Changan near Xi'an.
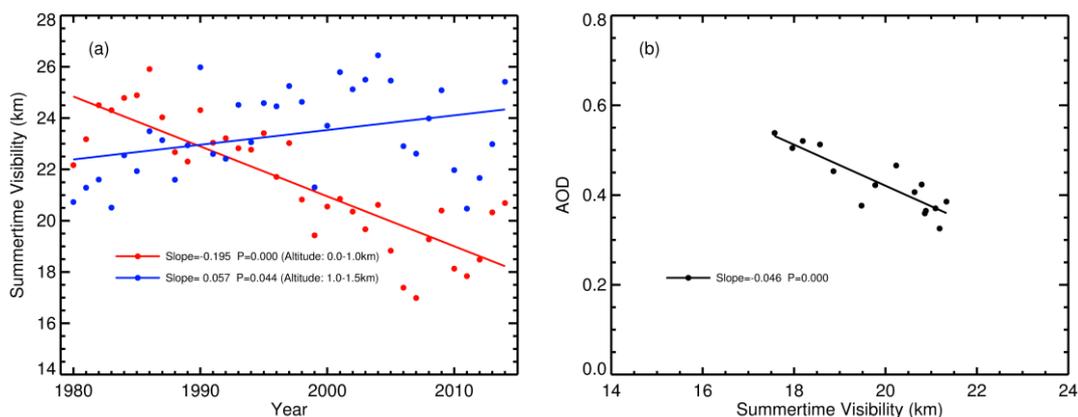

Fig. 2. (a) Long-term trends in visibility measured at meteorological stations located at different altitudes on the Guanzhong Plain and in the surrounding mountain region. (b) Correlation between AOD and visibility in the GZP.
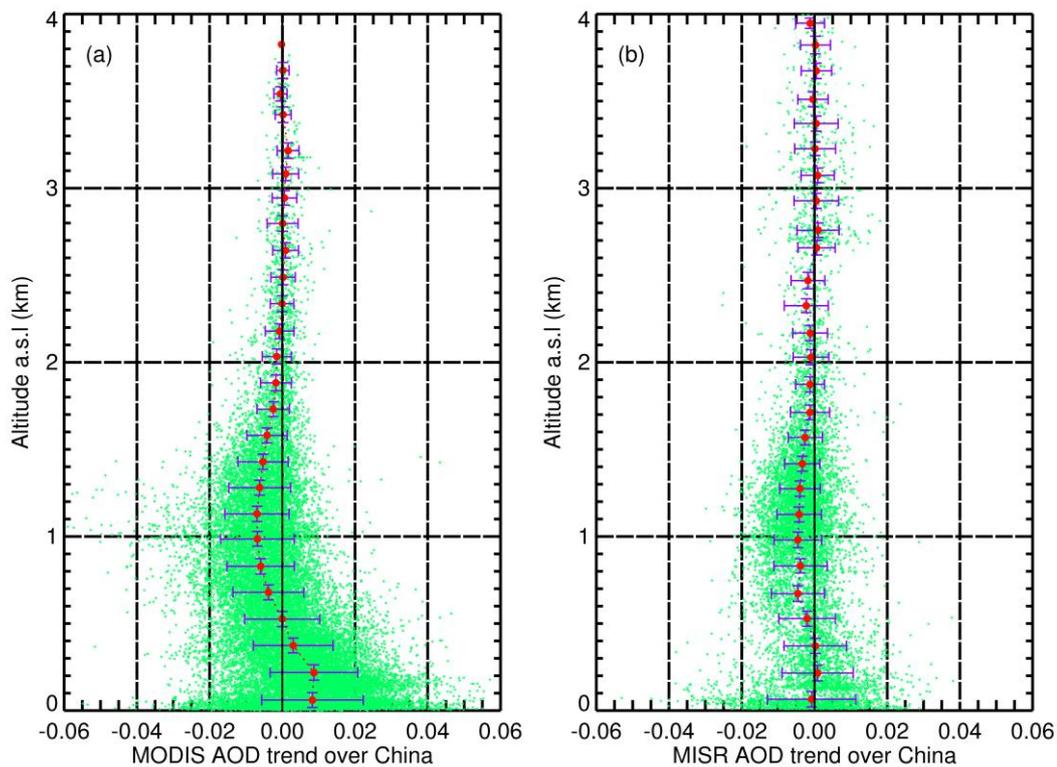

Fig. 3. Vertical profiles of AOD trends over China from (a) MODIS and (b) MISR retrievals from 2002 to 2014. Red dots and horizontal bars represent mean tendencies and standard deviations, respectively. The "a.s.l." in the ordinate labels stands for "above sea level".
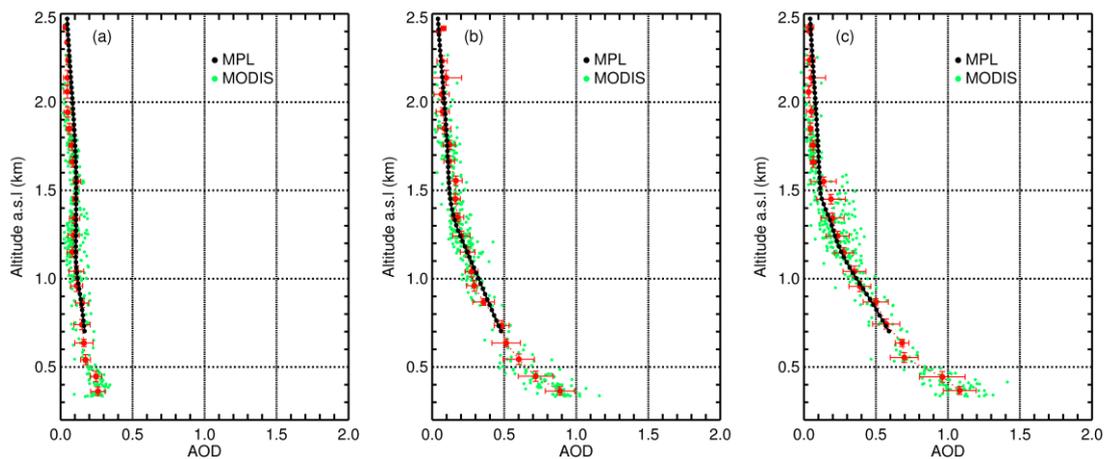

Fig. 4. AOD at different altitudes derived from MODIS retrievals over the study region shown in Fig. 1a (green dots) and MPL (black dots) data on (a) 13 September 2013 at 0600 Coordinated Universal Time (UTC), (b) 26 March 2014 at 0550 UTC, and (c) 29 September 2013 at 0600 UTC. Red dots and horizontal bars represent mean MODIS AODs and standard deviations, respectively. Only those MODIS five-minute granules with a sufficient amount of valid AOD data (> 75%) are chosen.
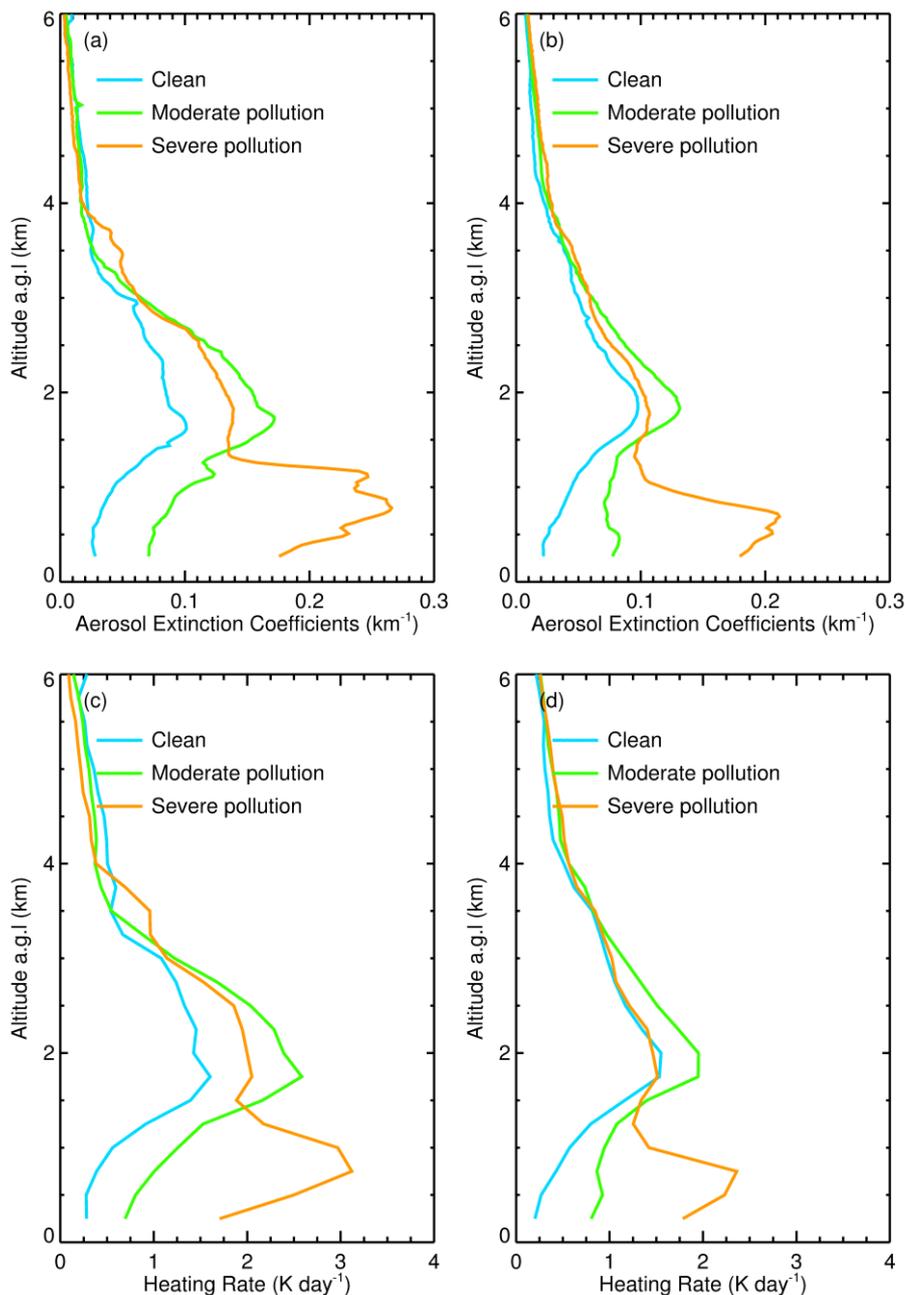

Fig. 5. Mean summertime aerosol extinction profiles measured by the MPL in (a) 2013 and (b) 2014, and summertime atmospheric heating rates induced by aerosols in (c) 2013 and (d) 2014. Profiles representing relatively clean, moderate pollution, and severe pollution scenarios are shown as blue, green, and yellow lines, respectively. The "a.g.l." in the ordinate labels stands for "above ground level".
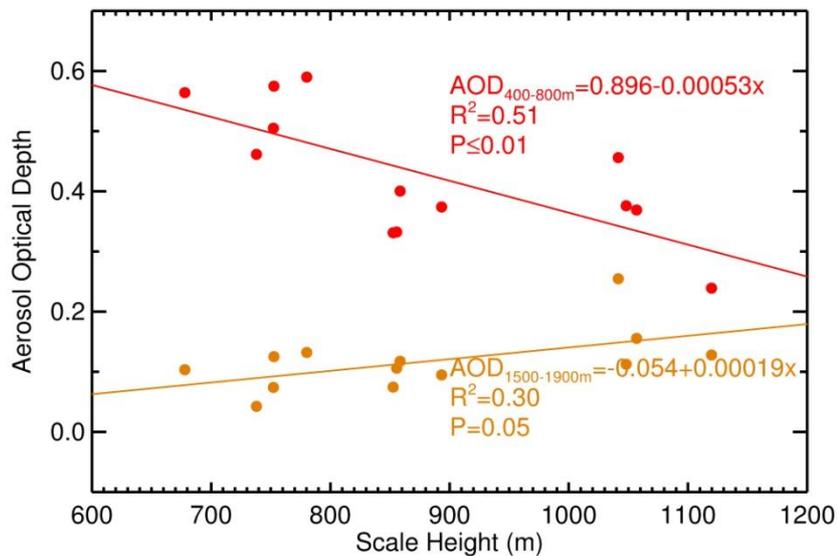

Fig. 6. AOD in the lower PBL ($AOD_{400-800m}$) and in the upper PBL ($AOD_{1500-1900m}$) as a function of aerosol scale height. Linear-fit equations, coefficients of determination, and p-values are given.
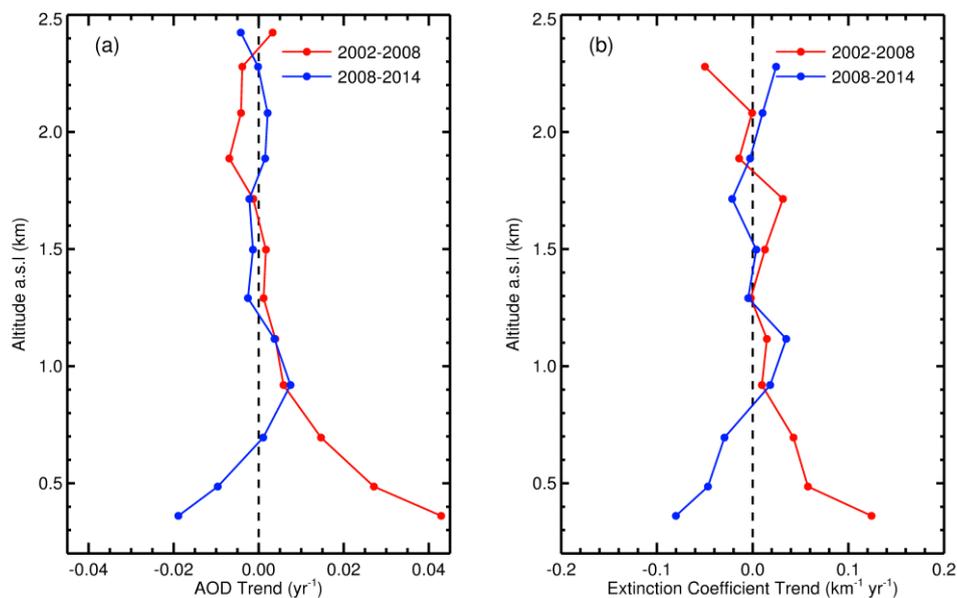

Fig. 7. Vertical distributions of trends in summertime mean (a) AOD and (b) aerosol extinction coefficient. The vertical resolution is 200 m. Red and blue lines represent tendencies during the period 2002–2008 and 2008–2014, respectively. The "a.s.l." in the ordinate labels stands for "above sea level".
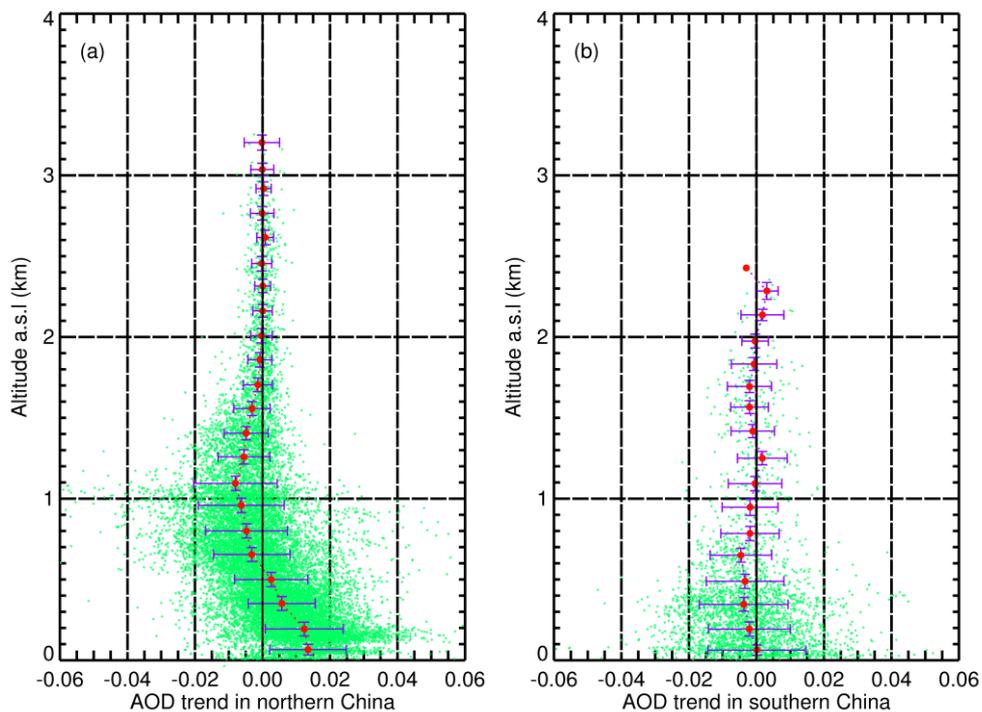

Fig. 8. Vertical distributions of the trend in AOD from MODIS-Aqua in (a) northern (> 40°N) and (b) southern (< 30°N) China from 2002 to 2014.
