33 **Abstract**

34

35 During the *Observations and Modeling of the Green Ocean Amazon (GoAmazon2014/5)*
36 campaign, size-resolved cloud condensation nuclei (CCN) spectra were characterized at a re-
37 search site (T3) 60 km downwind of the city of Manaus, Brazil, in central Amazonia for one year
38 (12 March 2014 to 3 March 2015). Particle hygroscopicity (κ_{CCN}) and mixing state were derived
39 from the size-resolved CCN spectra, and the hygroscopicity of the organic component of the aer-
40 osol (κ_{org}) was then calculated from κ_{CCN} and concurrent chemical composition measurements.
41 The annual average κ_{CCN} increased from 0.13 at 75 nm to 0.17 at 171 nm, and the increase was
42 largely due to an increase in sulfate volume fraction. During both wet and dry seasons, κ_{CCN} , κ_{org} ,
43 and particle composition under background conditions exhibited essentially no diel variations.
44 The constant κ_{org} of ~ 0.15 is consistent with the largely uniform and high O:C value (~ 0.8), in-
45 dicating that the aerosols under background conditions are dominated by the aged regional aero-
46 sol particles consisting of highly oxygenated organic compounds. For air masses strongly influ-
47 enced by urban pollution and/or local biomass burning, lower values of κ_{org} and organic O:C
48 atomic ratio were observed during night, due to accumulation of freshly emitted particles, domi-
49 nated by primary organic aerosol (POA) with low hygroscopicity, within a shallow nocturnal
50 boundary layer. The O:C, κ_{org} , and κ_{CCN} increased from the early morning hours and peaked
51 around noon, driven by the formation and aging of secondary organic aerosol (SOA) and dilution
52 of POA emissions into a deeper boundary layer, while the development of the boundary layer,
53 which leads to mixing with aged particles from the residual layer aloft, likely also contributed to
54 the increases. The hygroscopicities associated with individual organic factors, derived from PMF
55 analysis of AMS spectra, were estimated through multi-variable linear regression. For the SOA
56 factors, the variation of the κ value with O:C agrees well with the linear relationship reported

57 from earlier laboratory studies of SOA hygroscopicity. On the other hand, the variation in O:C of
58 ambient aerosol organics is largely driven by the variation in the volume fractions of POA and
59 SOA factors, which have very different O:C values. As POA factors have hygroscopicity values
60 well below the linear relationship between SOA hygroscopicity and O:C, mixtures with different
61 POA and SOA fractions exhibit a steeper slope for the increase of κ_{org} with O:C, as observed
62 during this and earlier field studies. This finding helps better understand and reconcile the differ-
63 ences in the relationships between κ_{org} and O:C observed in laboratory and field studies, there-
64 fore providing a basis for improved parameterization in global models, especially in a tropical
65 context.

66

67 **1 Introduction**

68 Atmospheric aerosols have a major impact on the radiative balance of the Earth's climate
69 system by changing the microphysical structure, lifetime, and coverage of clouds. For the same
70 liquid water content, high aerosol concentration leads to more, smaller cloud droplets, and there-
71 fore higher cloud albedo (Twomey, 1977). The smaller droplet size also delays or inhibits warm
72 precipitation, leading to increases in both cloud lifetime and coverage (Albrecht, 1989), and ul-
73 timately invigoration of convective clouds (Rosenfeld et al., 2008). Currently, the effects of aer-
74 osol on clouds remain one of the largest uncertainties in simulated climate change during indus-
75 trial era, and a large portion of this uncertainty is due to the natural aerosol properties and pro-
76 cesses represented in models (Carslaw et al., 2013; Ghan et al., 2013). The Amazon represents
77 more than half of the planet's rainforest and is a rapidly changing region where deforestation,
78 human activity and natural resource needs are all at play in changing the ecosystem (Andreae et
79 al., 2015; Batistella et al., 2013; Davidson et al., 2012). The Amazon basin also represents at
80 times one of the cleanest continental regions on the planet where it is still possible to find ex-
81 tended periods of little or no impact of anthropogenic activity, although the long-distance
82 transport of pollution is occasionally observed (Andreae et al., 2015; Hamilton et al., 2014;
83 Martin et al., 2010b; Wang et al., 2016a; Wang et al., 2016b; Williams et al., 2002). This makes
84 the Amazon Basin an ideal location to characterize aerosol under near natural conditions and as-
85 sess the impact due to urban emissions and biomass burning (Kuhn et al., 2010). The biogenic
86 activity of this region makes it a major source of organic carbon released into the atmosphere via
87 isoprene and monoterpenes (Guenther et al., 2006; Guenther et al., 2012; Kesselmeier et al.,
88 2002; Kuhn et al., 2007) which are mediated by biotic stress through heat, sunlight and changes
89 in CO₂ (Heald et al., 2009).

90 To understand the impact of aerosol on clouds and climate requires knowledge of the concen-
91 tration of cloud condensation nuclei, which are particles that are able to form cloud droplets un-
92 der relevant atmospheric conditions. The minimum supersaturation required to activate a particle
93 into a cloud droplet can be predicted using κ -Köhler theory based on particle size and the single
94 hygroscopicity parameter κ , which combines a number of thermodynamic properties required for
95 the description of water activity of the growing droplets (Petters and Kreidenweis, 2007). The
96 value of κ is determined by the physicochemical properties of the solutes, including their molar
97 volume, activity coefficient, and the effect on surface tension. For multi-component particles, κ
98 is the volume average of participating species. Hygroscopicity also describes particle growth un-
99 der sub-saturated conditions and can be derived from the particle growth factor (GF). However,
100 particles sometime exhibit larger κ values for droplet activation (derived from CCN measure-
101 ments under supersaturated conditions) than for particle growth (derived from particle GF under
102 sub-saturated conditions) (e.g., Duplissy et al., 2008; Good et al., 2010; Mikhailov et al., 2013;
103 Pajunoja et al., 2015; Wex et al., 2009). In this paper, “hygroscopicity” represents κ associated
104 with droplet activation derived from CCN measurements unless noted otherwise.

105 The hygroscopicities of typical inorganics in ambient particles are relatively well known.
106 However, atmospheric aerosols consist of a large number of organic compounds, which often
107 dominate the total fine aerosol mass (e.g., Zhang et al., 2007). The hygroscopicity of aerosol or-
108 ganics (κ_{org}) have been examined in both laboratory (e.g., Asa-Awuku et al., 2009; Duplissy et
109 al., 2011; King et al., 2009; Lambe et al., 2011; Massoli et al., 2010; Prenni et al., 2007;
110 Raymond and Pandis, 2003) and field studies (e.g., Cerully et al., 2015; Chang et al., 2010;
111 Dusek et al., 2010; Gunthe et al., 2009; Jimenez et al., 2009; Latham et al., 2013b; Mei et al.,
112 2013a; Mei et al., 2013b; Moore et al., 2011; Moore et al., 2012; Pöhlker et al., 2016; Rose et al.,

113 2010; Shantz et al., 2008; Wang et al., 2008). Overall, these studies show that aerosol organics
114 exhibit a wide range of κ values from 0 to ~ 0.3 , and κ_{org} often increases substantially during aer-
115 osol aging in the atmosphere (e.g., Duplissy et al., 2011; Jimenez et al., 2009; Lambe et al.,
116 2011; Massoli et al., 2010; Mei et al., 2013a).

117 A number of recent studies examined the sensitivity of predicted CCN concentration and
118 cloud droplet number concentration to aerosol properties (e.g., Ervens et al., 2010; Kammermann
119 et al., 2010; McFiggans et al., 2006; Mei et al., 2013a; Reutter et al., 2009; Rissman et al., 2004;
120 Roberts et al., 2002; Wang, 2007; Wang et al., 2008). These studies show that the predicted CCN
121 concentration is often sensitive to κ_{org} , especially for aerosol under background conditions where
122 organics tend to dominate submicron aerosol mass (Liu and Wang, 2010; Mei et al., 2013a). Us-
123 ing a constant κ_{org} may lead to large biases in predicted CCN concentrations and aerosol indirect
124 forcing (Liu and Wang, 2010). Therefore, it is imperative to understand organic hygroscopicity
125 under background conditions, such as in the Amazon forest, as well as the variation of organic
126 hygroscopicity due to anthropogenic emissions.

127 There have been several studies of aerosol hygroscopicity in the Amazon Basin over the past
128 20 years (Gunthe et al., 2009; Mikhailov et al., 2013; Pöhlker et al., 2016; Rissler et al., 2006b;
129 Roberts et al., 2001; Vestin et al., 2007; Whitehead et al., 2016; Zhou et al., 2002). Gunthe et al.
130 (2009) performed size resolved CCN measurements during the wet season in February and
131 March 2008 as part of the AMAZE-08 campaign (Martin et al., 2010a). That study reported no
132 diel cycle in the CCN concentration during periods with little or no influence of pollution.
133 Pöhlker et al. (2016) measured size-resolved CCN spectra at a remote background site (Amazon
134 Tall Tower Observatory ATTO) over a one-year period from March 2014 to February 2015 and
135 observed no diel cycle and only weak seasonal trends in derived particle hygroscopicity, while

136 CCN concentrations had a pronounced seasonal cycle as the background aerosol concentration
137 was strongly influenced by regional biomass burning during the dry season. During the SMOCC-
138 2002 campaign (Large scale Biosphere atmosphere experiment in Amazonia – SMOke, aerosols,
139 Clouds, rainfall, and Climate) particle hygroscopicity was derived from HTDMA measurements
140 in the state of Rondônia in the southwest of the Amazon region during the dry season from Sep-
141 tember to November of 2002 (Rissler et al., 2006b; Vestin et al., 2007). The study concluded that
142 the diel variation in the aerosol hygroscopicity could be linked to the structure and dynamics of
143 the boundary layer. Local sources dominated night-time aerosol properties with downward mix-
144 ing from the residual layer aloft as the day progressed. All of these studies found that particle
145 hygroscopicity increased with particle size (from the Aitken to accumulation modes), consistent
146 with higher sulfate content at larger sizes (Gunthe et al., 2009). The same boundary layer evolu-
147 tion has been found to influence particle number and CCN evolution in a number of other related
148 studies (Fisch et al., 2004; Martin et al., 2010a; Rissler et al., 2006b; Vestin et al., 2007;
149 Whitehead et al., 2010; Zhou et al., 2002).

150 In this study we present measurements of size resolved CCN spectra at five particle diame-
151 ters ranging from 75 to 171 nm downwind of Manaus, Brazil, in central Amazonia for a period
152 of one year from March 12, 2014 to March 3, 2015. Particle hygroscopicity, mixing state, and
153 organic hygroscopicity are derived from the size-resolved CCN activated fraction and concurrent
154 aerosol composition measurements. The diel variations of these properties are examined for dif-
155 ferent seasons (i.e., wet season, dry season, and transition seasons) and for different types of rep-
156 resentative air masses, including background conditions, as well as influences of urban pollution
157 plumes and/or local biomass burning. During the wet season, the background air mass represents
158 near natural conditions, with occasional impact from anthropogenic emissions, while in the dry

159 season, the background is dominated by regional biomass burning aerosol particles. The relation-
160 ship between organic hygroscopicity and particle oxidation level (i.e., O:C atomic ratio) is exam-
161 ined for both dry and wet seasons. Hygroscopicities associated with organic factors from Aerosol
162 Mass Spectrometry (AMS) Positive Matrix Factorization (PMF) analysis are derived, and their
163 relationship with the O:C ratio is compared with those from previous laboratory studies.

164 **2 Experimental Setup**

165 **2.1 Measurement Sites**

166 *Observations and Modeling of the Green Ocean Amazon (GoAmazon2014/5)*, sponsored by
167 the US Department of Energy (DOE) and several Brazilian and German agencies, took place at
168 multiple surface sites surrounding Manaus, Brazil, from January 2014 through December 2015
169 (Martin et al., 2016b). This work focuses on the measurements carried out at a downwind site
170 (T3, 3°12'47.82"S, 60°35'55.32"W, 60 km west of Manaus) from March 2014 to March 2015.
171 Depending on the wind direction, the T3 site experienced conditions ranging from nearly natural
172 to heavily polluted. More detailed characterizations of aerosol and gas phase chemical composi-
173 tion were carried out at the T3 site during Intensive Operating Periods (IOPs) from February 1,
174 2014 to March 31, 2014 and from August 15, 2014 to October 15, 2014. In addition, data from
175 two sites normally upwind of Manaus are also used in this study. These background sites include
176 the T0a site, (ATTO, 2° 8'47.88"S, 59° 0'18.00"W) (Andreae et al., 2015) and the T0t site,
177 (2.6091°S, 60.2093°W) (Martin et al., 2010a).

178 2.2 Activated Fraction of size-selected Particles

179 The CCN activation fraction of size-selected particles was measured using a Differential
180 Mobility Analyzer (DMA) coupled to a condensation particle counter (CPC, TSI Inc., 3010) and
181 a cloud condensation nuclei counter (CCNC, Droplet Measurement Technologies, Boulder, CO)
182 (Frank et al., 2006; Mei et al., 2013a; Moore et al., 2010; Petters et al., 2007). Aerosol particles
183 were sampled with a total flow rate (Q_a) of 1.53 L min^{-1} from a height of 5 m above ground level
184 and were dried to RH below 20% by a Nafion dryer immediately upon entering the instrument
185 container. The dried aerosol particles then reached steady state charge distribution inside a Kr-85
186 aerosol charger (TSI, model 3077A), prior to being introduced into the DMA operated with a
187 sheath flow rate (Q_{sh}) of 15.3 L min^{-1} to maintain a 10:1 sheath to aerosol flow ratio (Q_{sh}/Q_a).
188 The aerosol particles were size-selected by the DMA and the size-selected particles were simul-
189 taneously characterized by a CPC ($Q_{CPC} = 0.53 \text{ L min}^{-1}$) and a CCNC (see Fig. S1 in the Sup-
190 plementary Information for further details). This system had been operated in previous field
191 campaigns by scanning the particle size while CCNC supersaturation was held constant (Mei et
192 al., 2013a; Mei et al., 2013b). During GoAmazon2014/5 the particle size classified by the DMA
193 was stepped through seven particle diameters (51, 75, 94, 112, 142, 171, and 222 nm), while the
194 CCNC supersaturation was also changed at each diameter by stepping the flow rates (Q_{CCN} rang-
195 ing from 0.2 to 1.0 L min^{-1}) and temperature gradient ($\Delta T = 4.5, 5.5, 6.5, 8.0$ and 10.0°C). At a
196 given supersaturation, data were acquired for a minimum of 30 s and until 1500 particles were
197 counted by the CPC or up to a maximum time of 120 s. Depending on the aerosol number size
198 distribution, the measurement cycled through the seven particle sizes in 1 – 2 h (see Fig. S1 and
199 S2 for further details of the measurement setup and sampling protocol). The sampling sequence
200 was designed so that the change of CCNC supersaturation was mostly accomplished by stepping

201 flow rates, as the CCNC reaches steady state faster following flow changes than temperature
202 changes. Change of the temperature gradient was kept at a minimum frequency, but was neces-
203 sary given the wide range of supersaturation explored. Given the low particle number concentra-
204 tion (e.g., $\sim 200 \text{ cm}^{-3}$ under background conditions during the wet season), these approaches were
205 important to achieve adequate counting statistics with good time resolution to capture changes of
206 air mass within 10 – 20 minutes (Liu et al., 2016). The supersaturation of the CCNC was cali-
207 brated using ammonium sulfate aerosol, as described previously in the literature (e.g., Mei et al.,
208 2013a), at each operational set point (Q_{CCN} and ΔT), ranging from 0.075 – 1.1 %. Fluctuation of
209 the temperature inside the instrument container, ranging from 20 to 30°C over the course of a
210 day, led to substantial variation in the absolute temperature inside the CCNC growth chamber.
211 Calibrations were therefore repeated under a range of container and associated growth chamber
212 temperatures. The dependence of the supersaturation on the temperature at the top of CCNC col-
213 umn (instrument temperature T_i) was derived for each Q_{CCN} and ΔT pair and used to retrieve the
214 supersaturation over the range of the instrument operating conditions (see Fig. S3 and further
215 description in the Supplementary Information).

216 **2.3 Aerosol Chemical Composition**

217 Non-refractory sub-micron aerosol composition (organics, sulfate, nitrate, ammonium, and
218 chloride) was measured by a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-
219 AMS, Aerodyne Research Inc. (DeCarlo et al., 2006) during the two IOPs, and by an Aerosol
220 Chemical Speciation Monitor (ACSM, Aerodyne Research, Inc., Ng et al., 2011) from July 2014
221 to March 2015. The AMS sampled from an inlet equipped with a PM_{2.5} cyclone located at 5 m
222 above ground level. The ambient sample was first dried outside the container by a poly-tube
223 Nafion dryer (Perma Pure, model PD-100T). Once inside the container the sample was further

224 dried by a mono-tube Nafion dryer (Perma Pure, model MD-110) to achieve $RH < 40\%$ and was
225 split between the AMS and a Scanning Mobility Particle Sizer (SMPS, TSI, model 3081). Ambi-
226 ent measurements were obtained every 4 of 8 minutes. Further details of the AMS set up and op-
227 eration are described in de Sá et al. (2016).

228 The ACSM was a part of the Aerosol Radiation Measurement (ARM) Mobile Facility-1
229 (AMF-1) Mobile Aerosol Observation System (MAOS). Aerosol was sampled through an inlet
230 located 10 m above the ground. The aerosol sample was first dried through five large (40 x 1.75
231 cm I.D.) Nafion dryers before being distributed among various instruments including the ACSM.
232 The ACSM sampling alternated between with and without an in-line filter using a 3-way valve,
233 such that aerosol-free background could be subtracted from the ambient measurement. Twenty-
234 eight ambient and background scans of the quadrupole mass spectrometer (unit mass resolution)
235 were averaged to give one measurement every 30 min. The mass concentrations of organic spe-
236 cies, sulfate, nitrate, ammonium, and chloride were derived from measurements using approach-
237 es described in Ng et al. (2011).

238 Refractory black carbon (rBC) was measured using both a Single Particle Soot Photometer
239 (SP2, Droplet Measurement Technologies, Boulder, CO) and an aethalometer (Magee Scientific)
240 co-located with the AMS and ACSM. The SP2 measures rBC using laser-induced incandescence,
241 whereas the aethalometer measures equivalent black carbon (BC_e) (Andreae and Gelencsér,
242 2006) using light absorption from particles collected onto a filter. While these are fundamentally
243 different aerosol properties, both species (rBC and BC_e) were treated as equivalent in this study,
244 and BC_e concentration was adjusted to match that of rBC using the approach detailed in Section
245 2.2 of the Supplementary Information.

246 **2.4 Additional Relevant Measurements**

247 Additional measurements of aerosol microphysics, trace gas concentrations, and atmospheric
248 conditions used in this study are briefly described here. These measurements were part of the de-
249 ployment of the ARM AMF-1 facility during GoAmazon 2014/5 (Martin et al., 2016b). Relevant
250 aerosol measurements include dry particle number-size distributions from 10 to 480 nm by a
251 SMPS (TSI Inc. Model 3081) and the number concentration of particles with diameters greater
252 than 10 nm by a CPC (TSI Inc. Model 3772). Mixing ratios of CO and O₃ were characterized by
253 an Off-Axis Integrated Cavity Output Spectroscopy CO, N₂O and H₂O analyzer (model number
254 908-0014, Los Gatos) and UV Photometry O₃ analyzer (model 49i, Thermo Scientific Inc.), re-
255 spectively. Oxides of nitrogen (NO, NO_x, NO₂, NO_y) were measured using a chemiluminescence
256 technique (details given in Section S2.1 of the Supplementary Information). Meteorological data
257 included relative humidity (RH), ambient temperature, wind speed and direction, and rain accu-
258 mulation. The vertical profile of atmospheric backscatter (clouds and aerosol) and boundary lay-
259 er heights were estimated from ceilometer (model CL31, Vaisala) measurements.

260 **3 Methods**

261 **3.1 Derivation of Particle Hygroscopicity and Mixing State**

262 The particle hygroscopicity parameter, κ (Petters and Kreidenweis, 2007), was derived from
263 the activation spectrum (i.e., activated fraction as a function of supersaturation S) at the individu-
264 al particle sizes using approaches detailed in the literature (Bougiatioti et al., 2011; Cerully et al.,
265 2011; Lance et al., 2013; Mei et al., 2013a; Rose et al., 2008a). The activation spectrum of size-
266 selected particles was first corrected for the influence of multiply charged particles, which is es-
267 timated using the size distribution measured by the SMPS in MAOS and the activation spectrum

268 measured at the sizes of the doubly and triply charged particles (See Section S3.1). The corrected
269 activation spectrum of size selected particles was then fit with a cumulative lognormal (Mei et
270 al., 2013a; Rose et al., 2008b) functional form (See Fig. S6 for examples):

$$271 \quad R_a(S) = \frac{E}{2} \left[1 + \operatorname{erf} \left(\frac{\ln S - \ln S^*}{\sqrt{2\sigma_s^2}} \right) \right] \quad (1)$$

272 where R_a is the activated fraction as a function of supersaturation S , E is maximum activated
273 fraction, and $(1-E)$ represents the number fraction of particles consisting of only non-hygroscopic
274 species (e.g., uncoated rBC) that cannot serve as CCN under typical atmospheric supersatura-
275 tions. S^* is the supersaturation at which R_a reaches 50% of E , and represents the median critical
276 supersaturation of size-selected particles that serve as CCN. The value of σ_s is related to the slope
277 of the increasing R_a with S near S^* and reflects the heterogeneity of critical supersaturation,
278 which to a large degree arises from the heterogeneity of the hygroscopicity among size-selected
279 particles (Cerully et al., 2011; Mei et al., 2013a). The probability density function of hygroscop-
280 icity for size-selected particles is derived from the $R_a(S)$. The average hygroscopicity $\overline{\kappa_{\text{CCN}}}$ and
281 dispersion of the hygroscopicity $\sigma(\kappa)/\overline{\kappa_{\text{CCN}}}$ for the size-selected CCN were then derived from
282 the probability density function of hygroscopicity using the approach detailed in Section S3.4 in
283 Supplementary Information. The dispersion of the hygroscopicity reflects the composition hetero-
284 geneity (i.e., mixing state) among size-selected particles (Mei et al., 2013a). For simplicity, we
285 use κ_{CCN} to represent the average hygroscopicity of size-selected CCN in the following sections.

286 3.2 Derivation of Organic Aerosol Hygroscopicity

287 The average particle hygroscopicity was then combined with the chemical composition data
288 to derive the hygroscopicity of the organic component of the size-selected particles, κ_{org} . Collec-
289 tively, the AMS, ACSM, SP2, and aethalometer provided mass concentrations of organic spe-
290 cies, sulfate, nitrate, ammonium, and rBC. The concentration of chloride was negligible ($\ll 1\%$
291 of aerosol mass) and was not included in the analysis. Given the low concentrations during
292 GoAmazon 2014/5, size-resolved mass concentrations at the time resolution of the CCN meas-
293 urement were not directly derived from AMS particle time of flight (PToF) mode data. For IOP
294 1, measurements were classified into three groups based on bulk organic mass fraction and the
295 characteristic mass size distribution of each species was averaged from measurements in each
296 group. For the dry season, the measurements were classified into three groups each for day and
297 night periods based on the bulk aerosol organic mass fraction, and the mass size distribution of
298 each species was averaged from measurements in each of the six groups. The size-resolved mass
299 concentrations of sulfate, nitrate, and organics at the time resolution of the CCN measurement
300 were then derived by scaling the total mass concentration using the average mass size distribu-
301 tions for the corresponding group (based on the bulk organic mass fraction) of either wet or dry
302 season (de Sá, 2017). The shape of the NH_4^+ mass size distribution was assumed to be the same
303 as that of sulfate, as ammonium cations were primarily associated with sulfate. rBC was as-
304 sumed to have the same size distribution shape as the total aerosol mass (i.e., mass fraction of
305 rBC was independent of particle size); though this assumption may not always be appropriate,
306 the effect is expected to be very small as the monthly average volume fraction of rBC was al-
307 ways less than 4% (Fig. 1). A detailed description of the derivation of the size-resolved mass
308 concentrations is given in Section S4.1.

309 In most cases, NH_4^+ was insufficient to completely neutralize SO_4^{2-} . The concentrations of
310 both organonitrate and inorganic nitrate during the two IOPs were retrieved from AMS data
311 based on the ratio of ions NO^+ and NO_2^+ (de Sá, 2017; Fry et al., 2009). When the inorganic ni-
312 trate mass concentration was negligible (i.e., less than 30 ng m^{-3}), as in most of the cases, the
313 contributions of ammonium sulfate and ammonium bisulfate were calculated based on the mass
314 concentrations of SO_4^{2-} and NH_4^+ (Nenes et al., 1998). In rare cases when the mass concentra-
315 tion of inorganic nitrate was greater than 30 ng m^{-3} , sulfate was assumed to be ammonium sul-
316 fate. During non-IOP periods, only the total nitrate mass concentration is available, all nitrate
317 was assumed to be organonitrate (Cerully et al., 2015; Lathem et al., 2013a; Nenes et al., 1998;
318 Zhang et al., 2005), and sulfate fully neutralized by ammonium (see Section S4.2 in the Supple-
319 ment for a sensitivity study of these assumptions for non-IOP periods). The $-\text{ONO}_2$ portion of
320 the organonitrate was added back to the organic mass. We note that the amount of $-\text{ONO}_2$ added
321 back was typically small given the low mass fraction of nitrate in the aerosol. Cloud condensa-
322 tion nuclei were assumed to be internal mixtures of $(\text{NH}_4)_2\text{SO}_4$, NH_4HSO_4 , NH_4NO_3 , organics,
323 and rBC, and the volume fractions of the species were derived from the mass concentrations and
324 densities. Densities of organics were estimated from the ratios of O:C and H:C measured by the
325 AMS (Kuwata et al., 2012) and were on average 1450 ± 100 and $1470 \pm 80 \text{ kg m}^{-3}$ for IOP1 and
326 IOP2, respectively. Densities of 1770, 1790, 1730, 1800 kg m^{-3} were used for $(\text{NH}_4)_2\text{SO}_4$,
327 NH_4HSO_4 , NH_4NO_3 , and rBC (Bond and Bergstrom, 2006; Park et al., 2004), respectively. In
328 very rare cases, E was less than 100%, suggesting some of the size-selected particles were non-
329 hygroscopic. The non-hygroscopic particles were assumed to consist entirely of rBC (Mei et al.,
330 2013a). The volume concentration of the non-hygroscopic particles was derived as the product of
331 $(1-E)$ and the total volume concentration (i.e., the sum of volume concentrations of organics,

332 (NH₄)₂SO₄, NH₄HSO₄, NH₄NO₃ and rBCs) at the size classified by the DMA. The volume con-
333 centration of rBC internally mixed within the CCN-active particles was then calculated as the
334 difference between the total rBC volume concentration and the volume concentration of the non-
335 hygroscopic particles. (Mei et al., 2013a; Mei et al., 2013b). Assuming a κ value of zero for rBC,
336 we can derive the hygroscopicity of the organic component of the CCN κ_{org} as:

$$337 \quad \kappa_{\text{org}} = \frac{1}{x_{\text{org}}} \left(\kappa_{\text{CCN}} - x_{(\text{NH}_4)_2\text{SO}_4} \kappa_{(\text{NH}_4)_2\text{SO}_4} - x_{\text{NH}_4\text{HSO}_4} \kappa_{\text{NH}_4\text{HSO}_4} - x_{\text{NH}_4\text{NO}_3} \kappa_{\text{NH}_4\text{NO}_3} \right) \quad (2)$$

338 where x_i is the volume fraction of the respective species. The κ values are 0.61, 0.7 and 0.67 for
339 (NH₄)₂SO₄, NH₄HSO₄, and NH₄NO₃, respectively (Petters and Kreidenweis, 2007). The uncer-
340 tainty in κ_{org} using these calculations has been derived using the approach detailed in earlier
341 studies (Mei et al., 2013a; Mei et al., 2013b) and is on the order of 0.01 – 0.02 (which was gen-
342 erally between 10 and 20%) for this data set.

343 **3.2.1 Derivation of κ for AMS PMF Factors**

344 PMF was applied to the AMS mass spectra (Lanz et al., 2008; Ulbrich et al., 2009), and six
345 organic factors were identified for each of the two IOPs (de Sá, 2017). For IOP2 the PMF analy-
346 sis included data from 24 August to 15 October 15, 2014, excluding a major regional biomass
347 burning event from 16 to 23 August, which was treated separately in the PMF analysis. For IOP1
348 (wet season), the six factors were isoprene-epoxydiol-derived secondary organic aerosol (IE-
349 POX-SOA), more-oxidized oxygenated organic aerosol (MO-OOA, i.e., highly oxidized organ-
350 ics), less-oxidized oxygenated organic aerosol (LO-OOA), biomass burning organic aerosol
351 (BBOA) with characteristic peaks at $m/z = 60$ and 73 and correlated with the concentrations of
352 levoglucosan and vanillin, a factor with high contribution from $m/z = 91$ (Fac91) and correlated

353 with anthropogenic emissions of aromatics, and hydrocarbon-like organic aerosol (HOA). The
354 six factors for IOP2 included IEPOX-SOA, MO-OOA, LO-OOA, an aged biomass burning or-
355 ganic aerosol factor (aged-BBOA), a fresh biomass burning organic aerosol factor (fresh-
356 BBOA), and HOA. Further details of PMF analysis and the characteristics of the factors can be
357 found in de Sá (2017). The O:C ratio and calculated density for each factor are presented in Ta-
358 ble 1. In this study, the O:C ratio was derived using Improved-Ambient Method (Canagaratna et
359 al., 2015).

360 For each IOP, hygroscopicities associated with the six factors were attributed based on multi-
361 linear regression of κ_{org} with respect to the volume fractions of the factors (Levenberg-Marquardt
362 algorithm, IGOR Pro, Wavemetrics):

$$363 \quad \kappa_{org} = \sum_i^n \kappa_i x_i \quad (3)$$

364 where κ_i and x_i are the hygroscopicity and volume fraction of the individual organic PMF factors.
365 The volume fraction was derived from mass concentrations and the densities of the factors. κ_{org}
366 represents the average organic hygroscopicity at particle diameters (D_p) of 142 and 171 nm. As
367 the PMF analysis is based on the mass spectra of the bulk sub-micrometer aerosol (i.e., MS mode
368 measurements), an implicit assumption of Eq. (3) is that the bulk volume fractions of the factors
369 represented those over the sizes at which κ_{org} was derived (i.e., $D_p = 142$ and 171 nm). The va-
370 lidity of this assumption is discussed in the results section. The robustness of the factor hygro-
371 scopicity derived through linear regression depends on the variation of the factor volume fraction
372 during the measurement period. The HOA hygroscopicity was assumed as zero based on the re-
373 sults from previous studies (Cappa et al., 2009; Cappa et al., 2011; Jimenez et al., 2009), and the

374 hygroscopicity of the other five factors were derived by multilinear regression as described
375 above.

376 **3.3 Classification of Seasons and Air Masses**

377 The one-year sampling period was divided into different seasons by grouping months accord-
378 ing to the similarity of the aerosol properties and trace gas concentrations measured at the two
379 background sites, T0a and T0t, as well as monthly accumulated rainfall. In this study, the sea-
380 sons were defined as follows: the first wet season: March, April and May of 2014; the first tran-
381 sition season: June and July 2014; the dry season: August and September of 2014; the second
382 transition season: October, November and the first half of December 2014; and the second wet
383 season: the second half of December 2014 and January, February and the first few days of March
384 2015.

385 For each season, the air masses arriving at the T3 site were classified into three different
386 types: background, urban pollution, and local biomass burning based on trace gas and aerosol
387 measurements at all sites. During the wet season, the background air mass represented near natu-
388 ral conditions, with occasional impact from anthropogenic emissions, while in the dry season, the
389 background was dominated by regional biomass burning aerosol particles. Polluted air masses
390 represent those with strong influence from urban emissions, which were mostly from Manaus.
391 The local-biomass-burning type describes those air masses strongly influenced by local (i.e.,
392 fresh) biomass burning activities, which dominated over the impact from urban pollution, if any.
393 For each season, background conditions were identified when CO and CN concentrations were
394 below the thresholds derived from measurements at the background T0a and T0t sites, and the
395 NO_y mixing ratio was below 1.5 ppb. Non-background conditions were identified by CN and CO

396 concentrations above the respective threshold levels. As biomass burning aerosol typically has a
397 higher fraction of accumulation mode particles, and the emissions from Manaus were more dom-
398 inated by Aitken mode particles, the fraction of particles with diameter less than 70 nm was used
399 to differentiate air masses strongly influenced by local biomass burning from those with more
400 impact from urban pollution (see Table S2 in Supplementary Information for details). Contami-
401 nation by the emissions from an on-site diesel generator, grass cutting activities, tractors, and
402 other vehicles were evidenced by rBC concentrations above $1.0 \mu\text{g m}^{-3}$ or CN concentration
403 above $10,000 \text{ cm}^{-3}$. Over the one-year measurement period, background, urban pollution, and
404 local biomass burning represented 12.4%, 38.5%, and 28.4% of the CCN measurements, respec-
405 tively (Table S3). We note that the air masses arriving at the T3 site often included contributions
406 from different sources. The classification of the air masses using the above three types clearly
407 represents a simplification, but is very helpful for understanding the properties of aerosols influ-
408 enced by the various major sources.

409 **4 Results**

410 **4.1 Seasonal Trend and Size Dependence of Hygroscopicity and Chemical Composition**

411 The monthly average κ_{CCN} at the T3 site varied from 0.1 to 0.2 at five particle diameters
412 ranging from 75 nm to 171 nm (Fig. 1a), and was substantially lower than the value of 0.3 ± 0.1
413 suggested for continental sites (Andreae and Rosenfeld, 2008). This was due to the large organic
414 volume fraction, up to 95% observed at the T3 site. In this study, measurements at 51 and 222
415 nm were not included, because the range of supersaturation sampled inside the CCN counter on-
416 ly adequately captured the activation spectrum for 51/222 nm particles with relatively high/low
417 κ_{CCN} values, leading to a positive/negative bias of the average κ_{CCN} . The value of κ_{CCN} exhibited

418 similar seasonal variations at all five sizes. During the transition from wet to dry season, κ_{CCN}
419 decreased by 20-30% with the absolute minimum of 0.116 occurring at 75 nm in September and
420 October (Fig. 1a).

421 The seasonal trend of κ_{CCN} was mainly driven by the variation of κ_{org} , which shows the low-
422 est value in September during the dry season (Fig. 1b). Despite a strong increase of aerosol mass
423 concentration from wet to dry season due to biomass burning emissions, the organic volume
424 fraction exhibited little season variation, and was ~90% or higher at the four sizes from 94 to
425 171 nm (Fig. 1c). A minor increase in organic volume fraction in October might have also con-
426 tributed to the lower κ_{CCN} value observed. The species volume fractions at 75 nm are not shown
427 due to the very low signal-to-noise ratio of the AMS PToF data in the small particle diameter
428 range. No clear seasonal trend was observed for sulfate volume fraction, which ranged from 3%
429 to 9% at the four sizes. Nitrate and rBC represented a small fraction of aerosol volume, and were
430 less than 1% and ~4%, respectively.

431 The average κ_{CCN} increased with increasing particle size for all three air mass types and dur-
432 ing all the seasons (Fig. 2), consistent with decreasing organic volume fraction with increasing
433 particle size (Fig. 1c). The κ_{CCN} at 75, 94, 112, 142, and 171 nm averaged for the one-year meas-
434 urement period were 0.130 ± 0.028 , 0.144 ± 0.039 , 0.148 ± 0.043 , 0.164 ± 0.046 , and $0.167 \pm$
435 0.042 respectively. The value of κ_{CCN} and its size dependence under background conditions were
436 largely consistent among different seasons, and were in good agreement with those observed un-
437 der near natural conditions during the AMAZE-08 campaign at T0t in the wet season (Gunthe et
438 al., 2009) and during the one-year period from March 2014 to February 2015 at the background
439 T0a site (Pöhlker et al., 2016). Compared to κ_{CCN} , κ_{org} was largely independent of particle size
440 for all three air mass types, indicating that the size dependence of κ_{CCN} was mainly due to the

441 size dependence of the organic volume fraction and particle composition (Fig. 1c – f). During
442 the dry season, aerosols classified as urban pollution and local biomass burning exhibited lower
443 κ_{org} values compared to background aerosols, contributing to the lower values of overall κ_{CCN} .

444 **4.2 Diel Trends of Particle and Organic Hygroscopicities**

445 The diel variations of aerosol properties are presented in Figs. 3-7 for different air masses
446 during the two IOPs. Aerosol properties derived from the size-resolved CCN measurements, in-
447 cluding κ_{CCN} , $\sigma_{\kappa_{\text{CCN}}} / \bar{\kappa}_{\text{CCN}}$, and κ_{org} , and the volume fractions of different species were averaged
448 at the three largest sizes ($D_p = 112, 142, \text{ and } 171 \text{ nm}$). The fraction of organic mass at $m/z = 44$
449 (f_{44}) and O:C were derived from the AMS bulk measurements. Also shown are diel variations of
450 planetary boundary layer height, CN, and aerosol volume concentrations based on 5-minute av-
451 erage data.

452 **4.2.1 Wet Season Aerosol**

453 *Background conditions*

454 Figures 3 and 4 show the diel variations of aerosol properties during the wet season of 2014
455 for background and urban pollution air masses, respectively. There were only 0.7% of data clas-
456 sified as local biomass burning (see Table S3), which is insufficient to evaluate the diel trends.
457 During the wet season, the background air mass represents near-natural conditions, with mini-
458 mum impact from anthropogenic emissions, although long-distance transport of African biomass
459 burning may contribute to the aerosols observed (Chen et al., 2009; Wang et al., 2016b). Back-
460 ground aerosol constantly exhibited relatively high hygroscopicity of ~ 0.19 throughout the day.
461 The lack of a diel trend in κ_{CCN} is also in agreement with the results from the T0a site (ATTO),

462 which is upwind of Manaus and served as a background site (Fig. 8). The particle composition
463 averaged for the three particles diameters was dominated by organics, representing ~ 90% of the
464 aerosol volume. The lack of a diel trend in κ_{CCN} and κ_{org} suggest little variation in particle com-
465 position throughout the day. The nearly constant κ_{org} of ~0.16 is also consistent with the lack of a
466 diel trend in f_{44} and O:C. The values of f_{44} and O:C are ~0.2 and ~0.8, respectively, indicating
467 that the aerosol under background condition during the wet season was dominated by the aged
468 regional aerosol particles consisting of highly oxygenated organic compounds.

469 Aerosol number and volume concentrations exhibited a minimum at $\sim 310 \text{ cm}^{-3}$ and $\sim 0.3 \mu\text{m}^3$
470 cm^{-3} , respectively, just before sunrise. The number and volume concentrations started increasing
471 after sun rise, and peaking at 400 cm^{-3} and $0.8 \mu\text{m}^3 \text{ cm}^{-3}$ in the afternoon. These diel variations
472 are partially attributed to the wet scavenging of accumulation mode particles, which dominate
473 the submicron particle concentrations under background conditions, and the mixing of the parti-
474 cles from the residual layer aloft down to the surface as the boundary layer develops in the morn-
475 ing. During the night, the radiative cooling at the surface leads to a shallow nocturnal boundary
476 layer with low and variable winds. RH near surface was near 100%, and fog or mist was identi-
477 fied by the weather station (Present Weather Detector, Visalia) 62% of the time during the one-
478 year measurement period. The gradual decrease of particle number and volume concentration
479 during these fog events were due to the wet deposition of the accumulation mode particles acti-
480 vated into droplets. Similar decreases of particle number concentration were previously reported
481 during night fog events in the tropical rainforest in Borneo (Whitehead et al., 2010). After sun-
482 rise, the boundary layer deepened on average from less than 200 up to 800 m as a result of solar
483 heating (Fig. 3g). Consequently, particles in the residual layer aloft (Fisch et al., 2004; Rissler et
484 al., 2006b), which were not impacted by the fog, were mixed down to the surface, leading in part

485 to the observed increases in both number and volume concentrations. Such mixing of particles
486 from the residual layer in the morning had been observed previously in the Amazon basin during
487 the dry season (Rissler et al., 2006a). The formation of secondary organic aerosol (SOA) as a
488 result of photochemical oxidation (in both gas and particle phases) likely contributed to the in-
489 crease in volume concentration (Chen et al., 2015; Chen et al., 2009; Martin et al., 2010a; Pöschl
490 et al., 2010).

491 *Air masses impacted by urban pollution*

492 Air masses arriving at the T3 site frequently had passed over urban and industrial areas up-
493 wind. When the air mass was influenced by the urban pollution, κ_{CCN} and its dispersion exhibited
494 clear diel variations (Fig. 4). The value of κ_{CCN} was lower during the night at 0.15, and it in-
495 creased from the early morning hours, peaking at a value of 0.19 around noon (local time, UTC –
496 4 h). The dispersion was anti-correlated with κ_{CCN} , exhibiting higher values (i.e., increased het-
497 erogeneity in particle chemical composition) during night and a minimum value around noon. To
498 a large degree, the diel trend of κ_{CCN} was due to the variation of κ_{org} . The value of κ_{org} was lower
499 during night at 0.10 and increased to 0.16 at noon. The increase of κ_{org} is consistent with the var-
500 iation of O:C, which increased during the early morning and reached the highest value of 0.8
501 around noon time. The pollution strongly affected the particle number and volume concentra-
502 tions, both exhibiting similar diel trends. Under polluted conditions, particle number concentra-
503 tion ranged on average from 1500 to 2300 cm^{-3} , an increase by a factor of ~ 5 from that under
504 background conditions. In comparison, the increase of the volume concentration was only about
505 a factor of 2 (i.e., from a range of 0.3 - 0.75 to 1.0 to 1.3 $\mu\text{m}^3 \text{cm}^{-3}$), as the urban pollution is
506 dominated by Aitken mode particles that make a relatively small contribution to aerosol mass
507 and volume concentration.

508 The diel variations of κ_{CCN} , its dispersion, κ_{org} , and O:C are explained as follows. During
509 night, particles in freshly emitted pollution, which are dominated by primary organic aerosol
510 (POA) and have low hygroscopicity, are mixed with more aged particles within a shallow noc-
511 turnal boundary layer (Bateman et al., 2016). In the absence of photochemical oxidation and ag-
512 ing, this external mixture leads to higher dispersion of particle hygroscopicity, as well as overall
513 lower O:C and κ_{org} . As the pollution aerosols are mainly from isolated point sources, they are
514 confined in the shallow nocturnal boundary layer during night, and the residual layer above the
515 T3 site is expected to consist of aged background aerosols. Therefore, unlike under background
516 conditions, the mixing of aerosol aloft in the residual layer down to the surface cannot by itself
517 explain the increase in particle number and volume concentration during the day, both of which
518 were substantially above the background values. These increases under polluted conditions might
519 be due to the stronger urban influence at T3 during the day. The strong increase of CN concen-
520 tration at 16:00 UTC (local time 12:00) could be caused by the arrival at the T3 site of the Ma-
521 naus plume emitted during early morning traffic hours. To a large degree, the increases in O:C
522 and κ_{org} are due to the formation and aging of SOA in the pollution, while the development of the
523 daytime boundary layer, which leads to dilution of pollution and mixing with aged particles from
524 the residual layer, can also contribute to the increases. The condensation of secondary species
525 and photochemical aging also lead to more homogenous composition among particles (Mei et al.,
526 2013a), and therefore lower dispersion of κ_{CCN} , as was observed. The O:C reached a maximum
527 average value of 0.8, similar to that under the background conditions. This suggests that the for-
528 mation and photochemical aging of SOA quickly led to highly oxygenated organic compounds
529 (i.e. within several hours) (de Sá, 2017).

530 **4.2.2 Dry Season Aerosol**

531 ***Background conditions***

532 Figures 5-7 show the diel variations of the aerosol properties observed during the dry season
533 for background, urban pollution, and local biomass burning air masses, respectively. During the
534 dry season, the background aerosol (Fig. 5) is strongly influenced by regional biomass burning,
535 and air masses arriving at the T3 site often pass through urban and industrial areas along the
536 Amazon River and in northeast Brazil (Andreae et al., 2015), indicating that the background aer-
537 osol is also impacted by more aged urban and industrial emissions (Martin et al., 2016a). Despite
538 different aerosol sources and processes, the particle hygroscopicity, dispersion, and κ_{org} exhibited
539 similar values as those of background aerosol during the wet seasons, and a lack of obvious diel
540 variations. This is also consistent with the absence of a significant diel trend of κ_{CCN} observed at
541 T0a (ATTO) during the dry season (Fig. 8). The O:C value increased slightly from 0.8 during
542 night to 0.9 in the afternoon, possibly due to further oxidation and aging of background aerosols
543 during the day time. The high value of O:C is consistent with the relatively high value of κ_{org}
544 (0.15) and is close to that observed under background condition during the wet season, indicating
545 highly oxygenated organic aerosol. The number and volume concentrations were lower just be-
546 fore dawn and increased during the early morning, again a result of wet scavenging of particles
547 by fog followed by the mixing of aerosol aloft in the residual layer down to the surface as the
548 boundary layer develops in the morning.

549 ***Air masses impacted by urban pollution and local biomass burning***

550 For urban pollution (Fig. 6) and local biomass burning (Fig. 7) air masses during the dry sea-
551 son, κ_{CCN} (urban pollution: 0.12 – 0.20, local biomass burning: 0.10 – 0.17), its dispersion (urban

552 pollution: 0.4 – 1.0, local biomass burning: 0.4 – 0.9), κ_{org} (urban pollution: 0.10 – 0.15; local
553 biomass burning: 0.08 – 0.14), and O:C (polluted: 0.7 – 0.85; biomass burning: 0.7 – 0.86)
554 showed similar values and diel variations as those under polluted conditions during the wet sea-
555 son. This is consistent with the picture that freshly emitted particles (in either the case of urban
556 pollution or local biomass burning) lead to overall lower O:C, κ_{org} , and higher κ_{CCN} dispersion
557 during night, followed by increases in O:C, κ_{org} , and a decrease in the dispersion during day time,
558 which are mainly driven by the formation and photochemical aging of SOA, with contributions
559 from the mixing of background aerosol aloft in the residual layer down to the surface and dilu-
560 tion of fresh emission as the boundary layer develops. Compared to urban pollution, local bio-
561 mass burning air masses exhibited lower κ_{CCN} and κ_{org} values during night and stronger diel vari-
562 ations. In the afternoon, κ_{org} and O:C reached high values of 0.14 and 0.86, respectively, as ob-
563 served for background aerosols.

564 For urban pollution air masses, aerosol number and volume concentrations showed similar
565 trends for both seasons. The increases of number and volume concentration from early morning
566 to noon were similar, about 1000 cm^{-3} and $0.5 \mu\text{m}^3/\text{cm}^3$, respectively, for both wet and dry sea-
567 sons. The percentage increases were less pronounced in the dry season due to the higher back-
568 ground values. In contrast to urban pollution, local biomass burning showed higher aerosol num-
569 ber and volume concentrations at night, and decreased during the morning. Local biomass burn-
570 ing activities typically peaked during evening hours, consistent with frequent classification of the
571 night time aerosol as local biomass burning (Fig. 7i) (Vestin et al., 2007). Despite the wet re-
572 moval of particles by fog, the strong emission from local biomass burning, largely confined with-
573 in the shallow nocturnal boundary layer, led to higher surface aerosol concentrations than those
574 in the residue layer aloft, which likely represented the regional background. As the boundary

575 layer deepened in the morning, the mixing with aerosol from the residual layer led to decreases
576 in both aerosol number and volume concentration observed at the surface (Fig. 7e,f).

577 **4.3 Hygroscopicity of PMF Factors and the Variation of Organic Hygroscopicity with Oxi-** 578 **ation Level**

579 The hygroscopicities associated with the AMS PMF factors were estimated through multi-
580 variable linear regression using different subsets of the data, as well as the entire dataset for each
581 of the two IOPs (IOP1 in Fig. 9 and IOP2 in Fig. 10). The different subsets included measure-
582 ments during day, night, certain sampling periods, and ranges in particle hygroscopicity disper-
583 sion. Comparison of the hygroscopicities derived from the different subsets of data allowed us to
584 examine the robustness of this approach. Uncertainty in the derived κ for individual factors was
585 determined by the number of points available to fit in the time series, with greater data coverage
586 and therefore lower uncertainty during the dry season. For the wet season (IOP1), the hygroscopi-
587 city associated with PMF factors derived using different subsets of the data are largely in
588 agreement with those derived from the entire dataset. There are notable differences between the
589 hygroscopicities of MO-OOA and Fac91 factors derived using data under background conditions
590 only and those derived using the entire dataset. Such difference could be partially due to the lim-
591 ited data under the background conditions during IOP1 (Fig. 3). For the dry season (IOP2), the
592 hygroscopicities of PMF factors derived using measurements under background conditions or
593 data with hygroscopicity dispersion less than 0.4 are quite different from those derived using
594 other data subsets and the entire dry season dataset. The agreement among the PMF factor hy-
595 groscopicities derived using different sub datasets during the wet season and the disagreements
596 for the dry season are attributed to the applicability of the underlying assumption that the bulk
597 volume fractions of PMF factors (i.e., derived from MS mode data) represented those at the sizes

598 of CCN measurements. For the wet season, the average f_{44} was largely independent of particle
599 size from 130 to 400 nm (Fig. S10), the size range that dominated bulk aerosol mass concentra-
600 tion measured by AMS. This is consistent with the assumption that the bulk volume fractions of
601 the PMF factors represent those at the two CCN sizes (142 and 171 nm). For the dry season, the
602 f_{44} averaged over local biomass burning air masses and the entire IOP2 exhibited an increase
603 with particle diameter from 100 to 300 nm (Fig. S10). For periods with hygroscopicity dispersion
604 less than 0.4 or under background conditions, the average size distribution of f_{44} was noisier due
605 to fewer data points. Nevertheless, the size distribution shows f_{44} was largely independent of the
606 particle size under these conditions, consistent with the assumption described above. In the fol-
607 lowing discussion, we focus on the PMF factor hygroscopicities derived using all data during the
608 wet season, and under background conditions in the dry season.

609 The MO-OOA factors for the two IOPs exhibit very similar O:C and κ values. The O:C val-
610 ues were 1.19 and 1.24, and κ values were 0.20 and 0.21 for IOP1 and 2, respectively (Table 1).
611 The O:C and κ values are consistent with those of some typical SOA compounds, such as malo-
612 nic acid, which has an O:C value of 1.33 and a κ value of 0.23 (Kumar et al., 2003), and succinic
613 acid, which has an O:C value of 1 and a κ value of 0.23 (Hori et al., 2003). For the LO-OOA and
614 IEPOX-SOA factors, the hygroscopicities vary between the two IOPs. The κ of IEPOX-SOA
615 were 0.18 and 0.08 during IOP1 and IOP2, respectively, and the κ of LO-OOA factor varied
616 from 0.12 to 0.20 between IOP 1 and IOP 2. The difference in κ may be partially due to the
617 change of O:C values of the factors derived for the two IOPs. Difference in SOA precursors and
618 therefore composition in LO-OOA (Ng et al., 2010) may also contribute to the difference in its κ
619 values between the two IOPs. The variation of IEPOX-SOA κ between the two IOPs could be a

620 result of the different RH conditions, which may strongly influence the composition of IEPOX-
621 SOA (Riva et al., 2016).

622 During the wet season, a factor with high contribution from $m/z = 91$ (Fac91) was identified.
623 The Fac91 factor correlates with several tracers for anthropogenic emissions, including NO_x ,
624 benzene, toluene, trimethylbenzene (TMB) and xylenes, but not high NO_x isoprene products (e.g.
625 methylglyceric acid) (de Sá, 2017). This factor likely represents SOA formed from aromatics
626 emitted from urban areas, possibly combined with a mixture of freshly oxidized biogenic com-
627 pounds within the urban-influenced air (de Sá, 2017). The Fac91 factor has a hygroscopicity val-
628 ue of 0.10, and a much lower O:C ratio of 0.328 compared to those of MO-OOA and LO-OOA.

629 Less oxidized organic factors identified by the PMF analysis were HOA of both IOPs,
630 BBOA of IOP1 and fresh and aged BBOA of IOP2. These factors represent primary OA (POA),
631 except that the aged BBOA of IOP2 likely included contributions from oxidized POA or SOA.
632 The hygroscopicity of the HOA factors was fixed as zero in the multivariate regressions. All
633 BBOA factors have a distinctive $m/z = 60$ peak and correlate with biomass burning traces includ-
634 ing levoglucosan and vanillin (de Sá, 2017). The retrieved hygroscopicity values for the BBOA
635 factors are substantially lower than those of SOA factors, especially for the fresh BBOA factor
636 during IOP2. The extremely low hygroscopicity suggests that the fresh BBOA, likely produced
637 by local fires, behaves very similar to HOA in term of CCN activation despite a substantially
638 higher O:C.

639 Figures 11 and 12 show that for SOA factors, including IEPOX-SOA, LO-OOA, MO-OOA
640 for both IOPs and Fac91 for IOP1, the κ value increases with increasing O:C, and the variation of
641 κ with O:C agrees with the linear relationship derived from laboratory studies of SOA CCN ac-

642 tivities (Lambe et al., 2011). The low hygroscopicity of the HOA and the BBOA factors, which
643 are below the linear relationship for SOAs, are also consistent with laboratory results of POA
644 and oxidized POA (Lambe et al., 2011). Cerully et al. (2015) derived κ of LO-OOA, MO-OOA,
645 and IEPOX-SOA factors from data collected in the southeast US during Southern Oxidant and
646 Aerosol Study (SOAS). A different name, Isoprene-OA, was used for the IEPOX-SOA factor in
647 Cerully et al. (2015), as while this factor is mainly attributed to SOA formed from IEPOX up-
648 take, it might not be entirely due to IEPOX (Schwantes et al., 2015; Xu et al., 2015a; Xu et al.,
649 2015b). The O:C values calculated using the Improved-Ambient method (Canagaratna et al.,
650 2015) are 0.59, 0.61, and 0.92 for the IEPOX-SOA, LO-OOA, and MO-OOA factors reported in
651 Cerully et al. (2015), respectively (personal communication, L. Xu and N.L. Ng). For the LO-
652 OOA, MO-OOA factors reported in Cerully et al. (2015), κ and O:C values are largely consistent
653 with the linear relationship between κ and O:C derived from Lambe et al. (2011). Cerully et al.
654 (2015) also reported IEPOX-SOA (i.e., called Isoprene-OA in their study) factor κ of 0.2, simi-
655 lar to 0.18 derived for IOP1. The O:C value of the IEPOX-SOA factor during the SOAS study
656 was 0.59, somewhat lower than those derived from both IOPs of GoAmazon. While the IEPOX-
657 SOA factors identified using different datasets share many similar features, they are not identical
658 and can consist of different groups of compounds. Such differences may be due to varying de-
659 grees of oxidation in different environment between the two field campaigns.

660 For comparison with earlier field studies, the values of κ_{org} and O:C were averaged according
661 to the hours of the day over particle diameters of 142 and 171 nm for data under polluted condi-
662 tions during IOP1 and all data during IOP2 (Figs. 11 and 12). For the one-hour diel averages, the
663 slope of κ_{org} vs. O:C, derived through a bivariate least squares fit (i.e., Orthogonal distance re-
664 gression), is steeper than that derived from laboratory studies of SOA hygroscopicity, especially

665 during IOP2. This steep slope during IOP2 is consistent with the results from earlier field studies
666 (Mei et al., 2013b), although there is a clear offset between the two relationships. The O:C ratios
667 from Mei et al. (2013b) and Lambe et al. (2011) were scaled by a factor of 1.27 to account for
668 changes in the method of calculating the O:C ratio (Improved-Ambient, Canagaratna et al., 2015)
669 while all O:C values from this work were calculated using the Improved-Ambient method. This
670 offset between the field studies may be partially due to the different precursors of the SOA for
671 the campaigns, with higher anthropogenic VOC fraction expected for CalNex and CARES,
672 which took place near Los Angeles and Sacramento, respectively. In addition, biomass burning
673 represented a much smaller fraction of the organics during CalNex and CARES (Mei et al.,
674 2013a; Mei et al., 2013b). The factors associated with secondary processes (e.g., MO-OOA, LO-
675 OOA, and IEPOX-SOA), which have higher O:C values, exhibited higher volume fraction dur-
676 ing the day, whereas the factors associated with primary emissions (e.g. HOA and BBOA),
677 which have lower O:C, had higher volume fractions during the night (de Sá, 2017). As a result,
678 the diel trend of overall O:C was to a large degree driven by the variations in volume fractions of
679 the POA and SOA factors with very different O:C values. This is in contrast to laboratory stud-
680 ies, in which the increase of O:C was mainly driven by oxidation. As POA exhibits hygroscopicity
681 values well below the linear fit between SOA hygroscopicity and O:C, mixtures with dif-
682 ferent POA and SOA fractions lead to a steeper slope for the increase of κ_{org} with O:C, as shown
683 by the results from this and previous field studies (Mei et al., 2013b).

684 **5 Conclusions**

685 Size-resolved CCN spectra at five particle diameters ranging from 75 to 171 nm were
686 characterized down-wind of Manaus, Brazil, in central Amazonia for a period of one year from
687 March 12, 2014 to March 3, 2015 during GoAmazon2014/5. For each season, the air masses ar-

688 riving at the site were classified into different types, including background, urban pollution, and
689 local biomass burning. During the wet season, the background air mass represented near natural
690 conditions, at times with impact from anthropogenic emissions, while in the dry season, the
691 background was dominated by regional and long-distance biomass burning aerosol particles. Pol-
692 luted air masses represented those with strong influence from urban emissions, which were most-
693 ly from Manaus. The local-biomass-burning type describes those strongly influenced by local
694 (i.e., fresh) biomass mass burning activities that dominate over the impact from urban pollution,
695 if any.

696 Particle hygroscopicity (κ_{CCN}), mixing state, and organic hygroscopicity (κ_{org}) were derived
697 from size-resolved CCN activation fraction and concurrent aerosol composition measurements.
698 The monthly mean κ_{CCN} exhibits the lowest values during the dry season, largely due to lower
699 κ_{org} when aerosol was often strongly influenced by local biomass burning. The κ_{CCN} increased
700 with particle size during all seasons, consistent with decreasing organic volume fraction with in-
701 creasing particle size. Under background conditions, the value of κ_{CCN} and its size dependence
702 were largely consistent among different seasons, despite the very different aerosol sources. Dur-
703 ing the dry season, aerosols classified as urban pollution and local biomass burning exhibited
704 lower κ_{org} values compared to background aerosols, contributing to the lower values of overall
705 κ_{CCN} .

706 Under background conditions during both wet and dry seasons, the largely constant diel
707 trends of κ_{CCN} and κ_{org} suggest little variation in particle composition throughout the day. The
708 constant κ_{org} of ~ 0.15 is consistent with the lack of a diel trend in f_{44} and O:C. The high values
709 of f_{44} and O:C indicate that the aerosols under background conditions are dominated by the aged
710 regional aerosol particles consisting of highly oxygenated organic compounds. When the air

711 mass is influenced by urban pollution or local biomass burning, κ_{CCN} , κ_{org} , f_{44} , and O:C exhibit
712 clear diel variations. The value of κ_{CCN} (0.1 - 0.2) is lower during the night, and increases from
713 the early morning hours, peaking around noon (local time, UTC - 4 h). This diel trend of κ_{CCN} is
714 largely driven by the variation in κ_{org} (0.08-0.15), consistent with the variation of O:C. The dis-
715 persion of κ_{CCN} is anti-correlated with κ_{CCN} , exhibiting higher values during night and a mini-
716 mum value around noon, indicating an increased heterogeneity in particle chemical composition
717 during night time. These diel variations for air masses strongly influenced by urban pollution and
718 local biomass burning indicate that during night, freshly emitted particles, dominated by POA
719 and with low hygroscopicity, are mixed with more aged particles within a shallow nocturnal
720 boundary layer. In the absence of photochemical oxidation and aging, this external mixture leads
721 to higher dispersion of particle hygroscopicity, as well as overall lower O:C and κ_{org} . The in-
722 creases in O:C and κ_{org} during daytime are driven by the formation and aging of SOA and dilu-
723 tion of POA emissions into a deeper boundary layer, while the development of the boundary lay-
724 er, which leads to mixing with aged particles from the residual layer, likely also contributes to
725 the increases.

726 The hygroscopicities associated with individual PMF organic factors were derived through
727 multi-variable linear regression. For the SOA factors, κ increases within increasing O:C, and the
728 variation of κ with O:C agrees well with the linear relationship derived from laboratory studies of
729 SOA hygroscopicity (Lambe et al., 2011). The low hygroscopicity of HOA and the BBOA fac-
730 tors, which are below the linear relationship, are also consistent with laboratory results of POA
731 and oxidized POA (Lambe et al., 2011). In contrast, the slope of κ_{org} (i.e., overall organic hygro-
732 scopicity) vs O:C is much steeper when compared to that derived from laboratory studies of
733 SOA hygroscopicity, especially for IOP2. Such difference is because the increase of O:C was

734 driven primarily by oxidation in laboratory SOA studies, while the variation in O:C of ambient
735 organics is to a large degree due to the variations in volume fractions of POA and SOA factors,
736 which have very different O:C values. As POA factors show hygroscopicity values well below
737 the linear fit between SOA hygroscopicity and O:C, mixtures with different POA and SOA frac-
738 tions lead to a steeper slope for the increase of κ_{org} with O:C, as shown by the results from this
739 and earlier field studies (Mei et al., 2013).

1169

1170 **Figures**

1171

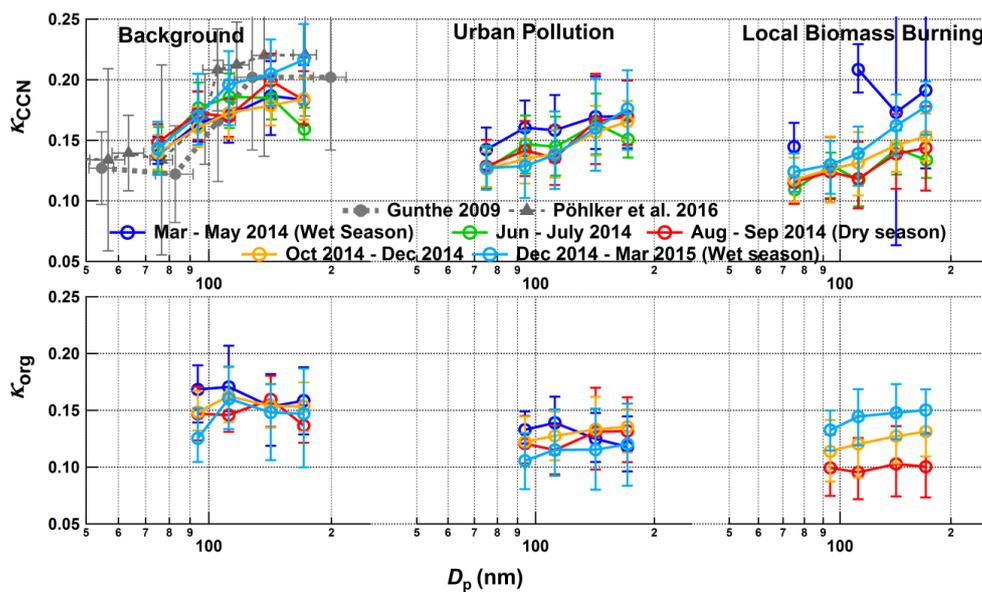

1172

1173 Figure 1: Seasonal variations of aerosol properties observed at the T3 site from March 2014 to
1174 March 2015, including (a) κ_{CCN} , (b) κ_{org} , and size resolved volume fraction of (c) organics, (d)
1175 sulfate, including $(NH_4)_2SO_4$ and NH_4HSO_4 , (e) nitrate, and (f) refractory Black Carbon. Data
1176 points are the monthly mean; error bars represent the 25th and 75th percentiles.

1177

1178

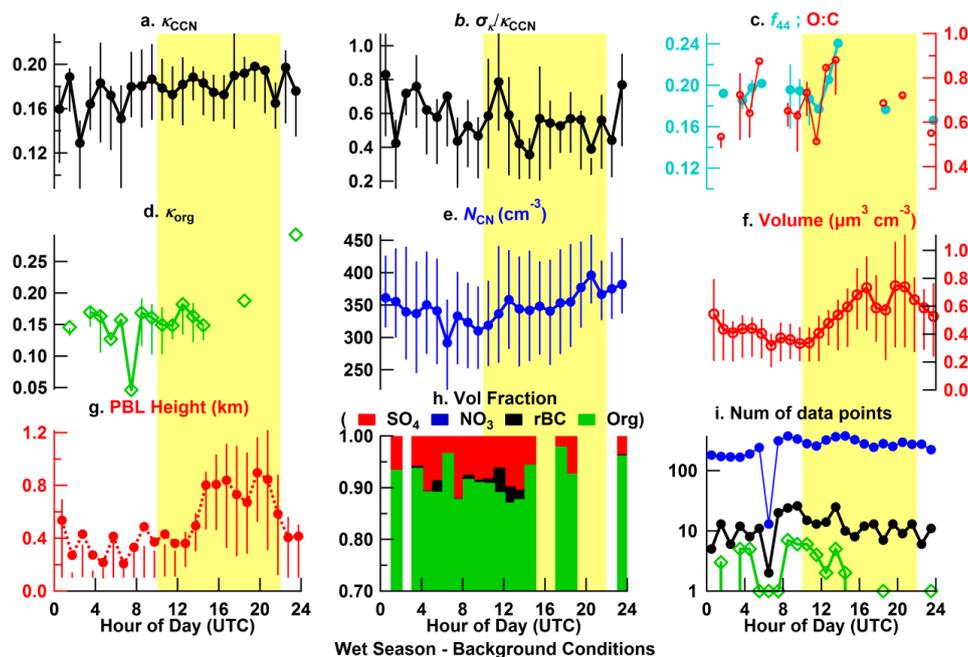

1179

1180 Figure 2: The variation of κ_{CCN} and κ_{org} with particle diameter during different seasons for each
1181 of three air mass types. Data points are the mean values; error bars are the 25 and 75 percentiles.

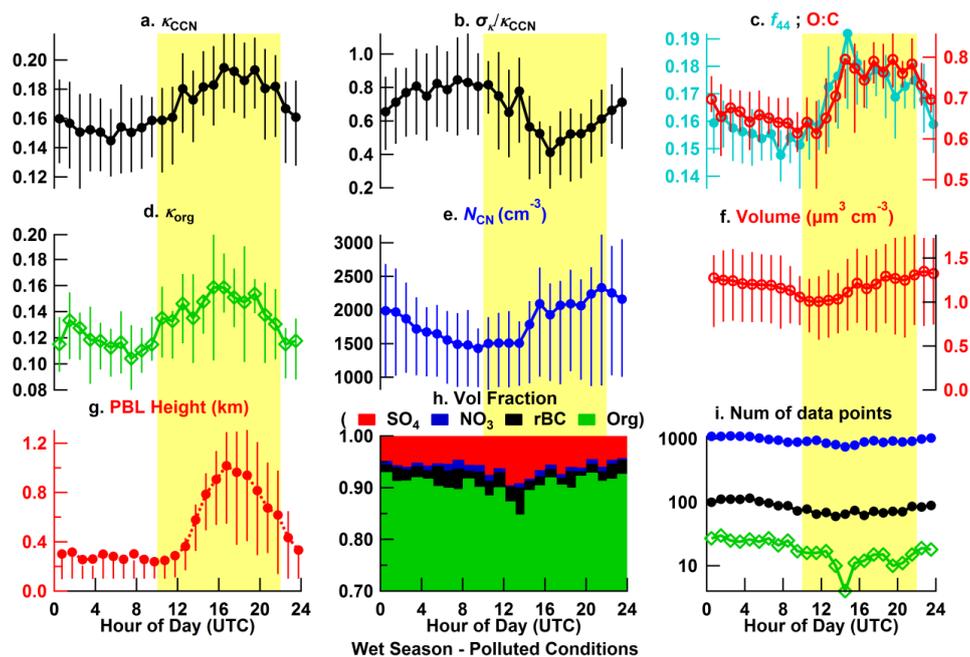

1182

1183

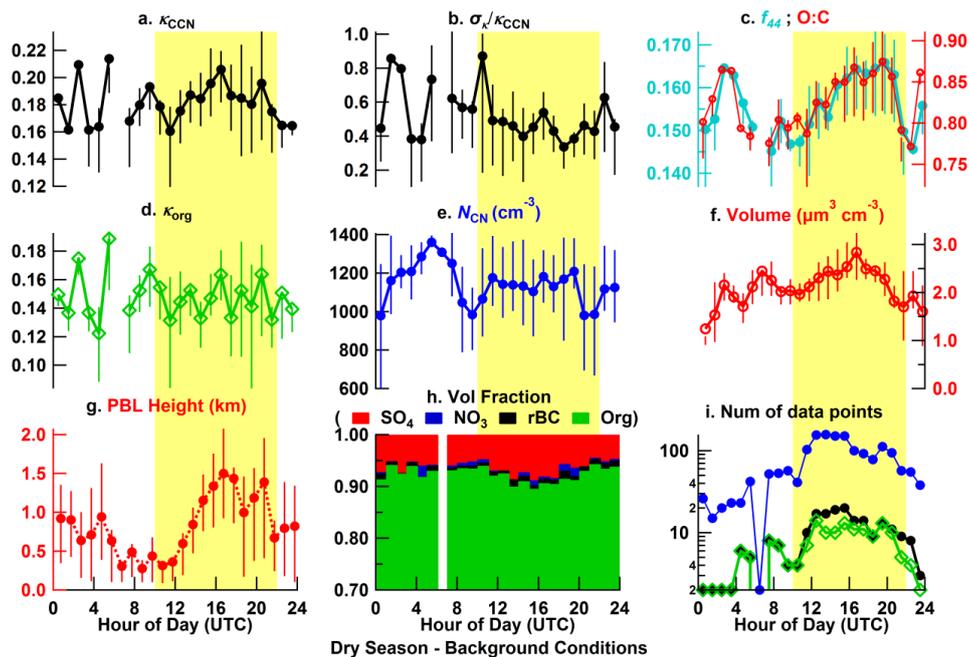

1184

1185
 1186 Figure 3: Diel variations of aerosol properties and meteorological parameter under background
 1187 conditions during the wet season, including (a) κ_{CCN} , (b) $\sigma_{\kappa_{\text{CCN}}} / \bar{\kappa}_{\text{CCN}}$, (c) fraction of the organic
 1188 mass at $m/z = 44$ (f_{44}) and the elemental ratio O:C, (d) κ_{org} derived using size resolved particle
 1189 composition, (e) the total number of condensation nuclei (N_{CN}), (f) the total aerosol volume de-
 1190 rived from size distribution measured by the SMPS in MAOS, (g) planetary boundary layer
 1191 height as estimated using the ceilometer data, (h) the volume fractions of aerosol species, and (i)
 1192 the number of samples in each hour bin corresponding to the data by the same colors and sym-
 1193 bols in their respective panel. The values of κ_{CCN} , $\sigma_{\kappa_{\text{CCN}}} / \bar{\kappa}_{\text{CCN}}$, κ_{org} , and volume fraction of aero-
 1194 sol species were averaged over three particle diameters of 112, 142 and 171 nm. The values of f_{44}
 1195 and O:C were derived from the AMS bulk measurements. Data include the last two weeks of
 1196 March 2014 when valid data from both size-resolved CCN system and AMS were available. Da-
 1197 ta points are hourly averaged mean values; error bars represent the 25 and 75 percentiles of the
 1198 data. Yellow shading represents the local daytime (10:00 – 22:00 UTC).

1199
 1200 Figure 4: Diel variations of aerosol properties and meteorological parameters for urban pollution
 1201 air masses during the wet season (analogous to Fig. 3).

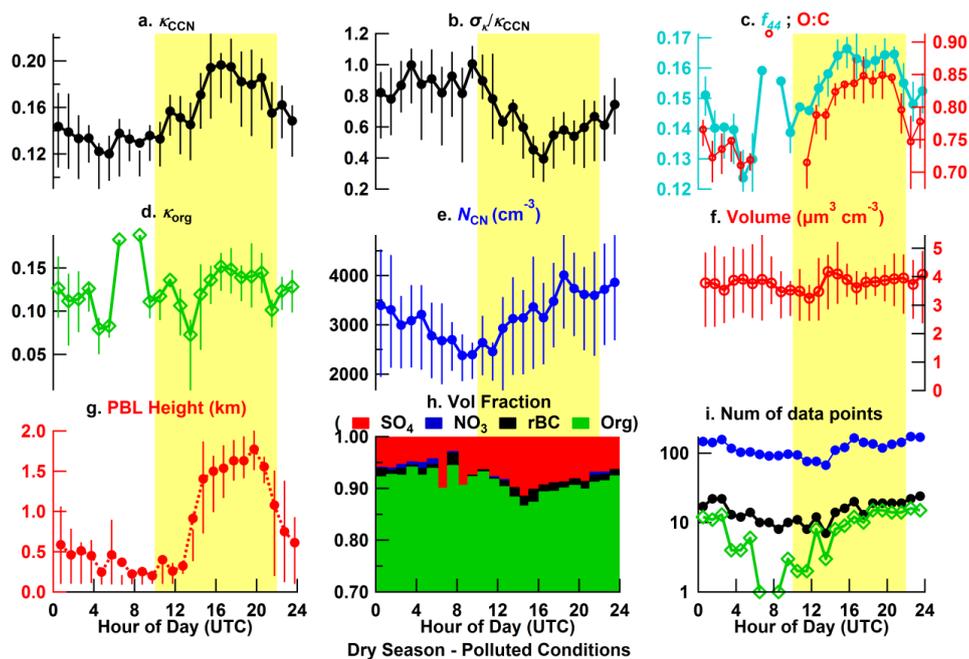

1202

1211 air masses during the dry season (analogous to Fig. 3).

1212

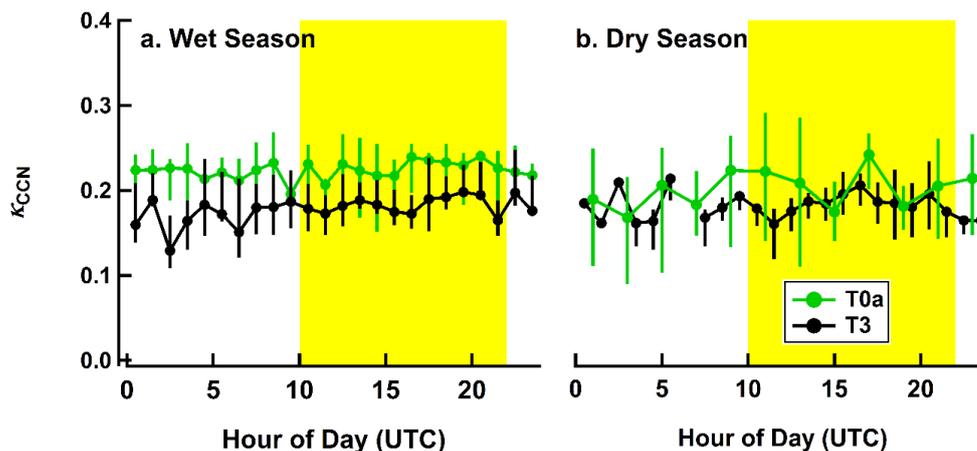

1213

1214 Figure 7: Diel variations of aerosol properties and meteorological parameters for local biomass
1215 burning air masses during the dry season (analogous to Fig. 3).

1216

1217

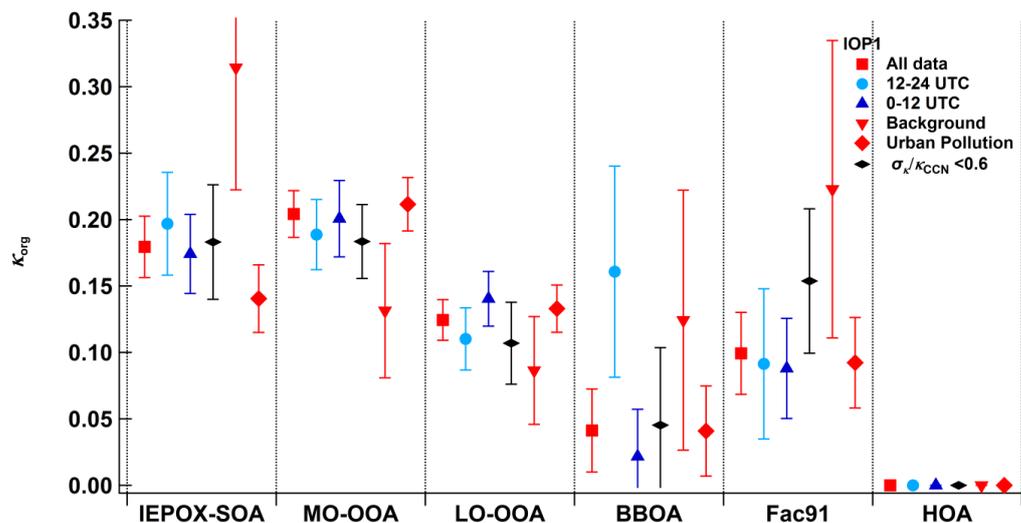

1218

1219 Figure 8: Comparison κ_{CCN} values derived from measurements at the T0a (ATTO) site (Pöhlker
1220 et al., 2016) and at the T3 site under background conditions (this study) during the (a) wet season
1221 (April and May 2014) and (b) dry season. The size resolved CCN data at T0a was collected by
1222 stepping the particle size at given CCNC supersaturations (Rose et al., 2008a). Data displayed
1223 for T0a is averaged over critical particle diameters ranging from 44 to 175 nm, while the T3 data
1224 is averaged from measurements at 112, 142, and 171 nm.

1225

1226
