Abstract

Gasoline vehicle exhaust is an important contributor to secondary organic aerosol (SOA) formation in urban atmosphere. Fuel composition has potentially considerable impact on gasoline SOA production, but the link between fuel components and SOA production is still poorly understood. Here, we present chamber experiments to investigate the impacts of gasoline aromatic content on SOA production through chamber oxidation approach. A significant amplification factor of 3 - 6 for SOA productions from gasoline exhausts is observed as gasoline aromatic content rose from 29% to 37%. Considerably higher emission of aromatic volatile organic compounds (VOCs) using high-aromatic fuel plays an essential role in the SOA production enhancement, while the semi volatile organic compounds (e.g., gas-phase PAHs) may also contribute to the higher SOA production. Our findings indicate that gasoline aromatics significantly influence ambient PM_{2.5} concentration in urban area and highlight that more stringent regulation on gasoline aromatic content will achieve unexpected benefit on urban air quality.

1 Introduction

Fossil fuel-powered vehicles, an important source of NO_x, volatile organic compounds

36 (VOCs) and atmospheric particulate matter (PM), are always associated with the severe haze
37 events, human health risks and climate forcing, particularly in urban areas (Parrish and Zhu,
38 2009; Guo et al., 2014; Huang et al., 2014; Kumar et al., 2014; Liu et al., 2015a; Kelly and
39 Zhu, 2016; Peng et al., 2016b). Gasoline is the most widely used vehicle fuel and accounts for
40 the largest total transportation energy consumptions in many countries, e.g., U.S. and China
41 (NBSC, 2015; EIA, 2015). Among all the gasoline related PM components, secondary
42 organic aerosols (SOA) produced via atmospheric oxidation of VOC precursors in the exhaust
43 have been proved by chamber experiments as a large fraction, if not the largest, of gasoline
44 vehicular PM (Zervas et al., 1999; Jimenez et al., 2009; Gordon et al., 2014a; Jathar et al.,
45 2014; Platt et al., 2014; Liu et al., 2015b). Moreover, ambient measurement also demonstrated
46 that gasoline SOA were the largest source of vehicular carbonaceous PM in megacities such
47 as Los Angeles (Bahreini et al., 2012). However, although increasingly stringent gasoline fuel
48 standards, especially on sulfur content, have been upgraded in the past decades in many
49 countries to reduce the emissions, the impacts of fuel compositions on SOA production have
50 not sufficiently been taken into account in the current gasoline fuel standards. This deficiency
51 is mainly attributed to the poor understanding of the effects of fuel properties on the related
52 SOA formation, and may ultimately lead to a policy bias on the control of vehicle emission
53 regarding to the reduction of atmospheric pollution.

54 Aromatic hydrocarbons, unsaturated compounds with at least one benzene ring, account
55 for 20% - 40% v/v of gasoline fuel. Aromatic VOCs (i.e., toluene, xylenes and
56 trimethylbenzenes) react exclusively with the OH radical in the atmosphere, leading to the
57 formation of a variety of semi- or low-volatile species (e.g., benzoic acid) (Zhang et al., 2015;
58 Schwantes et al., 2017), which will partition onto existing particle and be recognized as
59 anthropogenic SOA. Therefore, the higher emission of aromatic VOCs will likely result in
60 more SOA formation potential. Existing fuel-effect experimental and model studies have
61 shown that high-aromatic fuel in gasoline fuel will lead to more emissions of primary PM as
62 well as some aromatic VOCs (Zervas et al., 1999; EPA, 2013; Karavalakis et al., 2015; Wang
63 et al., 2016), indicating the considerable potential impact of gasoline aromatic content on
64 SOA production. Furthermore, though aromatic content in diesel fuel may have insignificant
65 impact on SOA formation (Gordon et al., 2014b), SOA production from gasoline vehicle is

66 considered more sensitive to aromatic content than that from diesel vehicle (Jathar et al.,
67 2013). However, until now, very few studies have successfully quantified the impact of
68 gasoline aromatic content on SOA production and directly revealed the possible pathway.

69 In this study, an in-depth comprehensive research was conducted to investigate the link
70 between gasoline fuel compositions, primary gas- and particle- phase emission, and
71 corresponding SOA formation. Gasoline exhaust emissions were examined on two platforms
72 under two different conditions. The first platform was the chassis dynamometer system
73 equipped with a constant volume sampler (CVS). Vehicle exhausts after CVS were
74 introduced into an outdoor environmental chamber and subjected to aging under typical
75 polluted urban conditions to simulate the SOA formation in ambient atmosphere. The second
76 platform was the experimental engine system on which emissions from a port gasoline
77 injection (PFI) engine and a gasoline direct injection (GDI) engine were examined. SOA
78 formation experiments from engine exhausts were carried out with relatively high OH
79 exposure compared to ambient conditions to obtain the SOA production potential. Most
80 importantly, different gasoline fuels blended from different refinery streams were utilized in
81 both platforms to probe the critical link among fuel components, VOCs emissions and related
82 SOA production.

83 **2 Materials and methods**

84 **2.1 Test fleet, cycle and engine.**

85 A commercial PFI vehicle, an experimental PFI engine and a GDI engine were tested in
86 this work.

87 The chosen PFI vehicle belonged to a commonly used vehicle model in China, which
88 certified to China IV emission standard (equivalent to Euro 4). The mileage of the test fleet
89 was about 3000 km. The fleet was driven on a chassis dynamometer system (Burke E. Porter
90 Machinery Company) using cold-start Beijing cycle in order to better simulate the actual
91 driving situation in Beijing. Beijing cycle was about 17 min long, with highest speed about 50
92 km h⁻¹ (Fig. S1). The temperature and the absolute humidity in the dynamometer room were
93 kept at 23.0 ± 1.0° C and 8.4 ± 0.9 g m⁻³, respectively, for all vehicle experiments (Table S1).

94 Vehicle exhaust underwent the first stage of dilution with filtered ambient air using a

95 constant volume sampler (CVS) operated at $5.5 \text{ m}^3 \text{ min}^{-1}$ for all experiments. Approximately
96 5.3 L min^{-1} of diluted exhaust from the CVS was introduced into the 1.2 m^3 chamber to be
97 further diluted with the clean air in the chamber (Fig. 1). The average dilution factor was
98 approximately 20 in the CVS and was approximately 15 in the chamber. During the entire
99 cycle, a light-duty gasoline vehicle emissions testing system (HORIBA, Ltd.) was used to
100 measure the average and real-time concentration of THC, CO_2 , CO and NO_x . Besides, a filter
101 based sampler (AVL SPC 472) was used to sample primary particles from gasoline vehicles
102 for chemical composition analysis.

103 The PFI and GDI engines were manufactured by a domestic Chinese automaker and
104 equipped with turbocharger together with downsized displacement. The PFI engine used in
105 this study was an experimental one with an old three-way catalyst (TWC), while the GDI
106 engine was a commercial one designed for vehicles meeting the national IV emission standard.
107 The operation mode of the PFI and GDI engine for chamber experiments was 2000 round per
108 minute with 50% load. After the engine became stable at this operating mode, the exhaust was
109 introduced into the chamber passing through a heater (150°C) and a filter, with a flowrate of
110 5 L/min and an injection time of 1 min. Particle number, mass and chemical composition, as
111 well as VOCs in the exhaust were characterized at the same operating mode. Primary particles
112 were sampled by a filter based sampler (AVL SPC 472) and particulate chemical
113 compositions, i.e., ions, EC, OC and polar and nonpolar organic species, were analyzed using
114 ion chromatography, EC/OC analyzer (SUNSET Laboratory Inc.) and gas chromatography
115 mass spectrometry (GC-MS) (Guo et al., 2013), respectively. Detail description of the engine
116 experiments can be found in our previous study (Du et al., 2017) and all engine experiments
117 used in this study are illustrated in Table S2.

118 **2.2 Fuels**

119 Three fuels (F1, F2 and F3) were utilized in this study to investigate the impacts of the
120 gasoline fuel on SOA formation. A commercial Phase V gasoline (F1 fuel) with equivalent
121 octane number of 93 was used as the base fuel. F1 fuel contains 29.8% aromatics and 4.1%
122 olefin content (Table 1). The most abundant species in Fuel 1 was i-pentane, followed by
123 toluene and 2-methylpentane (Table S3).

124 F2 fuel was blended from 80% of F6 fuel and 20% of refinery catalytic stream. Octane
125 (18.8%) and aromatic content (28.5%) in F2 fuel are very similar with that in F1 fuel, with the
126 only difference to be the olefin content.

127 F3 fuel was blended from 80% of F2 fuel, 15–20% of refinery reformat stream with
128 high aromatic content and very small amount of o-octane and n-heptane to keep the same
129 octane level. Compared with F2 fuel, F3 fuel contained similar olefin content (15.4%) but
130 higher aromatic content (36.7%) (Table 1). In particular, much higher toluene, ethylbenzene
131 and methylethylbenzene were found in F3 fuel (Table S3). Both F2 and F3 fuels meet the
132 Phase V gasoline standard. On the basis of the aromatic contents, the F2 and F3 fuel can be
133 well representative of the fuel normally used in the year around 2010 and after 2013,
134 respectively, in Chinese market such as Beijing and Shanghai.

135 **2.3 Chamber Simulation**

136 The quasi-atmospheric aerosol evolution study (QUALITY) chamber was utilized to
137 quantify SOA formation from both gasoline engine exhaust and gasoline vehicle exhaust. The
138 1.2 m³ two-layer chamber composed of an inner layer of 0.13 mm PFA Teflon and an outer
139 rigid 5.6 mm thick acrylic shell (Cryo Industries Acrylite, OP-4). Both layers allowed for
140 efficient transmission of sunlight in UV ranges (Peng et al., 2016b). Pre-experiments showed
141 that wall loss decreased the particle number concentration by about 50% in about 3.5 hours.
142 SO₂ and NO_x decreased to about 50% after 20 hours, while toluene and isoprene did not show
143 obvious wall loss during a two-day experiment (Peng et al., 2017).

144 Prior to each experiment, the QUALITY chamber was covered with two layers of
145 anti-UV cloth to shield the chamber from sunlight and flushed by zero air with a flowrate of
146 10 L min⁻¹ for more than 15 hours to ensure a clean condition. In both vehicle and engine
147 experiments, excess (1 ml, 30% v/v) H₂O₂ was also injected into the chamber via the makeup
148 zero air as an extra hydroxyl radical (OH) source after adding the exhaust. Chamber
149 experiments were normally conducted from noon to later afternoon, with inside temperature
150 of 30 - 35 °C and relative humidity (RH) of 40 - 60%. A suite of high time resolution
151 state-of-the-art aerosol instruments were utilized to measure the gas concentration and a
152 comprehensive set of particle properties throughout the experiments, including concentrations

153 of HONO, SO₂, NO_x, O₃, CO, CO₂ and several VOCs, the particle diameter, mass, chemical
154 composition (Fig. 1 and Table S4).

155 Particle number distributions were measured with a scanning mobility particle sizer
156 (SMPS) system, which was composed by one differential mobility analyzer (DMA, TSI, Inc.,
157 model 3081) and one condensation particle counter (CPC, TSI, Inc., model 3772). The mass
158 concentration and size distribution of particle chemical compositions, including organic
159 aerosol (OA), sulfate, nitrate, ammonium and chloride, were measured by a high-resolution
160 time-of-flight aerosol mass spectrometer (HR-ToF-AMS, Aerodyne Research, Inc.). The
161 evolution of several VOCs was measured continually by a proton transfer reaction mass
162 spectrometer (PTR-MS, Ionicon HSL experiments). Dedicated gas monitors, including the
163 SO₂, NO_x, CO, CO₂ and O₃ monitors (Thermo Inc.), were utilized, and calibrated each
164 experiment day. VOCs in the chamber were also sampled by canisters every 1 hour during
165 vehicle experiments and analyzed by GC-MS/FID system (Wang et al., 2015).

166 Zero airflow was connected to the chamber over the entire experiment to make up
167 volume of air withdrawn by the instruments. To minimize the sampling volume by the
168 instruments, all instruments except SMPS were connected with several three-way valves,
169 which were successively switched between the ambient air and the chamber very 15 or 30
170 min.

171 **3 Results**

172 **3.1 Simulation of SOA formation from gasoline exhausts.** The temporal evolution of gas-
173 and particle- phase species during the chamber experiment is illustrated in Figure 2. The
174 initial concentration of NO_x, benzene and toluene in the chamber were 163 ppb, 5.6 ppb and
175 16.8 ppb, respectively, corresponding to the severe urban haze condition in the megacities
176 (Guo et al., 2014). After the chamber was exposed to the sunlight, 99% of NO was converted
177 to NO₂ within the first 10 min. This is because the fast photolysis of H₂O₂ produced large
178 amount of OH radical and further HO₂/RO₂ radicals inside the chamber, which reacted with
179 NO to form NO₂ (Seinfeld and Pandis, 2006). Then, the concentration of O₃ increased rapidly
180 to approximately 400 ppb after 1 h exposure, and gradually decreased later in this experiment
181 (Fig.2a).

182 Over the entire experiment, benzene and toluene experienced gentle decay in the

183 concentrations, but with different decay coefficients (Fig. 2b). Aerosol evolution is always
184 characterized by a photochemical-age-based parameterization method in ambient
185 measurements as well as chamber experiments (Hu et al., 2013; de Gouw et al., 2005; Peng et
186 al., 2016a). Therefore, in order to compare our SOA productions in different experiments (in
187 which solar flux were different), OH exposures were calculated based on the ratios of benzene
188 and toluene concentrations, which reacted at different rates with OH radical (de Gouw et al.,
189 2005). Besides, to compare the OH exposure in our chamber experiments with the previous
190 ambient measurements, the OH concentration in the ambient air was assumed as 1.6×10^6
191 molec cm⁻³ (Hu et al., 2013; Peng et al., 2016a), and the equivalent photochemical ages of
192 chamber experiments were then estimated by the ratio of OH exposure in the chamber to the
193 assumed OH concentration in the ambient air.

194 New particle formation occurred inside the chamber within 10 min of exposure to the
195 sunlight (Fig. 2c). These newly formed particles performed as seeds for the further formation
196 of secondary species. A large quantity of secondary aerosols was then formed in the chamber,
197 leading to the fast growth in the diameter of these particles to approximately 70 nm after 3h
198 aging. The measurement of the particle compositions by the AMS reveals that the largest
199 mass fraction of secondary aerosols in the chamber was SOA (approximately 95%, Fig. S2),
200 indicating the critical role of the SOA for the secondary aerosol formation from gasoline
201 exhausts. Because of the low aerosol loading (initially lower than $2 \mu\text{g m}^{-3}$) and low relative
202 humidity (40 - 50%) inside the chamber, heterogeneous reactions and aqueous phase
203 processing were not important for the formation of SOA in this study (Zhang et al., 2015).
204 Furthermore, the O:C ratio of SOA formed in the chamber stayed stable around 0.4 over the
205 entire experiment, indicating that condensed phase reactions, i.e., aqueous or heterogeneous
206 reactions, which produce highly oxidized oligomers, was not significant in the chamber
207 experiments in this study. These SOA, therefore, were likely formed via condensation of less
208 volatile products oxidized through gas phase reactions of VOCs precursors with limited
209 multigenerational chemistry (Robinson et al., 2007; Jimenez et al., 2009; Jathar et al., 2014).
210 The AMS spectrum profile of gasoline SOA obtained in this study was highly correlated with
211 the ambient low oxidized secondary organic aerosols (LO-OOA) in Beijing ($R^2=0.99$, Fig.
212 S3), further confirming the important contribution of gasoline emission on ambient PM_{2.5}.

213 SOA productions per fuel consumption or mileage were calculated on the basis of SOA
214 mass concentration inside the chamber, dilution factors both in the CVS and inside the
215 chamber, and fuel consumption/mileage of our working cycle. SOA mass concentration inside
216 the chamber was corrected according to the particle wall loss curve (Fig. S4) as well as the
217 dilution effect of both particles and gas precursors due to the make-up zero air (Fig. S5). SOA
218 production at the end of this experiment was calculated to be 80 mg kg-fuel⁻¹, or 6.7 mg km⁻¹
219 after 3.5-hour aging (Fig. 2d). These values were 6.8 times higher than the emission factors
220 (EFs) of primary particles (including both primary organic matters and elemental carbon) at
221 the same cycle.

222 **3.2 Fuel impacts on SOA production.** The average fuel consumption per unit distance using
223 F1, F2 and F3 fuels were 0.113, 0.112 and 0.113 L km⁻¹, respectively, indicating no difference
224 in fuel economy among the three fuels. On the other hand, high-aromatic content gasoline led
225 to noticeably large enhancement on SOA production from both vehicle and engine
226 experiments. As illustrated in Figure 3a, the final SOA production from gasoline vehicle
227 exhaust ranged from 30 mg kg-fuel⁻¹ to 98 mg kg-fuel⁻¹ at the end of each experiment,
228 comparable to the results from cold start experiments in previous studies (Gordon et al.,
229 2014a; Jathar et al., 2014). Experiments using F3 fuel (with 36.7 % v/v aromatic content)
230 exhibit the highest SOA production factors, followed by F1 fuel (with 29.8 % v/v aromatics
231 content) and F2 fuel (with 28.5 % v/v aromatics content), successively. The average SOA
232 production at 12 equivalent photochemical-hours using F3 fuel was 76 mg kg-fuel⁻¹ (6.3 mg
233 km⁻¹), equivalent to 3 times of that using F2 fuel (25 mg kg-fuel⁻¹, 2.1 mg km⁻¹). Additionally,
234 we observed much larger amount of the SOA formation in the first few photochemical hours
235 in all experiments. The average production rates of SOA were as high as 5 - 13 mg kg⁻¹ h⁻¹
236 over each experiment, suggesting that the first-generation oxidation of some precursors inside
237 the chamber produced large amount of SOA. This indicated the existence of some
238 semi-volatile organic compounds (SVOCs) (Robinson et al., 2007; Keyte et al., 2013). It is
239 worth to mention that as the concentrations of gas pollutants and formed SOA in the chamber
240 using F3 fuel were 2-3 folds of those using F2 fuel, the partitioning of SVOCs in the
241 experiments using F3 fuel might slightly favor the SOA formation. This partitioning, however,
242 would not qualitatively change the experiment conclusion that higher fuel aromatics led to

243 higher SOA production.

244 SOA formation experiments from the PFI engine exhaust were conducted under high
245 oxidizing condition to obtain the SOA formation potential. As illustrated in Figure 3b, most
246 of the SOA were formed within the first half an hour of each engine experiment and very little
247 increase was observed over the following hours. The SOA formation potential from the
248 engine exhaust using F3 fuel was $3.3 \text{ g kg-fuel}^{-1}$ at this condition, equivalent to 5.8 times of
249 that using F2 fuel, which was $0.57 \text{ g kg-fuel}^{-1}$ on average. The high emission of the
250 experimental PFI engine suggests that the results of engine experiments could represent the
251 SOA production from gasoline vehicles with higher emission factor. Therefore, our results
252 with two different experimental sets (vehicle and engine experiments) demonstrate the
253 applicability of the SOA formation enhancement using high-aromatic fuel for gasoline vehicle
254 with either high or low emission factor, at either representative cycle condition or steady-state
255 operating condition.

256 Though good reproducibility was found for SOA production using either F2 or F3 fuels,
257 there were inevitably several biases in the chamber simulation approach. For example, the
258 SOA production in both vehicle and engine experiments might be underestimated due to loss
259 of SVOC vapors to the chamber wall as well as the condensation of low organic vapor onto
260 the particles that already lost on the chamber wall (Zhang et al., 2014). Also, the SOA
261 production in engine experiments could be overestimated because the high concentration in
262 the chamber might drive the gas-particle partitioning of the SVOCs into particle phase
263 (Robinson et al., 2007). Nevertheless, the relative enhancement factor of SOA for different
264 fuels was not largely influenced by these biases.

265 **3.3 Aromatic emission and SOA production.** To reveal the reason of this large
266 amplification on SOA production owing to fuel constitution, gasoline PM and VOC emissions
267 using F2 and F3 fuels were investigated (Fig. 4). Significant differences in the EFs among
268 different gas- and particle-phase species were observed. For example, the EFs of primary PM
269 in both number and mass concentration using F3 fuel were only 20% larger than those using
270 F2 fuel, consistent with previous studies (EPA, 2013; Karavalakis et al., 2015). Similar results
271 were also obtained for most of the alkane VOCs as well as NO. On the contrary, the EFs for
272 SOA, aromatic VOCs and particle-phase Polycyclic Aromatic Hydrocarbons (PAHs)

273 exhibited marked enhancement using high-aromatic gasoline fuel. The EFs of each aromatic
274 VOCs from the exhaust experiment increased by a factor of 0.2 - 9.5 using high-aromatic
275 gasoline fuel, with enhancement factors of 3.3 and 2.7 for total aromatic VOCs in vehicle and
276 engine experiments, respectively (Fig. 4). Coincidentally, the total particle-phase PAHs
277 emission was amplified for 1.8 times using high-aromatic gasoline fuel (F3 vs F2), with the
278 amplification factor of each PAH species varied from 1.1 to 2.2. Since both gas-phase
279 aromatic VOCs (one ring) and particle-phase PAHs (mostly 3-7 rings) exhibited much higher
280 EFs using high-aromatic gasoline fuel, it is reasonable to speculate higher EFs of the
281 semi-volatile PAHs (2-3 rings) in our experiments.

282 Aromatic components in the exhaust mainly come from two routes, which are the
283 survival of fuel aromatic contents and the combustion-derived formation in the engine.
284 Ethylene and acetylene are the key species for the combustion-derived aromatics. High
285 concentrations of ethylene and acetylene accelerate the acetylene addition reaction, which
286 generates light aromatic VOC as well as PAHs in the engine (Wang and Frenklach, 1997;
287 Frenklach, 2002). In this study, when the high-aromatic fuel was used, the concentrations of
288 ethylene and acetylene from GDI engine were enhanced by a factor of 3.3 and 2.7,
289 respectively, indicating that more aromatics were formed through the addition reaction of
290 acetylene and ethylene in the engine.

291 SOA production ($\Delta OA_{predicted}$) from VOC precursors in the exhaust was roughly
292 estimated by multiplying the mass loss of each VOC precursors (Δi) by its SOA yield, Y_i
293 (Donahue et al., 2006):

$$294 \quad \Delta OA_{predicted} = \sum_i (\Delta i \times Y_i)$$

295 (1)

296 The SOA precursors here included benzene, toluene, C8-aromatics, C9-aromatics and styrene,
297 which were all measured by PTR-MS during each experiment. The contributions of the
298 alkenes and alkanes (7-11 carbons) to SOA formation in our experiments were also estimated
299 using Eq. 1 based on the off-line GC-MS measurement. Results showed that the measured
300 alkenes and alkanes (7-11 carbons) only accounted for approximately 4% of the total
301 predicted SOA concentration (Fig. S6) duo to the low emission factors as well as the small

302 reacted proportion of these species inside the chamber. The yields of VOC_i under high NO_x
303 condition are used (Ng et al., 2007; Platt et al., 2013), due to the low initial VOCs/NO_x ratios
304 which ranged from 0.5 to 1.0.

305 Figure 5 exhibits the two typical vehicle experiments with observed and predicted SOA
306 concentration as a function of photochemical age using F2 and F3 fuels, respectively. The
307 predicted SOA in the end of the two experiments accounted for 46% and 30% of the observed
308 SOA formation with toluene and C9-aromatics to be the largest contributors, consistent with
309 the previous results (Nordin et al., 2013; Platt et al., 2013; Gordon et al., 2014a). Predicted
310 SOA concentration using F3 fuel was about 90% higher than that using F2 fuel, suggesting
311 the import role of single-ring aromatic VOCs on the enhancement of SOA formation using
312 high-aromatic fuel. However, more than 50 % of the SOA concentration cannot be explained
313 by gas-phase oxidation of these single-ring aromatic VOCs. This value was even higher (up to
314 80%) in the first few photochemical hours in both experiments. Additionally, much larger
315 percentage of SOA using F3 fuel cannot be explained by the single-ring aromatic VOCs. This
316 suggests the existence of some unspecified organic vapors, most likely SVOCs, which are
317 considered to have high SOA yield and might partition to particle phase after the
318 first-generation oxidation (Robinson et al., 2007; Chan et al., 2009; Jathar et al., 2014; Liu et
319 al., 2015b). Two-ring and three-ring PAHs, e.g., naphthalene and phenanthrene, which were
320 proved to have higher EFs using high-aromatic fuel (Chan et al., 2009), likely contributed
321 importantly to the SVOC vapors and might play a crucial role for the enhancement of SOA
322 production using high-aromatic fuel.

323 **4 Discussion**

324 Our results exhibit the critical impact of gasoline aromatics on urban SOA formation.
325 We observed an amplification factor of 3-6 on SOA formation using high-aromatic gasoline,
326 which was mainly caused by the high emission of one-ring aromatic VOCs as well as SVOC
327 such as gas-phase PAHs. This enhancement of SOA formation, meanwhile, was found using
328 not only a new vehicle meeting China IV emission standard, operated at a representative cycle
329 condition in Beijing, but also an experimental engine which emitted more gaseous pollutants
330 and was operated at steady state, suggesting the extensive applicability of our results.

331 Moreover, photo-oxidation of aromatics leads to significant production of small

332 dicarbonyls, i.e., glyoxal and methylglyoxal, which have high SOA yield via aqueous
333 reactions (Zhang et al., 2015). If this aqueous SOA pathway is taken account, the influence of
334 fuel on SOA formation will be much more remarkable. More work is needed to evaluate the
335 aqueous pathway of SOA formation from gasoline exhaust.

336 Currently, aromatic content in gasoline fuel is increasing continuously in China, where
337 more stringent standard on gasoline sulfur content has been upgraded and the oil refining
338 procedure are changing to meet the new standard. For example, we found the average
339 aromatic content for gasoline fuel in the market meeting Beijing III, IV and V standards
340 were 23.4%, 28.5% and 36.3%, respectively. Recent study found that gasoline aromatic
341 content in China was 9.6% higher than that in USA (Tang et al., 2015). Hence, the
342 enhancement in SOA formation exerted by the increase of aromatic content in gasoline fuel
343 from 29% to 37 % in this study can well represent the extra SOA formation due to the
344 gasoline standard change in Beijing. Neglect of this side effect of fuel standard change may
345 potentially offset the tremendous endeavors on vehicle emission control by the local
346 government. From another perspective, our findings provide a new direction in controlling air
347 pollution from vehicles, which is to decrease the aromatic content in the gasoline fuel. This
348 may require more hydrogenation catalysis process in the petroleum refining procedure instead
349 of catalytic reforming process, in which large amount of aromatic contents might be produced.
350 Compared with the vehicle restriction regulation that met the shrill opposition voice from the
351 society and the elimination of polluted vehicles that brought large amount of expenses, this
352 direction might be more acceptable, efficient and economical. Additionally, current vehicle
353 emission evaluation system, which mainly measures the emissions of PM, THC, NO_x and CO,
354 will fail to tell the consequences of using the high-aromatic gasoline fuel, as these species do
355 not increase much when high-aromatic fuel is using (Fig. 4). Aromatic VOCs, especially the
356 SVOC, should be considered in future vehicle emission evaluation.

357 Furthermore, this influence of gasoline aromatic content on air quality is not only
358 adoptable in China. Strikingly, the current standard on gasoline aromatic content are not
359 stringent enough in most of the countries and regions in the world, where fuel standards with
360 very high maximum gasoline aromatic content (ranging from 35 % to 42% in different
361 countries, Table S6) are implemented, even including some developed countries and regions,

362 i.e., Europe, Japan, Australia. Our findings highlight the necessity of a more stringent
363 regulation on gasoline aromatic content in the next renewal of the gasoline standard.

550

551 **Figure 1.** Schematic diagram of chamber experiments.

552

553

554 **Figure 2.** Evolution of gas-phase species (a, b), particle size distribution (c), and SOA

555 concentration and production (d) during a typical chamber experiment (V2). OH exposure and

556 photochemical age are calculated based on the ratios of benzene and toluene concentrations,

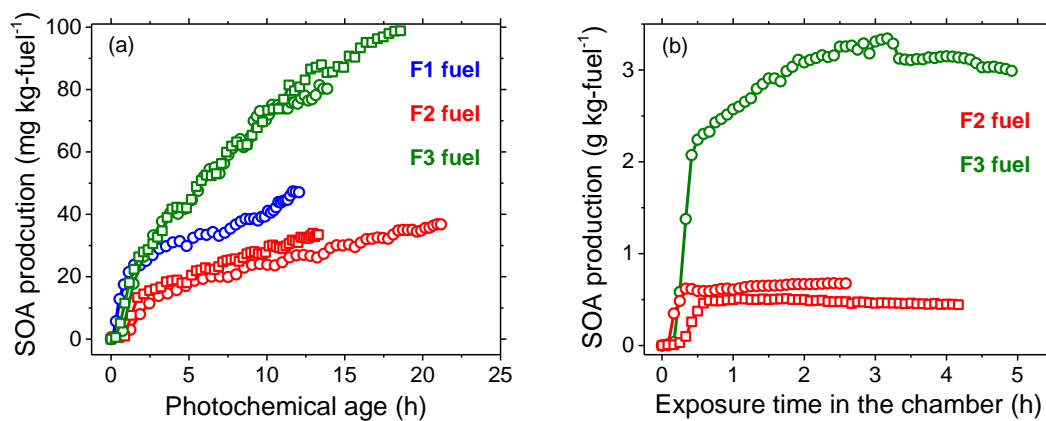

557 assuming that OH concentration is 1.6×10^6 molec cm^{-3} . The SOA mass concentration is

558 obtained by intergrading size distribution of particles inside the chamber on the basis of

559 measured particle density. The measured SOA mass concentration is corrected according to

560 the particle wall loss curve as well as the dilution effect for both particles and gas precursors.

561

563

564 **Figure 3.** SOA production in the vehicle experiments as a function of photochemical age (a)
 565 and in the engine exhaust experiments as a function of exposure time (b). The green squares,
 566 green circles, red squares, red circles and blue circles (a) represent the experiment V1, V2, V3,
 567 V4 and V5 shown in Table S1, respectively. The green circles, red squares and red circles (b)
 568 represent the experiments E1, E2 and E3 shown in Table S2, respectively.

569

571

572 **Figure 4.** Comparison of emission factors (EFs) of gas- and particle species using
 573 high-aromatic fuel (F3 fuel) to those using low-aromatic fuel (F2 fuel). The total
 574 hydrocarbons (THC) were measured by vehicle emissions testing system, HORIBA, Ltd.),
 575 and the total aromatics and non-methane hydrocarbons (NMHCs) were measured by offline
 576 GC-MS. The black line denotes that the ratio of EFs using aromatic-rich fuel over
 577 aromatic-poor fuel is 1:1, and dashed lines stand for the ratios of 10:1, 2:1, 1:2, and 1:10,
 578 respectively. Note that the PAHs and VOCs data for the GDI engine were measured before
 579 the three-way Catalyst (TWC). Value in the figure can be found in Table S5.

580

581 **Figure 5.** Observed and predicted SOA concentration, and SOA fraction from unspeci-ated
 582 VOCs as a function of photochemical age in typical chamber experiments using (a) F2
 583 (experiment V4) and (b) F3 (experiment V2) fuels. Black line and triangles represent the
 584 corrected SOA concentrations in the chamber experiments. The purple, red, blue, green and
 585 yellow areas represent the predicted SOA from the oxidation of benzene, toluene,
 586 C8-aromatics, C9-aromatics and styrene, respectively. The pink circles represent the SOA
 587 fractions that cannot predicted by the one-ring aromatic VOC precursors.
