Abstract

The effects of an initially overlying layer of solar-absorbing aerosol on the transition of stratocumulus to trade cumulus clouds are examined using large-eddy simulations. For lightly drizzling cloud the transition is generally hastened, resulting mainly from increased cloud droplet number concentration (N_c) induced by entrained aerosol. The increased N_c slows sedimentation of cloud droplets and shortens their relaxation time for diffusional growth, both of which accelerate entrainment of overlying air and thereby stratocumulus breakup. However, the decrease in albedo from cloud breakup is more than offset by redistributing cloud water over a greater number of droplets, such that the diurnal-average shortwave forcing at the top of atmosphere is negative. The negative radiative forcing is enhanced by sizable longwave contributions, which result from the greater cloud breakup and a reduced boundary layer height associated with aerosol heating. A perturbation of moisture instead of aerosol aloft leads to greater liquid water path and a more gradual transition. Adding absorbing aerosol to that atmosphere results in substantial reductions in LWP and cloud cover that lead to positive shortwave and negative longwave forcings on average canceling each other. Only for heavily drizzling clouds is the breakup delayed, as inhibition of precipitation overcomes cloud water loss from enhanced entrainment. Considering these simulations as an imperfect proxy for biomass burning plumes influencing Namibian stratocumulus, we expect regional indirect plus semi-direct forcings to be substantially negative to negligible at the top of atmosphere, with its magnitude sensitive to background and perturbation properties.

1 **1. Introduction**

2 Aerosols affect the earth’s radiation budget in at least three ways. First, they
3 directly absorb and scatter solar radiation. Second, they affect radiative fluxes indirectly
4 through their role as cloud condensation nuclei, influencing cloud microphysics and
5 thereby affecting cloud albedo and cloud cover. Third, solar-absorbing aerosols can alter
6 atmospheric heating rates and stability, leading to rapid adjustments in cloud properties;
7 the resulting impact on radiative fluxes is referred to as the semi-direct effect (Hansen et
8 al., 1997).

9 Aerosols have been identified as contributing the greatest uncertainty to
10 anthropogenic climate forcing (Forster et al. 2007). For instance, the observational study
11 of Indian Ocean Experiment (INDOEX) (Jayaraman et al., 1998; Satheesh and
12 Ramanathan, 2000) and some general circulation model (GCM) studies (e.g., Hansen et
13 al., 1997; Lohmann and Feichter, 2001; Jacobson, 2002; Cook and Highwood, 2004)
14 have found a net decrease in low-level cloud cover when solar-absorbing aerosols are
15 present, which corresponds to a positive radiative forcing at the top of the atmosphere
16 (TOA) that tends to warm the climate system, while other observational studies (e.g.,
17 Loeb and Schuster, 2008; Wilcox et al., 2010; Adebisi et al. 2015, hereafter A15) have
18 found the opposite, in which the cloud cover increases. Some GCM studies (e.g., Menon
19 et al., 2002, Penner and Zhang, 2003; Sakaeda et al, 2011) have found that the radiative
20 forcing depends crucially on the height of the absorbing aerosol. To better constrain
21 radiative forcing in climate models, a comprehensive understanding of regional cloud-
22 aerosol interactions and the corresponding radiative forcings is of value.

23 Here we focus on warm (liquid-phase) clouds in the planetary boundary layer

24 (PBL). Higher-level clouds are not considered. Process-level understanding of the
25 physical mechanisms underlying indirect and semi-direct aerosol radiative forcings has
26 been largely advanced through studies with large-eddy simulation (LES) models and in
27 situ observations. Regarding aerosol indirect forcing, with all else equal (particularly
28 cloud cover and liquid water path), increased cloud droplet number concentration (N_c)
29 resulting from increased aerosol concentration (N_a) increases cloud optical thickness and
30 thus albedo, thereby exerting a negative radiative forcing at TOA (Twomey 1974, 1991).
31 For precipitating clouds, increasing N_c can reduce precipitation and thereby enhance
32 liquid water path (LWP) and cloud cover (e.g., Albrecht, 1989; Ackerman et al., 1993;
33 Pincus and Baker, 1994; Hindman et al., 1994). However, for clouds with little
34 precipitation, modeling studies indicate that increased N_c tends to reduce LWP and cloud
35 cover by increasing PBL entrainment (Ackerman et al., 2004; Wood et al., 2007;
36 Ackerman et al., 2009), which can dry the PBL and reduce LWP when the overlying air
37 is sufficiently dry (Randall, 1984). Such a tendency is consistent with satellite
38 observations of LWP reduction in ship tracks, on average (Coakley and Walsh, 2002). At
39 least three microphysical mechanisms have been found to play a role in the entrainment
40 increase. First, in what we shall refer to as the "sedimentation effect", increased N_c leads
41 to smaller droplets that fall more slowly, which increases the amount of cloud water
42 available for evaporative cooling during entrainment events, thereby strengthening
43 entrainment (Bretherton et al., 2007). Second, in what we shall refer to as the
44 "evaporation effect", smaller droplets increase the total surface area of cloud droplets,
45 accelerating evaporation and driving stronger entrainment (Xue et al., 2008). Third,
46 increased N_c also suppresses drizzle, enhancing convective intensity and entrainment (e.g.,

47 Stevens et al. 1998, Wood et al. 2007). Under dry overlying air, all three effects tend to
48 reduce cloud cover and LWP, leading to a positive radiative forcing. However, if the
49 entrained air is sufficiently moist, entrainment can be expected to increase LWP (Randall,
50 1984).

51 Aerosol semi-direct effects have been studied by Ackerman et al. (2000) in the
52 context of trade cumulus under a sharp inversion, in which absorbing aerosol within the
53 boundary layer increases solar heating in a manner that stabilizes the PBL, reducing the
54 moisture supply from the surface and the amount of cloudiness, leading to a positive
55 radiative forcing at TOA. More directly in such a scenario the relative humidity of the
56 PBL is reduced by enhanced solar heating, reducing cloudiness as originally found in
57 global model simulations by Hansen et al. (1997). In contrast, Johnson et al. (2004)
58 conducted large-eddy simulations of marine stratocumulus and found that an absorbing
59 aerosol immediately above the PBL (and not entrained) strengthens the inversion,
60 reducing entrainment and thereby increasing cloud cover, leading to a negative radiative
61 forcing, while they found the opposite (positive radiative forcing) for aerosol heating
62 within the PBL. That study was motivated at least in part by measurements of absorbing
63 aerosol from biomass burning advected from Africa over Namibian stratocumulus, where
64 biomass burning aerosol plumes may also be well separated from the PBL (Keil and
65 Haywood, 2003, Haywood et al., 2003b), a factor that has been found to be critical to
66 absorbing aerosol effects on cloud fraction (Feingold et al., 2005).

67 Further complexity arises when considering the possibility that absorbing aerosol
68 can act as cloud condensation nuclei (CCN) and thereby increase N_c , which was
69 neglected in the early studies of Johnson et al. (2004) and Feingold et al. (2005) and only

70 represented quite crudely by Ackerman et al. (2000), who simply imposed a sequence of
71 uniform N_c values in their simulations. Here we will consider both roles of absorbing
72 aerosol.

73 By considering two trade cumulus regimes, one transitional case with a sharp
74 inversion (ATEX) and a more downstream case with greatly reduced cloud cover
75 (BOMEX), Johnson (2005) found the semi-direct aerosol forcing to depend strongly on
76 the cloud regime, with the magnitude of the forcing increasing with (unperturbed) cloud
77 cover. This regime dependence is relevant to the stratocumulus-to-cumulus transition
78 (SCT), a climatological feature downstream of subtropical marine stratocumulus (Klein
79 and Hartmann, 1993; Sandu et al., 2010; Zhou et al., 2015). The SCT has been found in
80 modeling studies to be driven by easterly, equatorward advection over increasing sea
81 surface temperatures (SST), which increases surface latent heat fluxes, enhancing
82 buoyancy fluxes in the cloud layer and hence entrainment. The PBL deepening from
83 progressive entrainment inhibits the ability of circulations forced at cloud top to maintain
84 a well-mixed boundary layer, reducing the surface moisture supply and eventually drying
85 out the stratocumulus clouds (Bretherton and Wyant, 1997; Wyant et al., 1997). A recent
86 observational study has found that the time scale of the SCT over the eastern Pacific can
87 depart considerably from that in an idealized model framework driven only by increasing
88 SST (Zhou et al., 2015), suggesting that other factors, such as meteorological variability,
89 might play important roles in the time scale of SCT. Yamaguchi et al. (2015) (hereafter
90 Y15) investigated the impact of overlying absorbing aerosol and associated enhanced
91 moisture on the SCT and found that entrained absorbing aerosol in general delays the
92 SCT with a net negative change in TOA shortwave (SW) cloud radiative forcing (CRF).

93 It has been documented in recent observational studies near northern Namibia and
94 remote St. Helena Island in the South Atlantic that the sampled absorbing aerosol is often
95 accompanied by enhanced humidity, with an average moisture perturbation of $\sim 1 \text{ g kg}^{-1}$
96 relative to the underlying air (Haywood et al., 2003b; A15). This humidity is associated
97 with the outflow from the deep, continental boundary layer, and accompanies the
98 absorbing aerosol that results from biomass burning. The enhanced humidity induces
99 additional radiative heating, which can regulate cloud processes by reducing cloud-top
100 longwave (LW) cooling (A15) and by simply reducing the dryness of air entrained into
101 the PBL. Y15 located a stationary moist layer above the PBL and found that the
102 additional moisture itself enhances cloud breakup during the SCT, although they
103 acknowledge that their perturbation of $\sim 3 \text{ g kg}^{-1}$ likely represents an upper limit
104 compared with A15. We note that in our modeling framework it is simply assumed that
105 the model domain is advected equatorward by the trade winds, thus implicitly treating the
106 flow aloft as being easterly, despite observations that indicate the circulation over the
107 South Atlantic to be far more complex (e.g., Adebisi and Zuidema, 2016).

108 Here we perform an expanded investigation of the impact of absorbing aerosol
109 and moisture on the SCT. Because Y15 was published during the course of this work, our
110 simulation setups are similar but not identical, and we highlight similarities and
111 differences below. Like Y15, we adopt the Sandu and Stevens (2011) SCT case study,
112 with some modifications. Here we separate the responses to aerosol heating above and
113 within the PBL and on microphysical processes. We consider the impacts on lightly and
114 heavily drizzling stratocumulus decks. We also assess the impacts of additional overlying
115 moisture on the SCT and how it influences the effects of absorbing aerosol. The radiative

116 forcings in our study consider not only changes in SW but also LW fluxes. Our results
117 differ from Y15 in that initially overlying plumes of absorbing aerosol lead to positive
118 changes in SW CRF at TOA, and the aerosol and moisture perturbations never delay the
119 SCT in our simulations (unless we omit well-established physical processes).

120 The remainder of this manuscript is organized as follows. Section 2 documents
121 the model setup and case description. Section 3 presents analysis of the microphysical
122 and heating effects of absorbing aerosol during the transition of lightly drizzling
123 stratocumulus. In sect. 4, we investigate the impact of additional moisture in the aerosol
124 layer, and the influence of the initial altitude of the moist aerosol layer. The impacts of an
125 absorbing aerosol on the SCT of heavily drizzling stratocumulus are discussed in sect. 5.
126 In sect. 6 we discuss and summarize our findings.

127

128 **2. Model setup and simulated cases**

129 The Distributed Hydrodynamic Aerosol and Radiative Modeling Application
130 (DHARMA) (Ackerman et al., 2004 and references therein) simulations here are based
131 on the "reference case" 3-day Lagrangian SCT setup of Sandu and Stevens (2011). The
132 basis for the case is a composite of the large-scale conditions encountered along
133 trajectories over the northeast Pacific from June to August of 2006 and 2007. Following
134 Sandu and Stevens (2011) and de Roode et al. (2016), SST increases steadily from 293.75
135 K at 0 h to 299.17 K at 72 h, and a uniform divergence of large-scale horizontal winds of
136 $1.86 \times 10^{-6} \text{ s}^{-1}$ is imposed up to an altitude of 2000 m, above which the large-scale
137 subsidence is constant. Because the large-scale subsidence is imposed rather than
138 interactive, we omit any possible decrease in subsidence associated with solar heating by

139 absorbing aerosol (cf. Sakaeda et al. 2011). An intercomparison of six different LES
140 models shows that DHARMA results are consistent with others in representing the SCT
141 (de Roode et al., 2016), although differences between models do exist, as discussed
142 further below. Unlike Sandu and Stevens (2011) and Y15, here we begin simulations at
143 midnight local time (when turbulent mixing is vigorous, to accelerate spin-up) rather than
144 10:00 local time. Surface fluxes are computed following similarity theory as in Ackerman
145 et al. (1995). Note that because sea surface temperature is prescribed, it is not impacted
146 by changes in the overlying atmosphere.

147 The DHARMA domain size is 10.8 km x 10.8 km x 3.2 km and horizontal
148 resolution is set to $\Delta x = \Delta y = 75$ m. Vertically 240 levels are distributed between 0 and
149 3200 m, with variable vertical resolution ranging from 30 m near the surface to 10 m near
150 the inversion and up to 60 m near the model top; before using this grid with twice as
151 coarse of a grid as in de Roode et al. (2016), we confirmed that the DHARMA results
152 were not sensitive to the difference. The microphysics scheme is an adaptation of the
153 two-moment scheme of Morrison et al. (2005) with prognostic saturation excess
154 following Morrison and Grabowski (2008) and assuming the shape factor of the cloud
155 droplet size distribution to be 10.3 (equivalent to relative dispersion of 0.3) following
156 Geoffroy et al. (2010). Radiative transfer is calculated for each column every minute
157 using a two-stream model (Toon et al., 1989). An isothermal layer for the radiative
158 transfer calculations overlies the LES grid, with an ozone column following the
159 specifications of de Roode et al. (2016) and with temperature (180 K) and water vapor
160 column (0.5 g cm^{-2}) chosen to match the profile of downwelling LW flux of the other
161 models in the intercomparison. The ocean surface albedo is spectrally uniform at 7%.

162 Activation of aerosol follows Abdul-Razzak and Ghan (2000) using supersaturation
163 computed after the condensational adjustment of Eq. A10 in Morrison and Grabowski
164 (2008). The number and mass concentrations of cloud droplet and raindrops are
165 prognostic in the two-moment cloud microphysics scheme, but for aerosol it is only the
166 number concentration of unactivated plus activated particles for each aerosol species that
167 is prognostic; there is no evolution of the size and breadth of the underlying aerosol size
168 distribution for each species, nor are there sources or sinks of aerosol number.

169 Two species of aerosol are prescribed: ammonium sulfate and a solar-absorbing
170 aerosol; both aerosol types act as CCN and interact with the radiation before and after
171 activation. The optical properties for aerosol particles and hydrometeors are computed
172 following Ackerman et al. (1995) using Mie calculations on a 25-bin grid with geometric
173 spacing, in which we average over six sub-intervals within each bin to smooth any Mie
174 resonances. Soot cores with a fixed size are included in the Mie calculations for solar
175 absorbing aerosol (following Ackerman et al., 2000) as well as for the fraction of cloud
176 droplets in each grid cell that activated on solar absorbing CCN. The baseline case is an
177 ensemble of three simulations with different pseudo-random seeds for the initial
178 temperature perturbation field in the PBL, and includes only ammonium sulfate aerosol,
179 which are uniformly distributed in the vertical with $N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$ (without a vertical
180 gradient the aerosol scheme is completely diagnostic). Further simulations are conducted
181 that incorporate an absorbing aerosol profile initialized to increase linearly from zero
182 below 1250 m altitude up to $N_{a, \text{absorb}} = 5000 \text{ mg}^{-1}$ at 1300 m, maintain a uniform value up
183 to 2800 m, then decrease to zero at 2850 m and above. Log-normal size distributions are
184 specified for the sulfate and absorbing aerosol, with geometric mean radii of $0.05 \mu\text{m}$ and

185 0.12 μm and geometric standard deviations of 1.2 and 1.3, respectively. The
186 hygroscopicity parameter κ (Petters and Kreidenweis, 2007) is set to 0.55 for ammonium
187 sulfate and 0.2 for the absorbing aerosol. The size distribution for the absorbing aerosol is
188 based on the measurements of Haywood et al. (2003b) and the hygroscopicity (for aged
189 biomass burning aerosol) from those of Englehart et al. (2012). The absorbing aerosol
190 optical properties follow the approach of Ackerman et al. (2000) but here a soot core
191 radius of 0.04 μm is specified, resulting in a single scattering albedo (SSA) of 0.88 at
192 wavelength 0.55 μm . The extinction coefficient within the absorbing aerosol layer is
193 about 0.16 km^{-1} at 0.55 μm , consistent with the measurements reported by Haywood et al.
194 (2003a). The absorbing aerosol induces a heating rate of $\sim 2.6 \text{ K d}^{-1}$ at noon and a diurnal-
195 average heating rate $\sim 1.2 \text{ K d}^{-1}$, consistent with observations exploited by Johnson et al.
196 (2004) and Ackerman et al. (2000). The initial absorbing aerosol layer physical thickness
197 of 1.5 km is loosely based on observations over the southeast Atlantic by Chand et al.
198 (2009), Haywood et al. (2003b), and Labonne et al. (2007), who report characteristic
199 layer thickness over the Atlantic of 1 to 2 km. Sensitivities of the results to the assumed
200 SSA of the absorbing aerosol and to their initial number concentration are briefly
201 discussed.

202 To examine variations in bulk properties of the overlying aerosol layer, a further
203 simulation is performed with the initial location 400 m higher, in which the model top is
204 extended to 3.5 km and the column of overlying water vapor and ozone used for radiative
205 fluxes adjusted accordingly. An additional baseline case with a 3.5-km deep grid was run
206 for computing differences. Two other simulations consider a moist perturbation of 1 g kg^{-1}
207 based on observations at St. Helena Island of equatorward outflow from the continental

208 boundary layer (A15), scaled to the initial height of $N_{a, \text{absorb}}$ with and without absorbing
209 aerosol. Finally, the impact of overlying absorbing aerosol on heavily precipitating
210 stratocumulus is examined by reducing $N_{a, \text{sulfate}}$ to 25 mg^{-1} . To isolate the microphysical
211 effects of the overlying aerosol, a group of simulations with $N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$ is
212 performed where the interaction of the absorbing aerosol with radiation is omitted. The
213 aforementioned sedimentation and evaporation effects are examined by additional
214 simulations that exclude cloud droplet sedimentation and that fix the cloud droplet
215 relaxation time scale (instead of computing it per Equation A5 of Morrison and
216 Grabowski, 2008). Semi-direct aerosol effects are dissected through simulations that
217 restrict aerosol heating to the free troposphere (FT) or the PBL. Table 1 summarizes the
218 setups for all simulations in the main text and its last column lists the figures in which
219 each simulation appears.

220 Radiative forcings are computed from hourly time slices, which yield daily
221 averages that differ negligibly from those using radiative fluxes updated every minute.
222 We compute aerosol forcings following Ghan (2013), in which total forcing from a
223 perturbation is calculated as the change in net downward radiative flux at TOA relative to
224 the baseline: $\Delta F = F(\text{perturbed}) - F(\text{baseline})$. The sum of the indirect and semi-direct
225 forcings from the absorbing aerosol is computed similarly but with the absorbing aerosol
226 omitted when calculating $F(\text{perturbed})$. The direct aerosol forcing is then derived by
227 subtracting the sum of indirect and semi-direct forcings from the total forcing.

228 For the sake of comparison with Y15, in one instance we also compute cloud
229 radiative forcing as the difference of net downward radiative fluxes at TOA with and
230 without cloud: $F(\text{all sky}) - F(\text{clear sky})$. The difference between ΔF and the aerosol-

231 induced change in cloud radiative forcing is the direct aerosol forcing for clear sky:
232 $\Delta\text{CRF} = \Delta F - \Delta F(\text{clear sky})$. The enhancement of aerosol absorption associated with SW
233 reflection by an underlying cloud layer, which tends toward a positive forcing (e.g.,
234 Chand et al., 2009) and is implicitly included in ΔF , is offset in ΔCRF by the subtraction
235 of a direct forcing that tends more negative here, because the ocean surface is less
236 reflective than the cloud layer. Subtraction of a negative direct forcing thereby yields a
237 ΔCRF that tends to be more positive than total forcing ΔF .

238 In all forcing calculations for this study, net LW fluxes at TOA are scaled from
239 net LW fluxes at the top of the model domain using $F_{\text{TOA}} = 2.627F_{3.2\text{km}} + 0.0054F_{3.2\text{km}}^2$
240 for the 3.2-km deep grid, and using $F_{\text{TOA}} = 2.469F_{3.5\text{km}} + 0.0046F_{3.5\text{km}}^2$ for the 3.5-km
241 deep grid. These correlations were derived from the baseline case run on a 40-km deep
242 grid, with root mean square (RMS) errors of 0.3 and 0.2 W m^{-2} on the shallower grids,
243 with biases of less than 0.001 W m^{-2} . No TOA corrections for SW fluxes are made
244 because the radiative transfer scheme (Toon et al., 1989) provides accurate TOA fluxes
245 by treating Rayleigh scattering in the overlying atmosphere.

246

247 **3. Impacts on lightly drizzling SCT**

248 **3.1. Overview of SCT with and without absorbing aerosol layer**

249 Figs. 1 and 2 illustrate the transition from a compact stratocumulus layer to more
250 broken fields of cumulus as a response to increasing SST for the lightly drizzling baseline
251 case ($N_{\text{a, sulfate}} = 150 \text{ mg}^{-1}$, $N_c \sim 100 \text{ cm}^{-3}$). After ~ 2 h of boundary layer turbulence spin-
252 up in one member of the baseline ensemble (Fig. 1b), the PBL depth in general
253 increases with SST and reaches 2 km at the end of day 3 (Fig. 1a). The thinning of the

254 stratocumulus is observed in the afternoon of day 1 as solar heating offsets some of the
255 LW cooling that drives PBL mixing, when vertical wind variance profiles show bimodal
256 structure with a local minimum near cloud base (~ 12 h in Fig. 1b). Convection revitalizes
257 after sunset and deepens the stratocumulus, when the mean precipitation rate at cloud
258 base peaks at ~ 0.1 mm d^{-1} in the baseline ensemble (Fig. 2i). Starting around sunrise of
259 day 2 (~ 30 h), the PBL becomes continuously stratified, with a persistent cumulus layer
260 developing under the stratocumulus (Fig. 1a). This stratification reduces the subsequent
261 nocturnal recovery, and leads to further reduction in LWP (Fig. 2b) and cloudiness (Fig.
262 2c) after sunrise on day 3. Following Sandu and Stevens (2011) by defining the SCT as
263 the time at which cloud cover (the fraction of columns with $LWP > 10$ g m^{-2}) first
264 decreases to half of its initial value, the transition in the baseline case is at ~ 62 h.

265 When incorporating an overlying absorbing aerosol layer, the clouds and PBL
266 evolve in a notably different way with an evident radiative impact (Figs. 2 and 3; Table 2).
267 N_c increases gradually after the bottom of the ramp of subsiding aerosol contacts the
268 deepening PBL at ~ 15 h (Fig. 2a). The full strength of the aerosol layer reaches the PBL
269 at ~ 20 h (Fig. 2d). Before the subsiding aerosol layer contacts the deepening PBL,
270 absorption of SW radiation in the aerosol layer dominates the radiative impact and
271 reduces the diurnal-average upwelling SW radiative fluxes at TOA by ~ 7 W m^{-2} on day 1
272 (Fig. 2f, Table 2). This SW absorption by the aerosol layer decreases with time when the
273 cloud field is more broken, since less upwelling SW radiation is reflected back into the
274 layer (cf. Chand et al., 2009) and when it is mixed below cloud, where less SW radiation
275 reaches the absorbing aerosol. On day 3, SW absorption is overcome by scattering,
276 resulting in a negative direct forcing (Table 2).

277 As the absorbing layer approaches the PBL, the inversion strengthens (Fig. 2h),
278 which would tend to slow entrainment. However, as the layer makes contact with the
279 clouds, the entrained aerosol activate cloud droplets and lead to a pronounced increase of
280 N_c , which is ultimately increased by a factor of ~ 10 over the baseline to $\sim 1000 \text{ cm}^{-3}$ (Fig.
281 2a). The increased N_c acts to accelerate entrainment through the sedimentation and
282 evaporation effects, and opposes but does not overcome the opposing tendency from the
283 strengthening of the inversion (Figs. 2d and 2e). The entrainment of warmer air with less
284 RH leads to a reduction of LWP (Fig. 2b) and cloud cover (Fig. 2c), hastening and
285 enhancing the SCT on day 2 (Fig. 2c). This SCT acceleration is opposite to Y15 who
286 found that entrained absorbing aerosol delays the SCT and leads to overcast conditions
287 during the second half of 72-h simulations. As a result of substantially reduced LWP,
288 here the overlying absorbing aerosol case yields a positive change in TOA SW CRF
289 relative to the baseline during the 3-day simulation (Table 3). The daytime average SW
290 ΔCRF after the soot contacts the PBL is 9.3 W m^{-2} , opposite in sign to that of Y15.
291 Meanwhile, the negative LW contributions to ΔCRF are enhanced during the transition,
292 and overcome the positive SW ΔCRF on day 3. As explained further below, such LW
293 contributions result from microphysical and heating effects. While such LW forcings are
294 often ignored when considering aerosol impacts on low-lying clouds, much of the
295 subtropical and tropical atmosphere is not particularly moist, with column water vapor of
296 less than 30 mm (cf. Lindstrot et al. 2014) as it is here (initial and final values
297 respectively about 25 and 30 mm), allowing changes in low-level clouds to impact LW
298 fluxes at TOA.
299

300 **3.2 Microphysical effects**

301 The microphysical effects of the subsiding aerosol are isolated by omitting aerosol
302 heating and comparing to the same baseline (Fig. 4). The substantial increase of N_c as a
303 result of the entrained aerosol is seen to largely explain overall reductions of both LWP
304 and cloud cover relative to the baseline simulation, leading to a hastened SCT. Such
305 disparity in LWP and cloud cover with and without entrained aerosol is reduced when
306 either the sedimentation effect is excluded (by omitting cloud droplet sedimentation from
307 both simulations) or when the evaporation effect is excluded (by fixing the cloud droplet
308 diffusional growth relaxation time in both simulations). When both effects are excluded,
309 simulations with and without entraining aerosol exhibit negligible differences in LWP
310 and a reversed difference in cloud cover. Thus, the hastened SCT from absorbing aerosol
311 in DHARMA simulations can be attributed primarily to the microphysical effects of
312 increased N_c , specifically via sedimentation and evaporation effects.

313 With the semi-direct effect now excluded by omitting aerosol absorption, the
314 indirect forcing is isolated (Table 4). Despite the substantial reduction in cloud cover, the
315 entrained aerosol results in only a modest positive aerosol indirect forcing on day 2 and a
316 negative forcing on day 3 (Table 4). The negative forcing is driven by a negative LW
317 forcing, as a result of more broken clouds and emission from a warmer SST, and by a
318 significant Twomey effect, which does not fully offset the opposed, comparable SW
319 forcing induced by the sedimentation and evaporation effects (Table 5).

320

321 **3.3 Semi-direct effects**

322 Next we isolate the semi-direct effects of aerosol heating by considering aerosol
323 absorption in the FT, PBL and throughout the atmosphere and comparing to the
324 preceding case that only included microphysical effects of the entrained aerosol layer. By
325 doing so we build upon the results of the previous section, effectively evaluating the
326 semi-direct effect in the presence of microphysical effects rather than in their absence. As
327 seen in Fig. 5, aerosol heating in the FT substantially strengthens the PBL inversion as
328 the aerosol layer approaches the PBL (Fig. 5e), enhancing LWP and cloud cover (Figs. 5b
329 and 5c) by inhibiting entrainment (Fig. 5d). The increase of LWP delays and weakens the
330 SCT, contributing to a negative SW forcing (Table 6). In contrast, aerosol heating in the
331 PBL reduces LWP and cloud cover in the daytime (Figs. 5b and 5c) by lowering the
332 relative humidity in the PBL and by stabilizing the PBL (Fig. 6a), hampering the
333 moisture supply from the surface (Fig. 6b). The reduction in cloud amount amplifies the
334 diurnal contrast of cloud fraction and hastens the SCT, resulting in a positive SW forcing
335 (Table 6).

336 The competing effects of aerosol heating in the FT versus the PBL serve to
337 increase cloud water at night while reducing it during daytime, enhancing its diurnal
338 cycle (Fig. 5c). Diurnally averaged, the effect of aerosol heating in the FT is dominant
339 and leads to increased LWP and cloud cover and therefore a negative average SW forcing
340 during the 3-day transition (Fig. 5c, Table 6). The net SW forcing is smaller than the sum
341 of the SW forcings via individual FT and PBL aerosol heating, indicating interactions
342 that reduce the component forcings when combined (Table 6). Specifically, aerosol
343 absorption in the FT slightly reduces the SW flux available for aerosol heating in the PBL,

344 while the greater cloud breakup in the daytime reduces the reflected upwelling SW flux,
345 in turn reducing aerosol heating in the FT. The combined effects also result in LWP and
346 cloud cover intermediate between the results when considered separately (Fig. 5).

347 In contrast to the counteracting impacts on cloud water, FT and PBL aerosol
348 heating both inhibit entrainment by intensifying the inversion and by stratifying the PBL
349 (Fig. 5c). The reduced PBL depth corresponds to warmer cloud tops, which emit more
350 LW radiation upwards, leading to net negative LW forcing on days 2 and 3 despite an
351 increase of LWP and cloud cover (Table 6).

352

353 **3.4. Combined effects**

354 Comparing Tables 2, 4 and 6 it is seen that net SW forcing is weakened with all
355 effects included because the increased LWP from aerosol heating compensates for some
356 of the LWP loss from microphysical effects on day 2 (Table 2, Fig. 6), and the direct
357 aerosol heating on day 1 greatly counteracts the negative radiative forcings after the
358 aerosol layer contacts the PBL. As a result, the mean SW impact over the 3-day transition
359 nearly vanishes (Table 2). The LW radiative forcing, however, accumulates and
360 strengthens during the transition, and therefore is the dominant contributor to a negative
361 average forcing during the transition (Table 2). In a nutshell, although the subsiding
362 aerosol layer directly absorbs solar radiation and breaks up the clouds faster and more
363 thoroughly, the CCN source serves to distribute cloud water over a greater number of
364 drops, increasing the optical thickness of the remaining clouds but at a lower altitude,
365 increasing both upwelling SW and LW radiative fluxes, leading to a net negative forcing.
366 We note that day 3 net SW forcing is only negative when the aerosol is absorbing

367 (-1.2 W m⁻² in Table 2); otherwise, the Twomey effect is not strong enough to counteract
368 the reduction in cloud fraction and day 3 net SW forcing is equally positive (1.2 W m⁻² in
369 Table 4).

370 The study of the effects of absorbing aerosol on the SCT by Y15 considered only
371 SW forcings, which seems sensible given that studies of semi-direct effects in
372 stratocumulus (Johnson et al., 2004) and trade cumulus (Ackerman et al., 2000; Johnson,
373 2005) have found SW forcings to be dominant. However, here we find interactions of
374 aerosol and clouds in response to multiple effects leads to small net SW forcings: for
375 example, positive SW forcing from PBL aerosol heating and microphysical effects on
376 dynamics offset negative SW forcing from FT aerosol heating and the Twomey effect
377 (Table 5). By contrast, the negative LW forcings from multiple effects (i.e., cloud water
378 reduction and PBL deepening) work in the same direction and result in a substantial net
379 LW forcing for the SCT.

380 Sensitivity tests with varying values of the SSA and initial number concentration
381 of the absorbing aerosol are summarized in Appendix A1. A decrease of SSA at 0.55- μ m
382 wavelength from 0.88 to 0.71 hastens the SCT less but leads to a positive radiative
383 forcing averaged over the 3-day transition, attributable to direct absorption by the aerosol.
384 A decrease of the initial number concentration for the overlying aerosol with SSA of 0.88
385 serves to weaken its negative 3-day average radiative forcing.

386

387 **4 Variations in bulk properties of overlying aerosol layer**

388 **4.1. Higher initial elevation**

389 Increasing the initial height of the base of aerosol layer by 400 m delays contact
390 with the PBL by about half a day (Fig. 7a). The delayed contact reduces the entrainment
391 of aerosol relative to the case with the layer starting lower, thereby hindering cloud
392 breakup (comparing Figs.7b-c with Figs. 2b-c). The enhanced cloud amount leads to a
393 much greater SW negative forcing on days 2 and 3, despite greater direct absorption
394 owing to the extended duration of the aerosol aloft on day 2 (2 and 7). The delayed
395 contact also provides for a longer duration of heating aloft and thereby a stronger
396 inversion on day 3 (Fig. 7e), favoring maintenance of the clouds and thus a negative SW
397 forcing. Despite increased LWP and cloud cover, the SCT with a higher elevated aerosol
398 layer is still hastened relative to the baseline (Fig. 7). The greater negative SW forcing of
399 the more elevated aerosol layer after its contact with the PBL ultimately leads to a more
400 negative 3-day mean radiative forcing to the case with the layer starting lower (Tables 2
401 and 7).

402

403 **4.2. Additional moisture**

404 Given that observations indicate that biomass burning plumes over Namibian
405 stratocumulus are moister than the surrounding air (A15), next we additionally consider a
406 moisture perturbation relative to the baseline. As seen in Fig. 8, the moisture induces
407 additional SW heating and LW cooling (Figs. 8a, b), with the latter dominating. The net
408 cooling offsets some SW heating especially near the top of the moist layer (Fig. 8c).
409 Before the moist layer contacts the PBL, the additional downward LW radiative fluxes

410 from its moisture serve to reduce cloud-top radiative cooling and thereby drive weaker
411 PBL mixing that results in a more broken cloud field relative to the dry case (Fig. 9c).
412 Reduced LWP diminishes upwelling SW radiative fluxes, enhancing the positive SW
413 forcing on day 1 (Table 8). After the moist layer contacts the PBL, the entrained moist air
414 leads to greater LWP and cloud cover than for the baseline, despite a weaker inversion
415 (Figs. 8c and 9e). The increased cloud water greatly increases the net outgoing SW flux at
416 TOA on days 2 and 3 (Table 8), and delays the SCT relative to the dry baseline (Figs. 9b
417 and 9c). The SW changes in TOA radiative fluxes are seen in Table 8 to dominate the
418 LW changes.

419 When an absorbing aerosol is then added to the moist layer aloft, the SCT is faster
420 and more pronounced relative to the case with only a moisture perturbation (Fig. 9c).
421 Comparison of Tables 2 and 9 reveals that the LW forcings are comparable with and
422 without the additional moisture, but the SW forcings induced by indirect and semi-direct
423 effects are about 4 W m^{-2} greater on days 2 and 3 with the moisture aloft. A thicker cloud
424 layer with greater cloud cover has more to lose, and the more dramatic reduction in cloud
425 cover during daytime predominantly changes the SW forcing. During nighttime, however,
426 cloud cover diminishes less as a result of the entrained moist air (Fig. 9c). The
427 counteracting day and night impacts on cloud cover keep the PBL depth close to that in
428 the absence of the additional moisture (Fig. 9d), leading to little difference in the diurnal
429 average LW forcing (Fig. 9f, Table 9). The net result averaged over the 3-day transition is
430 a modest positive SW forcing that cancels out the negative LW forcing (Table 9).

431

432 **5. Impacts on heavily drizzling stratocumulus**

433 The background aerosol concentrations in our simulations result in negligible
434 drizzle for these conditions. As SCT is often observed in association with precipitation
435 (e.g., Zhou et al., 2015), we next consider the impact of absorbing aerosol on the SCT of
436 heavily drizzling stratocumulus by reducing the $N_{a, \text{sulfate}}$ by six-fold, to 25 mg^{-1} .
437 Throughout this section the aerosol layer base is initially at 1.3 km and the layer does not
438 include additional moisture.

439 The reduced $N_{a, \text{sulfate}}$ is associated with domain-mean drizzle at cloud base
440 reaching $\sim 2 \text{ mm d}^{-1}$ each night (Fig. 10f). With drizzle the stratocumulus deck retains the
441 essential features of the PBL growth and of the thinning and dissipation of the
442 stratocumulus layer during the SCT, but exhibits differences associated with a much
443 weaker diurnal cycle (Fig. 10), as also reported by Sandu and Stevens (2011). As
444 discussed in Sandu et al. (2008), a weaker diurnal cycle is attributable to depletion of
445 cloud water and stratification of the PBL via precipitation, which limits the stratocumulus
446 invigoration during the night. A reduced LWP in turn lessens solar heating after sunrise,
447 reducing daytime cloud thinning and breakup.

448 As seen in Fig. 10f, entrainment of aerosol inhibits drizzle and thereby thickens
449 the stratocumulus layer. This inhibition of drizzle restores more than enough cloud water
450 to overcome PBL drying tendencies from the increased entrainment on day 2. After
451 sunrise, cloud cover falls sharply as the reduced drizzle strengthens the diurnal cycle.
452 Owing to a thicker nocturnal cloud deck and a stronger inversion from aerosol heating
453 aloft, cloud breakup is delayed but amplified on day 2. On day 3, the aerosol heating in
454 the presence of a stronger diurnal cycle results in a hastened SCT.

455 The inhibition of drizzle on day 2 allows for greater mixing and entrainment (cf.
456 Stevens et al., 1998) despite the stronger inversion from aerosol heating aloft (Fig. 10d).
457 The deeper PBL is associated with cooler cloud tops that emit less LW radiation, leading
458 to a positive LW forcing during the transition (Table 10). Such positive LW forcing is
459 more than offset by the strong SW forcing attributable to a strong Twomey effect
460 (relative to a cleaner baseline for this heavily drizzling case), and the net impact is
461 therefore an amplified negative forcing (Table 10).

462

463 **6. Discussion and conclusions**

464 In this study we have examined the impact of an initially overlying layer of
465 absorbing aerosol on the stratocumulus-to-cumulus transition (SCT) of lightly and
466 heavily drizzling clouds via large-eddy simulations. Our results indicate that the
467 overlying aerosol can profoundly modify the breakup of stratocumulus as it advects over
468 increasingly warm SSTs. During the transition of lightly drizzling clouds, an overlying
469 absorbing aerosol results in a more broken cloud field, hastening the SCT and
470 strengthening the diurnal cycle. The hastened SCT in our simulations is primarily
471 attributable to an increased number concentration of cloud droplets leading to faster
472 evaporation of more cloud water that enhances entrainment. This result holds in the
473 presence of additional moisture in the aerosol layer and is insensitive to a 400-m increase
474 in its initial altitude. Drizzle constitutes another degree of complexity. Its inhibition from
475 aerosol entrainment thickens the stratocumulus and leads to a stronger diurnal cloud cycle
476 that ultimately hastens the SCT.

477 The hastening of the SCT in this study is notable in contrast with Y15, who found
478 the opposite in a similar study. The entrained aerosol in that study leads to increased
479 cloudiness and a delay of the SCT before precipitation develops, suggesting that
480 inhibition of precipitation is not the cause of delayed SCT in Y15. The strength of
481 sedimentation and evaporation effects in the Y15 simulations are not obvious; we do find
482 a delay in the SCT for a lightly drizzling case only when sedimentation and evaporation
483 effects are both omitted (see Appendix A2). It is noteworthy that direct numerical
484 simulation (DNS) indicates that the sensitivity of cloud-top entrainment is substantially
485 underpredicted in LES (de Lozar and Mellado, 2016), so in reality the microphysical
486 effects may be considerably stronger than represented here. Another likely source of
487 discrepancy between our studies could be differences in model formulations. Y15 use the
488 System for Atmospheric Modeling (SAM; Khairoutdinov and Randall, 2003) whereas
489 here we use DHARMA (Ackerman et al., 2004). As seen in the intercomparison of de
490 Roode et al. (2016), the evolution of cloudiness in SAM and DHARMA for that study's
491 reference case (after Sandu and Stevens, 2011, from the observational study of Sandu et
492 al., 2010) is notably different in that DHARMA tends to ultimately develop a more
493 broken cloud field than SAM. The cloud cover in DHARMA better resembles the
494 satellite observations of Sandu et al. (2010) than SAM does during the SCT (Fig. 3k in de
495 Roode et al., 2016), but that is not necessarily proof of model skill since case study large-
496 scale forcings tend to be insufficiently constrained by available observations (e.g.,
497 Vogelmann et al. 2015). Whereas here we neglect consumption of aerosol number
498 (activation into cloud droplets is reversible through evaporation) owing to an absence of
499 constraints on aerosol source terms. In contrast, Y15 include aerosol consumption, and a

500 fixed surface source, which together result in their in-cloud droplet number concentration
501 dropping rapidly to $O(10 \text{ cm}^{-3})$ within the final 12 h of their control simulation, inducing
502 a dramatic decrease in cloud cover that does not occur when an overlying aerosol layer is
503 included. The detailed dynamical and microphysical differences between the studies
504 warrant further investigation, and future observational studies are necessary to provide a
505 firmer foundation for establishing the impact of absorbing aerosol on the timing of SCT.

506 Our study suggests that even in the case of a hastened transition an initially
507 overlying absorbing aerosol layer can produce net negative aerosol indirect and semi-
508 direct radiative forcings during SCT. For lightly drizzling stratocumulus, such negative
509 forcing is mainly attributable to greater cloud albedo from a dominant Twomey effect and
510 to negative LW forcing from greater cloud breakup over warmer SSTs and reduced PBL
511 top height from aerosol heating. Diminishing already from the interactions between
512 microphysical and semi-direct processes, when combined with aerosol direct SW forcing,
513 the net SW forcing nearly vanishes, thus becoming even less significant relative to the
514 negative LW forcing during the SCT. We recommend that such sizable LW forcings not
515 be neglected when considering semi-direct aerosol forcings in the context of
516 stratocumulus breakup. Further sensitivity tests (Appendix A1) show that when SSA at
517 $0.5\text{-}\mu\text{m}$ wavelength decreases further, the negative contributions can be overcome by the
518 large positive SW forcing via direct absorption, leading to net positive aerosol forcings.
519 We find it likely that similar positive forcings occur with an increase of aerosol layer
520 thickness.

521 When the aerosol layer is initially placed at a higher altitude, the extended
522 duration of aerosol overriding the stratocumulus deck intensifies the positive SW forcing

523 from direct absorption, while largely enhancing the negative SW indirect and semi-direct
524 forcings from less LWP reduction owing to less entrained aerosol and a stronger
525 inversion, leading to a more negative net forcing when averaged over the 3-day transition.

526 A moist layer aloft associated with outflow from a deeper continental PBL tends
527 to intensify the radiative forcings by reducing cloud-top LW cooling and thus convective
528 intensity and increasing the positive SW forcing before contact with the PBL, and by
529 enhancing negative SW forcing after contact via greater LWP resulting from reduced
530 PBL drying. The net effect of the overlying additional moisture is to modestly increase
531 cloud water during the 3-day transition. Absorbing aerosol in the presence of additional
532 moisture tends to break up the cloud more dramatically relative to the effect of absorbing
533 aerosol without additional moisture aloft. The presence of moisture little affects the LW
534 forcing but leads to substantially more net downward SW flux at TOA. Averaged over
535 the 3-day transition, the positive SW forcing cancels out the negative LW forcing.

536 We note that the simulations in this study are derived from observations over the
537 northeast Pacific Ocean (Sandu et al., 2010) whereas the characteristics of the overlying
538 absorbing aerosol layer are based on observations from the southeast Atlantic (A15). The
539 different large-scale meteorological conditions at these two locations may limit the
540 generality of this study to the SCT over the Atlantic. However, we find it likely that
541 similarly complex interactions (as summarized in Table 4) do occur. Future LES and
542 global modeling studies based on conditions over the southeast Atlantic should be
543 developed to evaluate the results presented here and in Y15. This study may help inform
544 future analyses primarily by emphasizing the complexity of competing LW and SW
545 effects, and giving some indication of their relative strengths, which lead to a wide range

546 of indirect plus semi-direct forcings from slightly positive to -20 W m^{-2} over our 3-day
547 simulations, depending upon assumptions made (Tables 2, 9, 10, and A1). The duration
548 of time before the absorbing aerosol layer makes contact with the PBL, the strength of
549 drizzle prior to contact, the number concentration of aerosol entrained after contact and
550 the amount of moisture accompanying the aerosol are all found to be factors of leading
551 potential importance to regional radiative impacts of biomass burning over the southeast
552 Atlantic and elsewhere.

559

APPENDIX

560

a. Sensitivity to single scattering albedo of absorbing aerosol

561 Fig. A1 compares the 3-day transition with varying values of single-scattering albedo
562 (SSA, at 0.55- μm wavelength) for the absorbing aerosol. As discussed earlier, the
563 microphysical effect of aerosol acts to greatly reduce cloud water and hasten the SCT by
564 virtue of enhanced entrainment. This effect is also seen in the “SSA=1” case (no
565 absorption) in Fig. A1. The increased entrainment is reflected by the fact that the
566 deepening of the PBL varies little from the baseline simulation, despite substantially
567 reduced cloud cover and LWP. A decrease of SSA from 1 to 0.88 (the value used for the
568 absorbing aerosol throughout the study) serves to strengthen the inversion and enhance

569 the diurnal cycle. These trends are greater when SSA is further reduced to 0.71, which
570 strengthens the inversion by ~3 K on day 2 and ~4 K on day 3, and deepens the PBL 400
571 m less by the end of day 3. The strengthened inversion slightly hinders cloud breakup,
572 while still hastening the SCT relative to the baseline (Figs. A1b and A1c). Although the
573 decrease of SSA amplified the net negative LW forcing via the slower deepening of the
574 PBL, that LW forcing is more than offset by the positive SW forcing attributable to direct
575 absorption by the aerosol, and therefore the 3-day mean radiative forcing increases with
576 the decrease of SSA. Thus, for the strongly absorbing aerosol case (SSA = 0.71) it is seen
577 in Table A1 that the net radiative forcing is positive on average.

578

579 **b. Combined effects of overlying absorbing aerosol in the absence of**
580 **sedimentation and evaporation effects**

581 As seen in Fig. A2, an overlying absorbing aerosol results in a delayed SCT when
582 sedimentation and evaporation effects are both omitted. The lack of microphysical
583 effects on dynamics isolates the influence of aerosol heating, which increases LWP
584 and especially cloud cover during the night and delays the SCT. We note that Y15
585 also found a delay in the SCT, but the similarity with this result may be coincidental.

Fig. 1. Evolution of horizontal average profiles of (a) cloud fraction (defined by cloud water mixing ratio threshold of 0.01 g kg^{-1}) and (b) vertical velocity variance for lightly drizzling baseline case ($N_{a, \text{sulfate}}=150 \text{ mg}^{-1}$). The simulation starts at midnight local time. Gray shading indicates nominal nighttime (6 pm~6 am local time).

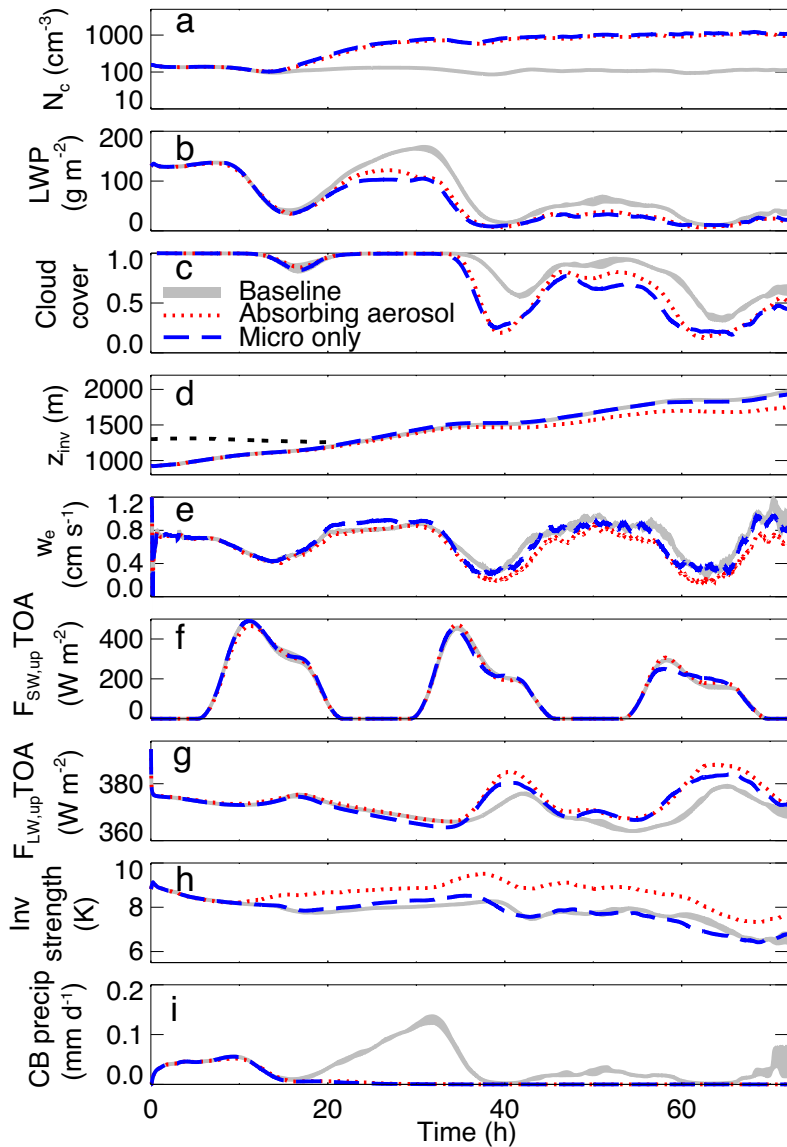

Fig. 2. Evolution of domain averages of (a) cloud droplet number concentration (N_c , average weighted by cloud water mixing ratio), (b) liquid water path (LWP), (c) cloud cover (columns with LWP $> 10 \text{ g m}^{-2}$), (d) inversion height (height of maximum potential temperature gradient), (e) entrainment rate (difference of inversion height tendency and subsidence rate at inversion height), (f) upwelling shortwave (SW) and (g) longwave (LW) radiative fluxes at TOA, (h) inversion strength (ΔT across inversion defined as the vertical extent with continuous positive temperature gradient), and (i) precipitation rate at

cloud base (mean over cloudy columns of lowermost height where cloud water mixing ratio exceeds 0.01 g kg^{-1}). Results shown as lagged 3-hour running averages to smooth entrainment rates. Range of three-member lightly drizzling baseline ensemble ($N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$) in gray. Results with absorbing aerosol layer shown as red dotted line. Results with aerosol layer excluding radiative interaction shown as blue dashed line. The black dotted line in (d) indicates the base of absorbing aerosol layer (lowest height where $N_{a, \text{absorb}}$ is full strength) before contacting the boundary layer.

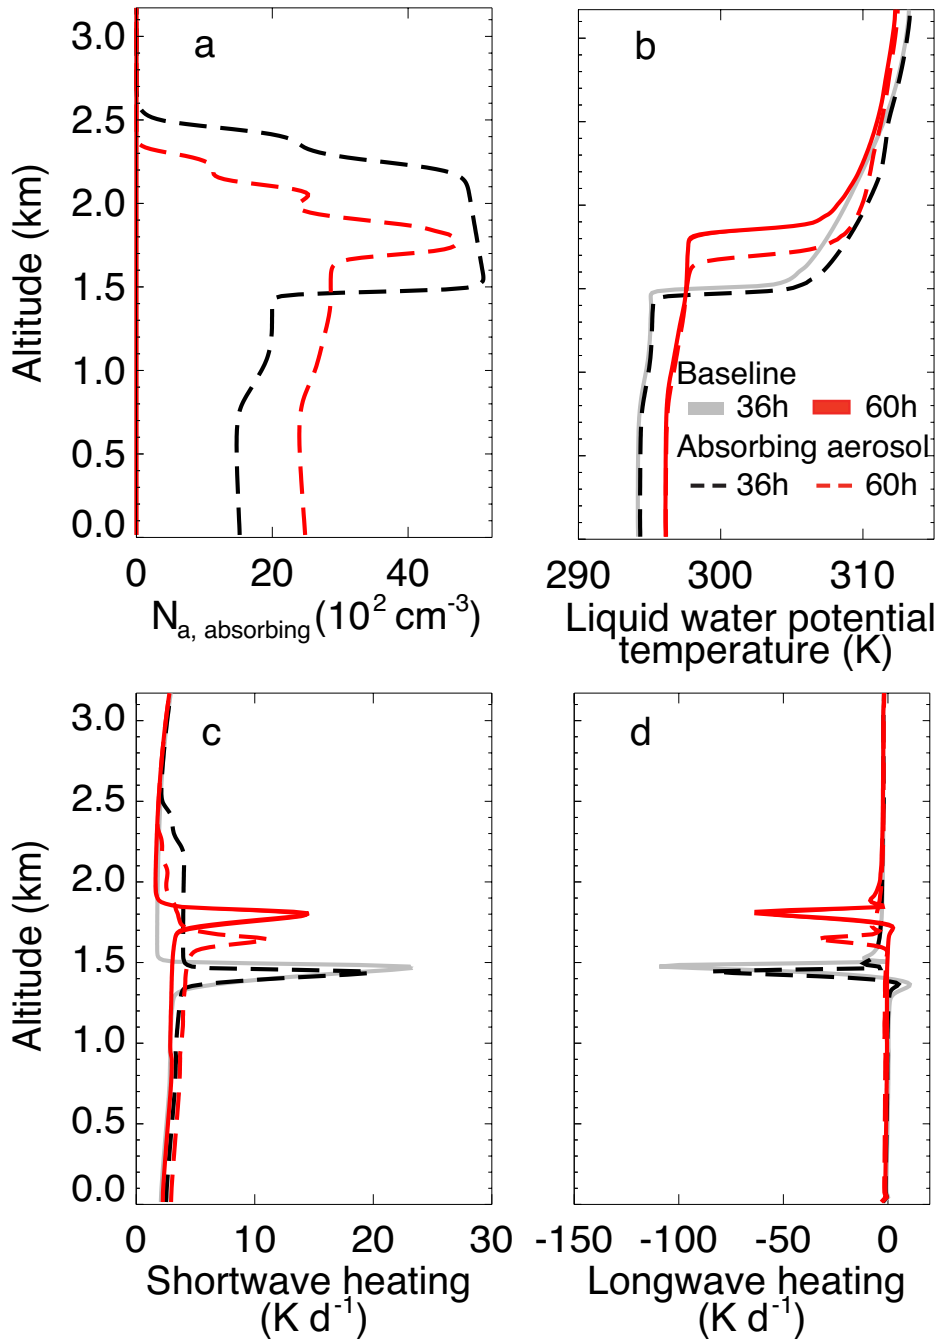

Fig. 3. Horizontally averaged profiles of (a) number concentration of absorbing aerosol, (b) liquid water potential temperature, (c) SW heating rate and (d) LW heating rate at 36th hour (gray solid line) and 60th hour (red solid line) for lightly drizzling baseline ensemble ($N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$) and with overlying absorbing aerosol (dashed line).

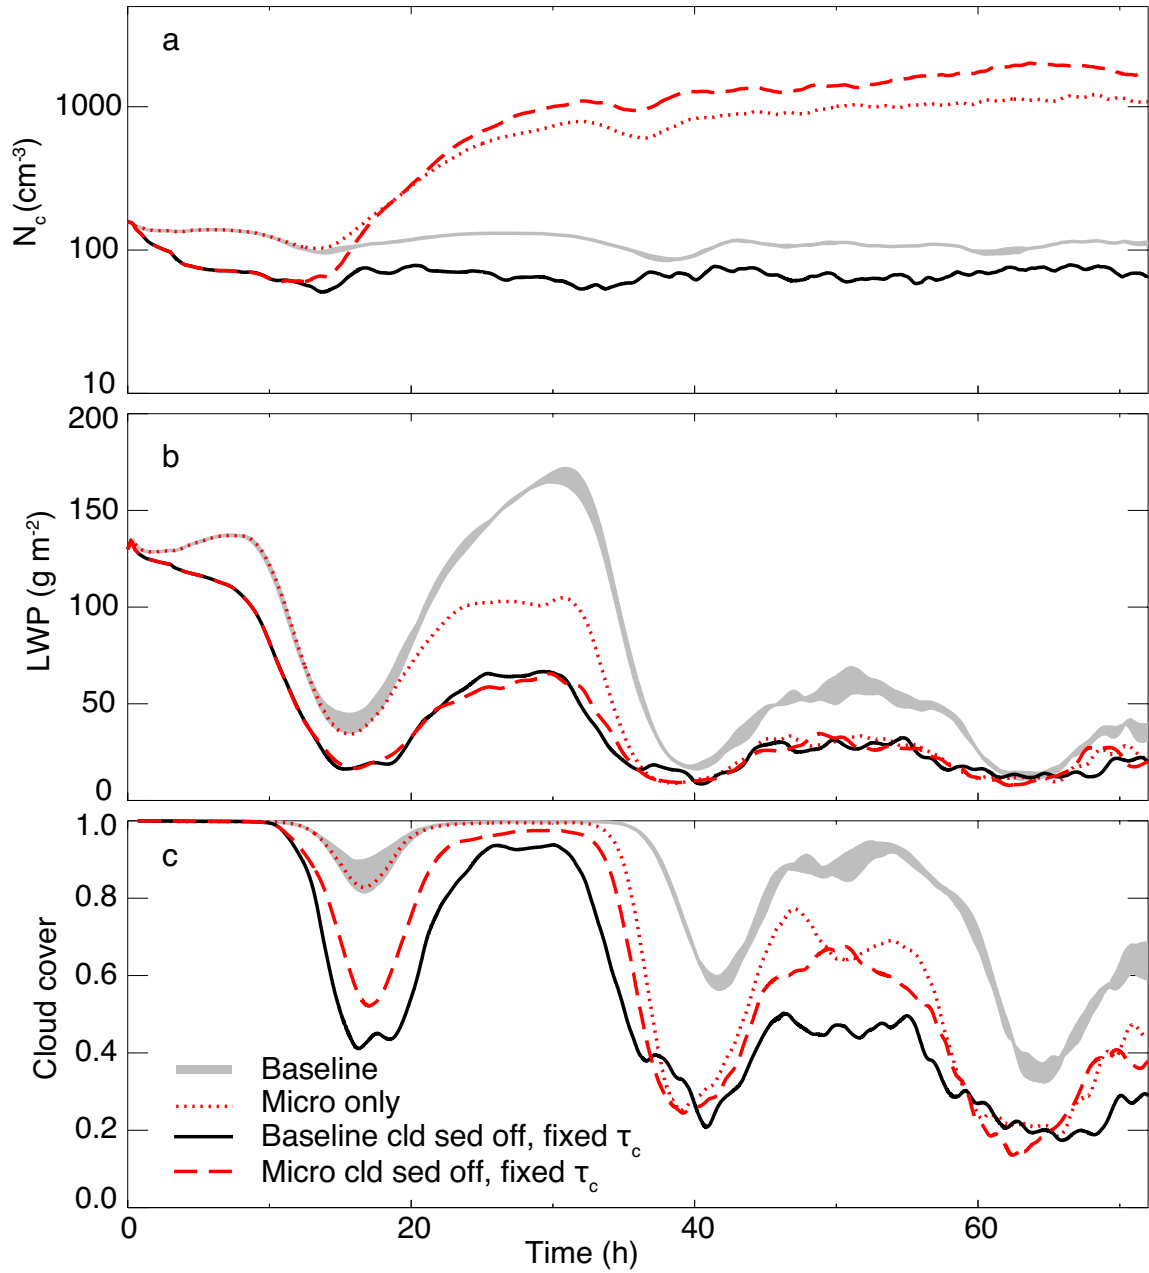

Fig. 4. As in Fig. 2 with baseline in gray and with overlying aerosol that does not affect radiation shown with dotted red line. Baseline and overlying aerosol cases in the absence of cloud-droplet sedimentation and with fixed relaxation time for diffusional growth of cloud droplet (τ_c) are shown with black solid and red dashed lines respectively.

Fig. 5. As in Fig. 2. All cases include initially overlying absorbing aerosol and allow them to act as CCN. For gray solid line the aerosol does not affect radiation. For long and short dashed lines, the aerosol affects radiation only in the free troposphere (FT) and planetary boundary layer (PBL), respectively. For red dotted line there are no restrictions on aerosol affecting radiation, as in Fig. 2.

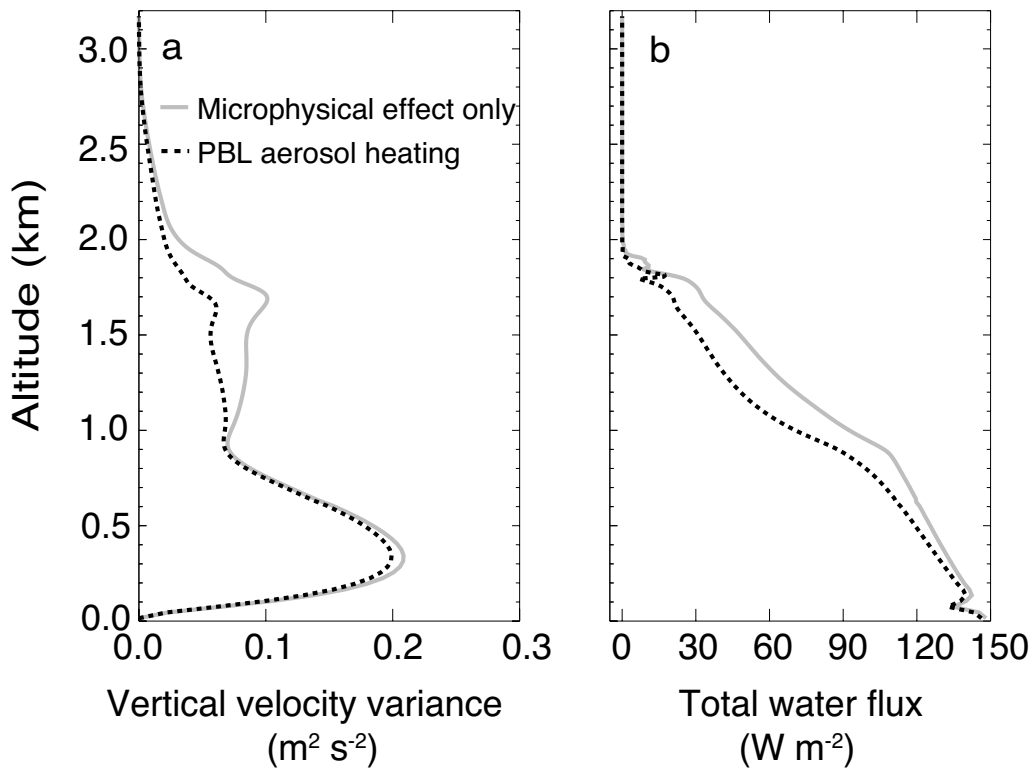

Fig. 6. Horizontally averaged profiles of (a) vertical velocity variance and (b) total water flux averaged over 10 AM to 2 PM local time on day 3 for simulations with (gray solid line) and without (black dotted line) absorbing aerosol affecting radiation in the PBL. Both simulations include microphysical effects of entrained aerosol layer.

Fig. 7. As in Fig. 2. The baseline with a 3.5-km deep grid ($N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$) shown as gray solid line. Results with aerosol layer initially 400 m higher shown as red dashed line, with corresponding aerosol layer base shown as black dashed line in (d).

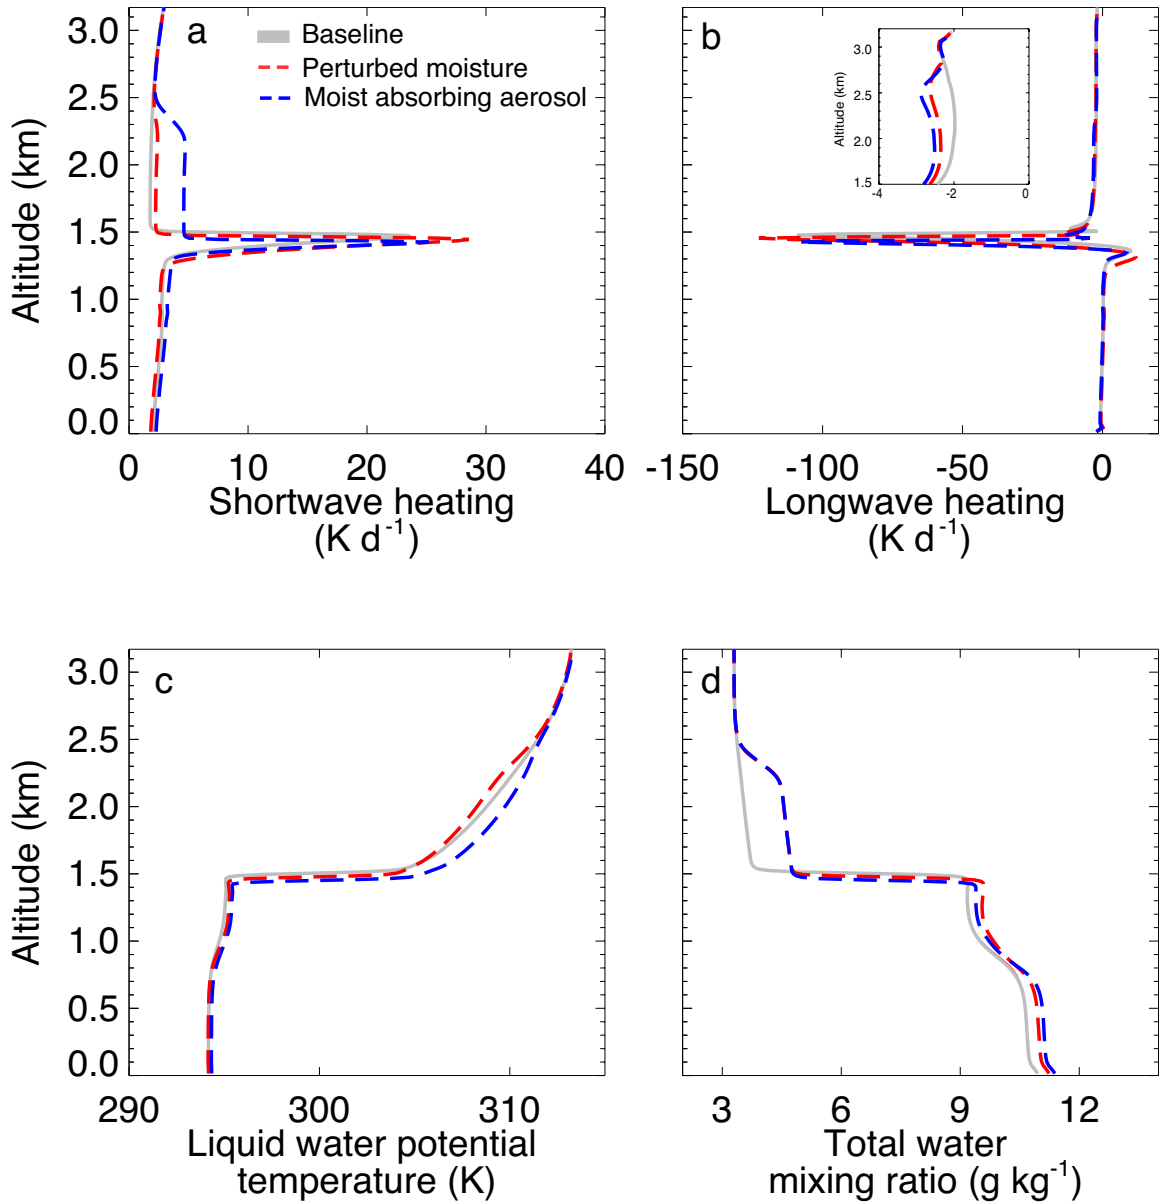

Fig. 8. Horizontally averaged profiles of (a) SW heating rate, (b) LW heating rate, (c) liquid water potential temperature, and (d) total water mixing ratio averaged over hours 35-37 for lightly drizzling baseline ensemble ($N_{a, \text{ sulfate}} = 150 \text{ mg}^{-1}$) (gray and black), perturbed moist case (red), and perturbed moist absorbing aerosol case (blue). The sub panel in (b) shows diurnal-average LW heating rate profile on day 1 from 1.5 to 3.2 km.

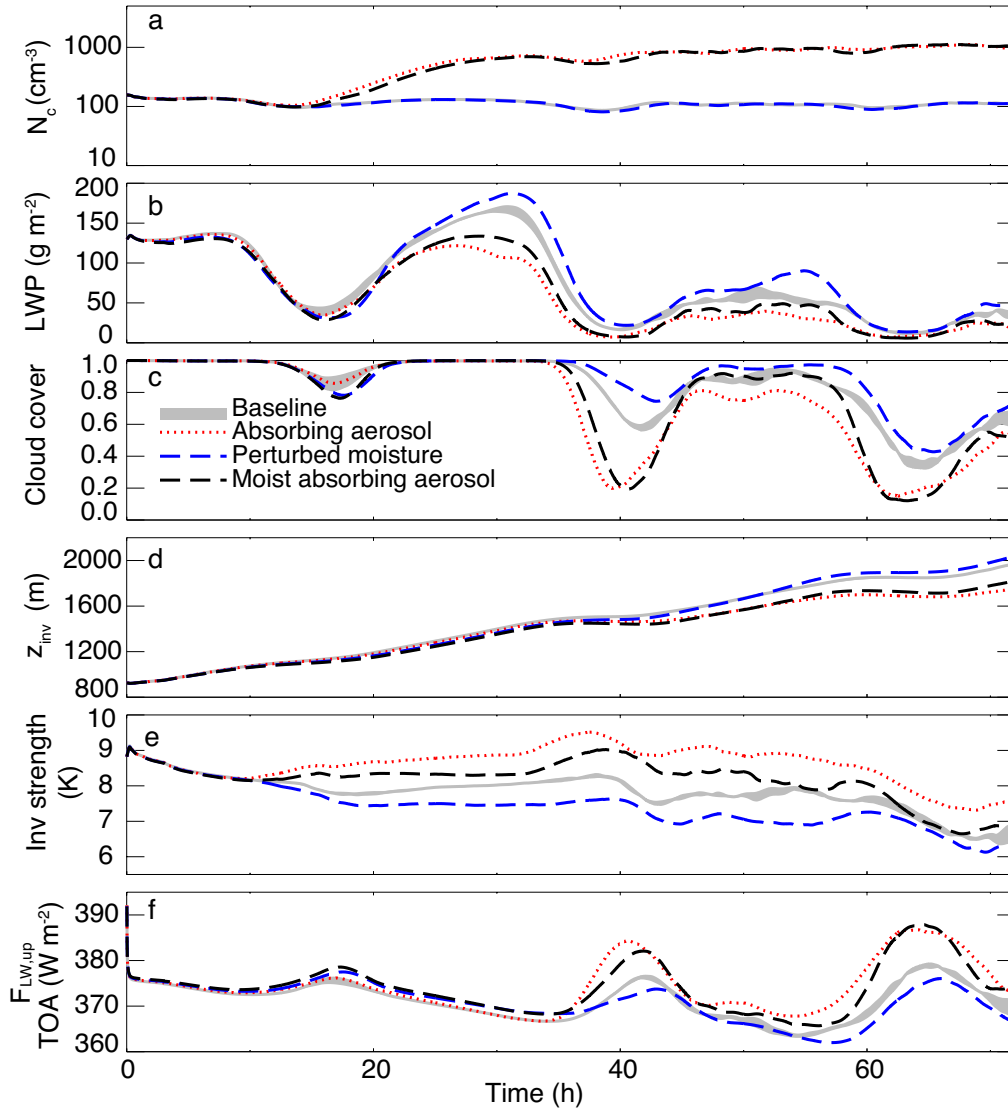

Fig. 9. As in Fig. 2. Range of three-member lightly drizzling baseline ensemble ($N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$) shown in gray. Results with absorbing aerosol layer shown as red dotted line. Baseline with moist layer aloft shown as blue dashed line. Results with moist absorbing aerosol shown as black dashed line.

Fig. 10. As in Fig. 2 but for heavily drizzling baseline ($N_{a, \text{sulfate}} = 25 \text{ mg}^{-1}$).

Fig. A1. As in Fig. 2. Range of three-member lightly drizzling baseline ensemble ($N_{a, \text{sulfate}} = 150 \text{ mg}^{-1}$) in gray. Varying single scattering albedo (SSA) of absorbing aerosol as given in legend.

Fig. A2. As in Fig. 2 but for lightly drizzling baseline and with absorbing aerosol in the absence of sedimentation and evaporation effects.

TABLES

Table 1. Summary of simulation setups. See text for details.

Table 2. Diurnal-average direct forcing, indirect plus semi-direct forcing, and sum of forcings (in $W m^{-2}$) from the overlying absorbing aerosol for the lightly drizzling case ($N_{a, sulfate} = 150 mg^{-1}$) on day 1 (0-24 h), day 2 (24-48 h) and day 3 (48-72 h). The three-day average radiative forcing is indicated in the last row. Boldface indicates results exceeding the uncertainty range derived from the baseline ensemble spread.

	Direct forcing			Indirect + semi-direct forcing			Total
	SW	LW	SW+LW	SW	LW	SW+LW	SW+LW
Day 1	7.3	-0.3	7.0	-1.6	-0.2	-1.8	5.2
