Abstract. Residential solid biomass cookstoves are important sources of aerosol emissions in India. Cookstove emission rates
15 are largely based on laboratory experiments conducted using the standard water-boiling test, but real-world emissions are often
higher owing to different stove designs, fuels, and cooking methods. Constraining mass emission factors (EFs) for prevalent
cookstoves is important because they serve as inputs to bottom-up emission inventories used to evaluate health and climate
impacts. Real-world EFs were measured during winter, 2015, for a traditional cookstove (“*chulha*”) burning fuel-wood (FW),
agricultural residue (AG) and dung (DG) from different regions of India. Average (\pm 95% confidence interval) EFs for FW,
20 AG, and DG were: 1) PM_{2.5} mass: 10.5 (7.7 – 13.4) g kg⁻¹, 11.1 (7.7 – 15.5) g kg⁻¹, and 22.6 (14.9 – 32.9) g kg⁻¹, respectively;
2) elemental carbon (EC): 0.9 (0.6 – 1.4) g kg⁻¹, 1.6 (0.6 – 3.0) g kg⁻¹, and 1.0 (0.4 – 2.0) g kg⁻¹, respectively; and 3) Organic
carbon (OC): 4.9 (3.2 – 7.1) g kg⁻¹, 7.0 (3.5 – 12.5) g kg⁻¹, and 12.9 (4.2 – 15.01) g kg⁻¹, respectively. The mean (\pm 95%
confidence interval) OC-to-EC mass ratios were 6.5 (4.5 – 9.1), 7.6 (4.4 – 12.2), and 12.7 (6.5– 23.3), respectively, with OC
and EC quantified by the IMPROVE_A thermal/optical reflectance protocol. These real-world EFs are higher than those from
25 previous laboratory-based measurements. Combustion conditions have larger effects on EFs than the fuel-types. We also report
the carbon mass fractions of our aerosol samples determined using the thermal-optical reflectance method. The mass fraction
profiles are consistent between the three fuel categories, but markedly different from those reported in past literature –
including the source profiles for wood stove PM_{2.5} emissions developed as inputs to receptor modelling studies conducted by
the Central Pollution Control Board of India. The OC₃ thermal fraction contributed nearly 50% of the total carbon mass for
30 emissions from all fuels.

1 Introduction

The Indian subcontinent is a regional hotspot for anthropogenic emissions (Ramanathan and Carmichael, 2008). Carbonaceous aerosol (black carbon – BC, and organic carbon – OC) in India is linked to surface dimming (Kambeididis et al., 2012), solar warming of the lower atmosphere (Ramanathan et al., 2001;2007), changing regional monsoon patterns (Chung and Seinfeld, 2005;Menon et al., 2002;Ramanathan et al., 2005), and accelerated melting of Himalayan glaciers (Ramanathan et al., 2007). Particulate matter (PM) emissions—particularly particles with aerodynamic diameters less than 2.5 μm (PM_{2.5})—are also associated with numerous adverse consequences for human health (Pope et al., 2009;Pope and Dockery, 2006). The Global Burden of Disease study has identified indoor air pollution as the largest risk factor and outdoor air pollution as the seventh largest risk factor for disability-adjusted life years in India (Murray et al., 2013) .

The most recent emissions inventory for India indicated that residential biomass cookstoves are the largest contributors to total annual PM_{2.5} emissions (Pandey et al., 2014;Sadavarte and Venkataraman, 2014). In 2010, 67% of Indian households, more than 160 million total, relied primarily on solid fuels for cooking (Census, 2011). Commonly used cooking appliances are mostly mud stoves, with some three-stone type brick stoves and metal stoves (Kar et al., 2012), that burn fuel-wood (FW), agricultural residues (AG), and dried cattle dung (DG). Traditional cookstoves have low combustion efficiencies, resulting in incomplete combustion and high PM emissions (Smith et al., 2000b).

Emissions performance of cookstoves is commonly expressed in terms of mass-basis emission factors (EFs) or mass of pollutant emitted per unit mass of fuel burned. PM emission rates depend on fuel properties, combustion device, operator behaviour and cooking patterns (Leavey et al., 2015;Sahu et al., 2011;Roden et al., 2009). Cookstove heating efficiencies and EFs and are often measured in a laboratory setting using a water-boiling test (WBT) with high- (boiling) and low- (simmering) power phases (Habib et al., 2008;Smith et al., 2000a;MacCarty et al., 2008). These standardized tests are useful for comparing different stove-fuel combinations, but they do not represent real-world stove behaviors found in the field (Roden et al., 2006;Roden et al., 2009;Smith, 2007). Habib et al. (2008) changed the amount of water boiled from 0.5 kg to 1.5 kg in the WBT test, thereby changing the fuel burn rate and burn cycle duration, and observed a factor of ~2.7 increase in the PM_{2.5} EF and a factor of ~2 increase in the OC fraction. A real-world study of Honduran wood-burning cookstoves (Roden et al., 2006) found higher PM_{2.5} EFs and OC content than those from previous laboratory studies. Roden et al. (2006;2009) found that real-world fire tending and cooking practices (and therefore burn conditions) were important factors determining PM EFs and compositions.

Real-world EFs for commonly used fuel types and cooking technologies in India are needed for accurate of bottom-up emission estimates (Bond et al., 2013;Bond et al., 2004;Pandey et al., 2014). Inventoried emission rates serve as inputs to regional and global atmospheric transport models that predict spatiotemporal profiles of pollutant burdens and associated impacts on climate and human health (Bond et al., 2013;Guttikunda and Calori, 2013;Sadavarte et al., 2016;Schulz et al., 2006). Alternatively, these inventories are used in conjunction with impact metrics such as intake fraction (Grieshop et al.,

2011) and global warming potential (Shindell et al., 2012) to evaluate mitigation policies (MHFW, 2015;Sagar et al., 2016). Such measurements identify key parameters to be monitored during laboratory testing and appliance certification.

65 With the above goals, we measured cookstove emission characteristics in a rural Indian household. Local meals were prepared with a traditional mud stove (“*chulha*”) using biomass fuels collected from different regions of India. Real-time measurements of emitted gas concentrations were conducted and PM filter samples were collected at regular time intervals during each cooking cycle. PM_{2.5}, OC and EC EFs are reported here as a function of fuel-type and combustion phase. Thermal carbon fractions provided by the IMPROVE_A protocol are also examined.

70 **2 Methods**

Thirty separate cooking tests were conducted between December 19 and 30th of 2015 in a rural household on the outskirts of Raipur, a city located in the central Indian state of Chhattisgarh (abbreviated as Chh.). ~77% of Chhattisgarh households are located in rural areas and rely almost entirely on solid biomass fuels for cooking (Census, 2011). On a national level, fuel-wood, agricultural residue and dung are used as primary cooking fuels by 49%, 9% and 8% Indian households
75 respectively (Census, 2011). Accounting for average combustion efficiencies and calorific values of these fuels, annual fuel usage estimates are 250 MT fuel-wood, 73 MT agricultural residue and 100 MT dung (Pandey et al., 2014). For this study, fuel-wood was obtained from Uttar Pradesh (U.P.), Rajasthan (Raj.), Andhra Pradesh (A.P.), Bihar, and Punjab which collectively account for 35% of the total fuel-wood user base in India. All wood fuels were in the form of chunks with typical dimensions of 5 – 15 cm. Cattle dung (in the form of dung cakes dried in the sun) was collected from U.P. and Bihar, which
80 account for 60% of the dung use for cooking in India. Agricultural residues from of *tur* crops (a type of woody stalk) and rice straw were procured from a village near the study location. Test fuels were collected and stored in sealed bags, and later analysed for elemental (carbon, oxygen, hydrogen, nitrogen) composition and moisture content. Fuel compositions are compared in Table 1. Per real-world practice, fuel samples were naturally dried in the sun and stored indoors, bringing moisture contents to < 9%. These compositions are consistent with those reported in other tests (Habib et al., 2008;Smith et al., 2000a).

85

90

Table 1: Elemental composition and moisture content of the biomass fuels in this study.

Fuel	Elemental composition (%)				Moisture content (%)
	Carbon	Hydrogen	Oxygen	Nitrogen	
U.P. dung	33.1	4.0	30.0	1.6	7.5
Bihar dung	41.4	5.1	33.6	2.1	8.6
Chh. rice straw	40.7	5.5	39.0	0.8	5.3
Chh. <i>tur</i> stalk	48.4	6.5	42.7	0.6	4.8
Punjab wood	50.3	0.2	40.9	0.4	6.2
Raj. Wood	49.7	5.6	42.9	0.1	8.1
U.P. wood	49.9	0.1	41.8	0.2	5.6
A.P. wood	48.3	0.1	43.4	0.7	3.1

95

Table 2 describes the fuels used and the foods cooked; replicate tests were made for some of these combinations with at least three for each fuel. Dung (20-50 g) was doused with approximately 10 ml kerosene for initial ignition and the test fuel was added after a steady flame was achieved. Additional fuel of the same type was added as needed to complete the recipe. A ten-minute period following lighting of the fire or the addition of kindling materials is designated as *ignition* phase. The remainder of the cooking cycle was designated as the *flaming* phase when a visible flame was present. Combustion entered the *smoldering* phase when the flame died down. The U.P. dung and Chh. rice straw could not sustain the flaming phase for more than a few minutes. Dung is typically smoldered for low-power cooking applications, and it is used as kindling material for igniting fuel-wood in a typical rural household. The low carbon content of U.P. dung (Table 1) possibly hinders its ability to sustain a flame, more so than Bihar dung. Rice straw has a low material density and high surface-to-volume ratio, and therefore tends to burn out very quickly. It also produces large amounts of smoke, making its use as a standalone fuel impractical and harmful for the cook's health. To circumvent these limitations, a few experiments established a steady flame using U.P. dung/Chh. rice straw mixed with U.P. wood (approximately 2.5:1 ratio of test fuel mass to wood mass).

110 **Table 2: List of cooking experiments conducted during the 10-day intensive study period. Abbreviations for Indian states: U.P. = Uttar Pradesh, Raj. = Rajasthan, A.P. = Andhra Pradesh, Chh. = Chhattisgarh.**

Day	Primary fuel used	No. of replicate experiments	Food cooked
1	Bihar dung	1	lentil-rice
2	U.P wood	2	rice, vegetables
3	U.P wood	1	tea
	Raj. wood	4	lentils, rice, vegetables
4	U.P. wood	2	lentils
	A.P. wood	1	rice
5	A.P. wood	2	rice, vegetables
	Bihar dung	1	tea
6	Chh. <i>tur</i> stalks	3	rice, vegetables, tea
7	U.P. dung ^a	3	vegetables, rice
	Bihar dung	1	tea
8	Chh. rice straw ^a	3	rice, vegetables
	Chh. wood	1	tea
9	Raj. wood	4	water heated, rice and curry
10	Punjab wood	1	milk porridge

^aTwo experiments for each fuel conducted with fuel-wood mixed with the test fuel

The test kitchen (Fig. S1) was on the first floor of house, separate from all other rooms. A permanently open door
 115 was the only entry from an open terrace. A partially covered window covered was a second ventilation source. The emissions testing system is shown in Fig. 1. The combustion device was a traditional mud *chulha*, such stoves have poor heat insulation, poor combustion efficiency and do not allow proper mixing of fuel and air (Smith et al., 2000a; Venkataraman et al., 2010). An eight-armed stainless steel probe (based on Roden et al. (2006)) sampled naturally-diluted emissions at ~1.2 m above the top of the stove. Each arm of probe was 0.5 m in length, with 4 uniformly placed holes facing the plume. This probe was
 120 connected to three real-time instruments—a Kanomax Portable Mobility Particle Sizer (PAMS) (Kulkarni et al., 2016), a TSI Sidepak (Zhu et al., 2007), and a Testo-350 gas analyser (Wang et al., 2012). The PAMS recorded particle size distributions from 10 – 400 nm mobility diameter. The Sidepak provides a light-scattering (670 nm) surrogate for measured PM_{2.5} mass that is calibrated with Arizona Road Dust (O'Shaughnessy and Slagley, 2002). PM concentrations exceeded the top range of these instruments for short periods during the plume monitoring. The Testo-350 gas analyser was factory-calibrated prior to
 125 the experiments for carbon monoxide (CO) and carbon dioxide (CO₂). Measured concentrations (acquired every second) were

at least five times the detection limits of 1 ppm CO and 0.01 % CO₂ by volume. PM_{2.5} was collected on 47 mm Teflon-membrane and pre-baked quartz-fiber filters several times during a cooking cycle using Minivol (5 L min⁻¹) samplers (AirMetrics Model 4.2) with greased impactor inlets located in the plume ~0.9m above the stove. Filter sample durations ranged from 0.5 to 4 minutes, based on the continuous SidePak reports, to prevent filter overloading. Field blanks were collected (minimum sampling duration of 15 minutes) each day before testing. The Teflon filters were weighed before and after sampling to obtain the net mass deposit which was divided by the sample volume (flow rate times duration) to obtain the concentration. The mass of Teflon filter deposits ranged 50 – 300 µg. Quartz filters were analysed using the Interagency Monitoring of Protected Visual Environments – A (IMPROVE_A) thermal-optical reflectance (TOR) method (Chow et al., 2007b;2011) to determine elemental and organic carbon fractions in the sampled particulates. The minimum detection limits of the TOR analysis are about 9 µg for OC and 1 µg for EC (Solomon et al., 2014).

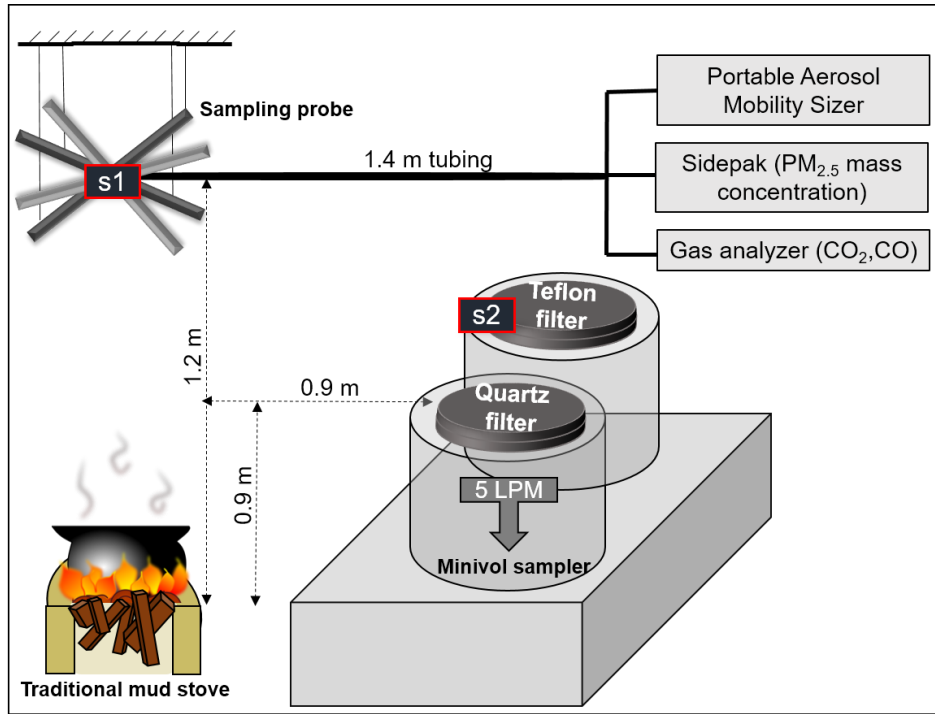

Figure 1: Schematic representation of the experimental setup. S1 and S2 denote the position of two wireless optical sensors.

Using the carbon mass balance technique, fuel-based EFs were calculated for each filter:

$$EF_i = CMF_{\text{fuel}} \frac{C_i}{\Delta C_{\text{CO}_2} \left(\frac{M_c}{M_{\text{CO}_2}} \right) + \Delta C_{\text{CO}} \left(\frac{M_c}{M_{\text{CO}}} \right)} \quad (1)$$

where EF_i is the EF of species i in grams emitted per gram of fuel consumed. CMF_{fuel} is the carbon mass fraction of the fuel, which ranged from 33% to 50% for the tested fuels. C_i is the concentration of emittant i , in this case PM_{2.5}, OC, or EC, in g m⁻³, determined for each Teflon and quartz filter. ΔC_{CO_2} and ΔC_{CO} are the concentrations above ambient levels of CO₂ and

CO in g m^{-3} , respectively. M_C , M_{CO_2} , and M_{CO} are the atomic or molecular weights of C, CO_2 , and CO in g mole^{-1} . Eq. (1) assumes that the carbon emitted in CH_4 , NMHC, and PM is negligible compared to that in CO and CO_2 .

145 Wireless optical particle sensors (details available in Patel et al. (2017)) were attached to the Minivol sampler and the sampling probe during six experiments to check for any significant differences in the particle concentrations measured at the two locations. Measurements where either sensor was saturated were discarded, and a linear regression analysis performed on the valid data points. A correction factor of 1.6 was applied based on regression slope (Supplemental Data). The equation above was also corrected to account for the small fraction of fuel carbon that gets converted to gaseous volatile organic carbon,
150 rather than CO_2 or CO, assumed as 2.4% (Habib et al., 2008; Roden et al., 2006).

3 Results and discussion

Figure 2 compares EFs for the different fuels. There are no statistically significant (unpaired t -test, 95% confidence intervals) EF differences for wood-fuels from different regions of India. Bihar dung EFs exceeded those for U.P. dung, possibly owing to the addition of wood to sustain flaming. On average, $\text{PM}_{2.5}$ and OC emission factors for dung were higher
155 than those for fuel-wood. EFs for dung, rice straw and *tur* stalk show a larger spread than corresponding EFs for fuel-wood.

Figure 2: Box plots of (a) PM_{2.5} emission factors, (b) OC emission factors, and (c) EC emission factors. All emission factors are expressed in g-pollutant per kg of fuel burnt. Boxes denote lower and upper quartiles; whiskers are 1.5 times the interquartile ranges of the upper and lower quartiles. The numbers above the error bars in panel (c) indicate the number of samples for each fuel.

160

Figure 3 compares EFs for the different burning phases. PM_{2.5} EFs are highest during the ignition phase for all fuels. The OC/EC ratio (Fig. 3b) increases from ignition and flaming, to smoldering for all fuels. CO EFs and modified combustion efficiencies (MCE, ratio of CO₂ concentration to CO+CO₂ concentration) show no correlation with PM_{2.5} emission factors or OC-to-EC ratios (Supplemental Data). MCEs exceeded 0.9 – a value associated with flaming (Reid et al., 2005; Zhang et al., 2008) – for nearly 90% of the test duration, even when no flaming was observed.

Figure 3: Fuel-wise average values of (a) PM_{2.5} emission factors, (b) OC-to-EC ratios, (c) OC emission factors, and (d) EC emission factors, categorized by observed combustion phases. All emission factors are expressed in g-pollutant per kg of fuel burnt. One-sided error bars are shown to denote one standard deviation from the mean. The numbers above the error bars in panel (d) indicate the number of samples for each fuel and combustion phase.

170

Average EFs for the entire burn cycle were calculated as a time-weighted sum of EFs for each phase of combustion. Fuel-wood and agricultural residue are used predominantly in flaming conditions to carry out the bulk of cooking operations, resulting in weights of 17% ignition, 66% steady flame and 17% smoldering. For dung, the weights are 17% ignition, 17% flaming and 66% smoldering because dung was used for longer low-power operations such as heating water/milk and roasting vegetables. These EFs are compared with other reported EFs in Figure 4. Average fuel-wood PM_{2.5} EFs and OC/EC ratios in this study are 20% larger than those reported by (Roden et al., 2006) for Honduran cookstoves, but they are 2-8 times as large as those reported for laboratory studies (Habib et al., 2008; MacCarty et al., 2008; Saud et al., 2012). For agricultural residue and dung, the average EFs and OC/EC ratios are 1.8 – 4.2 times and 1.3 – 2.2 times higher, respectively, compared to those reported by Saud et al. (2012) and Habib et al. (2008).

180

Figure 4: Average PM_{2.5} emission factors and OC-to-EC ratios for the three fuel categories in this study, compared with relevant studies. Error bars for values estimated in this study denote 95% confidence intervals based on standard errors of the means. Error bars for other studies are the bounds reported within those studies.

Thermal fractions of total carbon constituted by the IMPROVE_A protocol are compared in Fig. 5. OC1, OC2, OC3
 185 and OC4 refer to carbon that evolves at temperatures of 120 °C, 250 °C, 450 °C, and 550 °C respectively, in the inert helium
 atmosphere. OP denotes pyrolyzed carbon, OC charring in the inert helium carrier. EC1, EC2 and EC3 fractions evolve in a
 2% O₂/98% He oxidizing atmosphere at 550 °C, 700 °C and 800 °C, respectively. Fig.5 compares fractions from this study with
 those reported for controlled biomass (hardwood and softwood) burning reported in Chow et al. (2007a). We also compare our
 results with a source profile developed for PM_{2.5} emissions from wood *chulhas*, as part of source apportionment studies
 190 conducted by the Central Pollution Control Board (CPCB) of India (CPCB (2011)). This profile was based on laboratory burns,
 but details of the test fuel and burn protocol are not known. OC3 was the most abundant fraction, ~50% of OC3 by mass, while

the profiles in literature ranged 10%-34% in the OC3 fraction. The OC1 fraction for all fuels in this study was uniformly less than 3%, a finding comparable only to the 5% OC1 reported for softwood, but not for the other two profiles.

Carbonaceous aerosol source profiles are useful for source apportionment, and they may also have implications for climate and health impact assessments. In an previous study (Pandey et al., 2016), we reported that light absorbing OC may play a larger role in light absorption by cookstove emissions than that from earlier work on biomass burning in the U.S.A. The difference in constituents of OC emissions from the two sources might contribute to the observed difference in their optical characteristics, since thermal stability is known to be inversely related to the light absorption efficiency of organic compounds (Andreae and Gelencsér, 2006; Saleh et al., 2013).

200

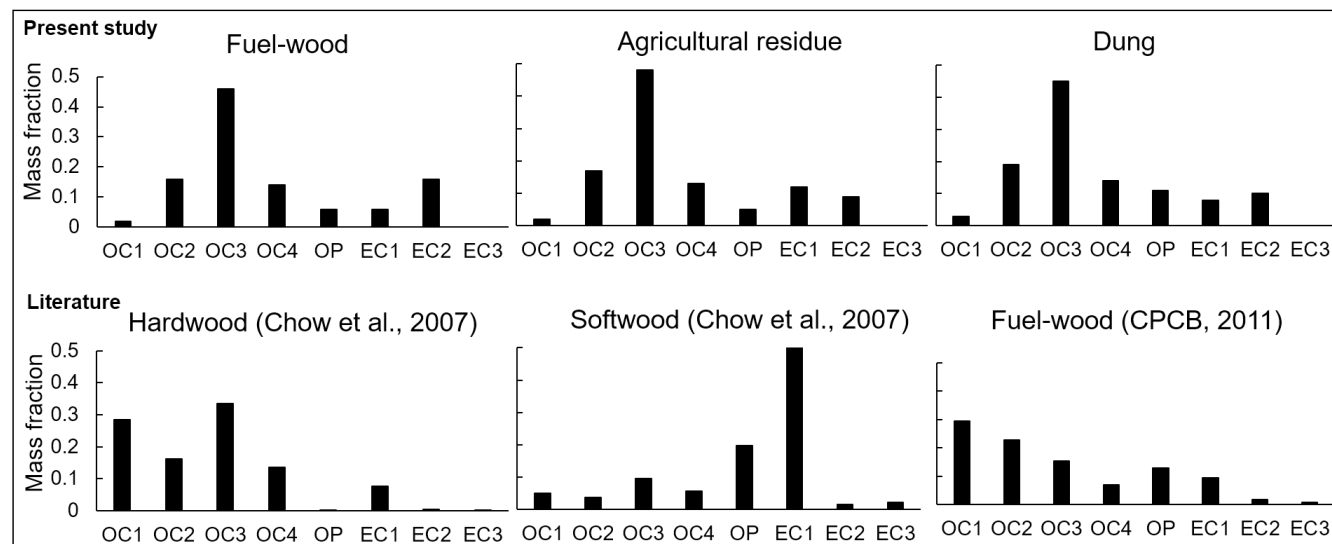

Figure 5: Fraction of total carbon contributed by the IMPROVE_A thermal carbon fractions.

4 Conclusions

We estimated $PM_{2.5}$, OC and EC mass emission factors from real-world combustion of commonly-used biomass fuels in India. EFs for fuel-wood and dung are more than twice those derived from laboratory tests for similar appliances and fuels. Earlier studies have shown that fuel burn rate (Habib et al., 2008) and fire-tending practices (Roden et al., 2009) affect cookstove emissions, therefore standardized burn protocols (typically a water boiling test) cannot replicate cookstove performance in the field. In a controlled test, variability in wood size may could be expected to affect emissions from fuel-wood combustion, hence, laboratory studies typically used identical wood chunks. The four wood fuel types in this study were used as chunks in a range of sizes, and yielded similar EFs even though these samples were gathered from widely separated parts of India. Overall, the variability in emissions between multiple measurements for the same fuel was larger than or comparable to the differences in average emission rates for different fuels.

A short period immediately following the ignition phase showed the highest and most variable PM_{2.5} EFs for all fuels, consistent with previous observations of high emissions from lighting and refuelling of stoves (Roden et al., 2009). The use of
215 variable amounts of kerosene and other kindling materials, as required in any burn, may explain the large spread in emission
measurements during ignition. The highest OC-to-EC ratios were observed during smoldering (no visible flame present), when
pyrolysis is the dominant process. The OC3 thermal fraction contributed nearly 50% of the total carbon mass for emissions
from all fuels, indicating that most of the PM emissions are non-evaporative. This could have implications for the climatic
220 impact effect of cookstove emissions, especially since volatility of OC emissions is inversely related to their light absorption
efficiency in the near-UV and visible wavelengths (Andreae and Gelencsér, 2006). The thermal fractions found in this study
differ from those found in other biomass burning tests, including the source profile used an input to receptor models of
particulate emissions in India (CPCB, 2011). Our findings suggest that combustion conditions may have a larger influence on
intrinsic properties of biomass combustion emissions than fuel variability. Connecting aerosol emissions from a given source
to their effects on climate and human health requires knowledge of their mass emission rates and physiochemical properties.
225 The EFs from this study could contribute toward improving evaluations of climate and health impacts of carbonaceous aerosols
over India. Further investigation is needed on the relationship between the composition of OC emissions and their climate and
health effects.
