22 **Abstract**

23 The global source-receptor relationships of sulfate concentration, direct and
24 indirect radiative forcing (DRF and IRF) from sixteen regions/sectors for years
25 2010-2014 are examined in this study through utilizing a sulfur source-tagging
26 capability implemented in the Community Earth System Model (CESM) with winds
27 nudged to reanalysis data. Sulfate concentrations are mostly contributed by local
28 emissions in regions with high emissions, while over regions with relatively low SO₂
29 emissions, the near-surface sulfate concentrations are primarily attributed to non-local
30 sources from long-range transport. Regional source efficiencies of sulfate
31 concentrations are higher over regions with dry atmospheric conditions and less
32 export, suggesting that lifetime of aerosols, together with regional export, is important
33 in determining regional air quality. The simulated global total sulfate DRF is -0.42 W
34 m^{-2} , with -0.31 W m^{-2} contributed by anthropogenic sulfate and -0.11 W m^{-2}
35 contributed by natural sulfate, relative to a state with no sulfur emissions. In the
36 Southern Hemisphere tropics, dimethyl sulfide (DMS) contributes 17–84% to the total
37 DRF. East Asia has the largest contribution of 20–30% over the Northern Hemisphere
38 mid- and high-latitudes. A 20% perturbation of sulfate and its precursor emissions
39 gives a sulfate incremental IRF of -0.44 W m^{-2} . DMS has the largest contribution,
40 explaining -0.23 W m^{-2} of the global sulfate incremental IRF. Incremental IRF over
41 regions in the Southern Hemisphere with low background aerosols is more sensitive to
42 emission perturbation than those over the polluted Northern Hemisphere.

43 **1. Introduction**

44 Sulfate is an important aerosol that poses health risks (Fajersztajn et al., 2013;
45 Xu et al., 2013; Peplow, 2014) and sulfur deposition is a major driver of ecosystem
46 acidification (Driscoll et al., 2010). Due to long-range transport, local sulfate pollution
47 could result from intercontinental influences, making domestic efforts of improving air
48 quality inefficient (Part et al., 2004; Bergin et al., 2005; Liu and Mauzerall, 2007). In
49 addition, sulfate aerosol substantially perturbs the radiation budget of the Earth
50 directly through scattering incoming solar radiation and indirectly through modifying
51 cloud microphysical properties (Lohmann and Feichter, 2005; Stevens and Feingold,
52 2009; Myhre et al., 2013). On a global average basis, anthropogenic sulfate aerosol
53 contributes a negative direct radiative forcing (DRF) of $-0.4 \pm 0.2 \text{ W m}^{-2}$ (Boucher et
54 al., 2013). The negative radiative forcing from sulfate partly offsets the positive
55 radiative forcing from greenhouse gases. Therefore, accurate understanding of
56 source attribution of sulfate and its radiative forcing is important for both regional air
57 quality and global climate mitigation (Shindell et al., 2012), which are of great interest
58 to not only science community but also the general public and policymakers.

59 Sulfate aerosol is produced through oxidation of sulfur dioxide (SO_2) by the
60 hydroxyl radical (OH) in gas phase and aqueous phase oxidation mainly by hydrogen
61 peroxide (H_2O_2) (Martin and Damschen, 1981). The SO_2 precursor is mainly emitted
62 from fossil-fuel combustion (Lu et al., 2010). In recent decades, SO_2 emissions from
63 many developing countries in East Asia and South Asia have increased substantially
64 as a result of accelerated urbanization and rapid economic growth (Streets et al.,

65 2000; Pham et al., 2005). In contrast, due to air pollution regulations, SO₂ emissions
66 in North America and Europe have decreased significantly since 1980–1990 (Smith
67 et al., 2011; Prechtel et al., 2001). As a consequence, source attribution of sulfate has
68 changed with time over recent decades.

69 Previous studies have reported that regional aerosols, including sulfate, are
70 produced not only by domestic emissions, but also by distant sources through
71 long-range transport (Jacob et al., 2003; Jaffe et al., 2003; Park et al., 2004; Heald et
72 al., 2006; Liu et al., 2008; Liu et al., 2009; Yu et al., 2012). For example, the strong
73 anthropogenic emissions over East Asia have led to an increasing interest in
74 quantifying the impact of aerosols exported from East Asia. Recent studies indicate
75 that the transpacific transport of sulfate from East Asia contributes to 30–50% of the
76 background (sulfate produced from non-local emissions) surface concentrations in
77 the Western U.S. and 10–30% in the Eastern U.S. (Park et al., 2004; Hadley et al.,
78 2007; Liu et al., 2008), which are larger than contributions from all other foreign
79 sources (Liu et al., 2009). In addition, among the major emitting regions assessed for
80 2001 conditions, European sources were shown to account for 1–5 µg m⁻³ of surface
81 sulfate concentration over northern Africa and western Asia, and their contribution to
82 East Asia (0.2–0.5 µg m⁻³) was twice as much as the contribution (0.1–0.2 µg m⁻³) of
83 Asian sources to North America (Chin et al., 2007).

84 Due to the important role of sulfate aerosol in the climate system, knowing the
85 relative significance of sulfate radiative forcing from different source regions is useful
86 for climate mitigation. Some previous studies examined the impact of emission

87 reductions on global and regional DRF and the influence of long-range transport (Yu
88 et al., 2013; Bellouin et al., 2016; Stjern et al., 2016). Yu et al. (2013) examined
89 changes in aerosol DRF resulting from a 20% reduction in anthropogenic emissions
90 from four major polluted regions (namely North America, Europe, East Asia, and
91 South Asia) in Northern Hemisphere, using simulations by nine models from the first
92 phase of the Hemispheric Transport of Air Pollution (HTAP1). They found that 31% of
93 South Asia sulfate aerosol optical depth over South Asia was contributed by non-local
94 sources. Based on the HTAP2, Stjern et al. (2016), using results from ten models,
95 further assessed global and regional DRF from a 20% reduction in emissions over
96 seven regions including North America, Europe, South Asia, East Asia, Russia, the
97 Middle East, and the Arctic. They found that the 20% reduction in emissions in South
98 Asia and East Asia largely perturbed the radiative balance for other regions. However,
99 these studies focused on only the limited number of source regions over the Northern
100 Hemisphere. Continents and subcontinents over the tropics and Southern
101 Hemisphere are also important source and receptor regions for the sulfate radiative
102 forcing, especially for indirect forcing due to stronger aerosol-cloud interactions in
103 clean environments (Koren et al., 2014). Bellouin et al. (2016) quantified the radiative
104 forcing efficiency based on simulations of a 20% reduction in emissions from four
105 source regions/sectors in year 2008, and reported that, with aerosol-cloud
106 interactions included, models simulated higher radiative forcing efficiency of sulfate
107 compared to previous studies (Myhre et al., 2013, Shindell et al., 2013; Yu et al.,
108 2013). Few studies have quantified systematically the global source-receptor

109 relationships of sulfate indirect radiative forcing that can be attributed to
110 local/non-local source regions and anthropogenic/natural source sectors.

111 This is the first study that examines source attribution of sulfate radiative forcing
112 with both anthropogenic and natural sources covering the whole globe. In this study,
113 we introduce an explicit sulfur tagging technique into the Community Earth System
114 Model (CESM), in which sulfate aerosol and its precursor emissions from sixteen
115 source regions/sectors (fourteen major source regions and two natural source sectors)
116 are tagged and explicitly tracked. This method allows us to efficiently quantify source
117 region/sector contributions to regional and global sulfate mass concentrations, and
118 direct and indirect radiative forcing (DRF and IRF) of sulfate.

119 Model description, emissions datasets, and model experiments are shown in
120 Sect. 2. Section 3 gives the comparison of modeled concentrations of sulfate and
121 SO₂ with a variety of observations. Section 4 shows model results for source
122 attributions of near-surface sulfate and SO₂ concentrations over various receptor
123 regions. Source attributions of DRF and IRF of sulfate are discussed in Section 5.
124 Section 6 summarizes all the results and main conclusions.

125

126 **2. Methods**

127 **2.1. Model description**

128 We use the version 5 of the Community Atmosphere Model (CAM5), which is the
129 atmospheric component of CESM (Hurrell et al., 2013), to simulate the sulfate aerosol
130 and calculate its DRF and IRF. The modal aerosol treatment in CAM5 (Liu et al., 2012)

131 predicts number mixing ratios and mass mixing ratios of aerosols, distributed in three
132 lognormal modes. A set of modifications to CAM5 that improves wet scavenging of
133 aerosols and convective transport reported by Wang et al. (2013) has also been
134 implemented in the model used in this study. Sulfate is internally mixed with other
135 species in the same aerosol mode and then externally mixed between modes. Sulfate
136 refractive indices at visible wavelengths is $1.43+0.00i$. Activation of cloud droplets
137 uses the scheme from Abdul-Razzak and Ghan (2000). The model simulates
138 aerosol-cloud interactions in stratiform clouds using a physically based two-moment
139 parameterization (Morrison and Gettelman, 2008). In addition to the standard
140 radiative fluxes calculated in the model by taking into account all aerosols, the CESM
141 has the capability of diagnosing radiative fluxes in parallel for a subset of aerosol
142 species. The difference between the standard and the diagnosed radiative fluxes can
143 then be attributed to the difference in aerosols considered in the radiation calculations.
144 For example, the difference in shortwave radiation fluxes at the top of the atmosphere
145 (TOA) represents the DRF of the excluded aerosol components in the diagnostic
146 calculation (Ghan, 2013). Using this same method, the DRF of sulfate from any of the
147 sixteen individual tagged regions/sectors can be derived from a pair of diagnostic
148 radiation calculations with and without the particular tagged sulfate considered. To
149 estimate IRF of sulfate from different sources, we define in this study an incremental
150 IRF, calculated as $\Delta(F_{\text{clean}} - F_{\text{clear, clean}})$, where F is the radiative flux at TOA, F_{clean} is
151 the flux calculated neglecting scattering and absorption by aerosols, $F_{\text{clear, clean}}$ is the
152 flux calculated neglecting scattering and absorption by both clouds and aerosols, and

153 Δ refers to the differences between the base and emission perturbed simulations.
154 Previous work found that the model did quite well at producing a reasonable
155 sensitivity of number of cloud droplets to sulfate mass concentration, reproducing a
156 significant fraction of the MODIS climatological variability of cloud droplet number
157 concentration (McCoy et al., 2017). Note that, the model only considers aerosol
158 effects on stratiform cloud (Morrison and Gettelman, 2008), and no microphysical
159 impact on convective clouds is included in the present version.

160 **2.2. Sulfur source-tagging**

161 To quantify the regional source attributions of sulfate, for the first time, we
162 implemented in CESM/CAM5 a sulfur source-tagging capability, similar to the black
163 carbon tagging method used in H. Wang et al. (2014) and Yang et al. (2017), through
164 which sulfur gases and sulfate aerosols produced by emissions from independent
165 sources are tagged. The tool can be used to quantify the source attributions of SO₂
166 and sulfate without perturbing source emissions. The sulfur tagging requires tagging
167 of interstitial and cloud-borne sulfate in each of the three modes as well as SO₂,
168 H₂SO₄ and dimethyl sulfide (DMS) gases. In this study, sulfur species produced by
169 emissions from fourteen geographical source regions and two natural source sectors
170 including volcanic eruptions and DMS from oceans are tagged. The tagged and
171 untagged models have been verified of producing the same SO₂/sulfate properties
172 and meteorology (Fig. S1). While emissions of organic carbon, black carbon, sulfate
173 and its precursor gases are all included in the simulations, the source tagging is used
174 for sulfate and its precursor gases emissions alone.

175 **2.3. Emissions**

176 The CEDS (Community Emissions Data System) anthropogenic emissions
177 (Hoesly et al., 2017) and open biomass burning emissions from Van Marle et al. (2017)
178 that were produced for the CMIP6 model experiments are used in our simulations. In
179 CAM5, 97.5% of SO₂ is emitted directly into the atmosphere and 2.5% is emitted as
180 sulfate aerosol. Natural emissions of volcanic SO₂ and DMS are the same as those
181 used in AeroCom following Neale et al. (2012), which are kept constant throughout the
182 selected years in this study. Figure 1a shows the fourteen geographical source
183 regions tagged in this study, which are consistent with source-receptor regions
184 defined in HTAP2, including North America (NAM), Central America (CAM), South
185 America (SAM), Europe (EUR), North Africa (NAF), Southern Africa (SAF), the
186 Middle East (MDE), Southeast Asia (SEA), Central Asia (CAS), South Asia (SAS),
187 East Asia (EAS), Russia/Belarus/Ukraine (RBU), Pacific/Australia/New Zealand
188 (PAN), and rest of the world (ROW, including oceans and polar continents). Table 1
189 summarizes emissions of combustion SO₂ (anthropogenic + open biomass burning),
190 volcanic SO₂ emissions (VOL), and DMS emissions over the sixteen tagged source
191 regions/sectors averaged for the most recent five years (2010–2014) and Figure 1b
192 presents relative contributions from individual source regions to the global
193 combustion SO₂ emissions. The global combustion SO₂ emissions rate is 57.6 Tg S
194 yr⁻¹, of which more than 98% come from anthropogenic sources. The combustion SO₂
195 and sulfate are referred to anthropogenic SO₂ and sulfate hereafter. Detailed
196 information on the anthropogenic emissions of SO₂ can be found in Hoesly et al.

197 (2017). East Asia, with regional emission of 17.8 Tg S yr⁻¹ (31% of global
198 anthropogenic SO₂), has the largest total SO₂ emissions, compared to the other
199 tagged regions. South Asia also emits a large amount of SO₂, 6.4 Tg S yr⁻¹ (11%),
200 followed by 3.4 Tg S yr⁻¹ (6%) from the Middle East, 3.3 Tg S yr⁻¹ (6%) from Europe,
201 3.1 Tg S yr⁻¹ (5%) from North America, and 2.7 Tg S yr⁻¹ (5%) from Southern Africa.
202 The other individual tagged regions have weaker emissions, with a combined
203 contribution of less than 5%. However, emissions from ROW contribute 11.2 Tg S yr⁻¹
204 (19%) of SO₂ that are mainly from shipping emissions near the continents. In addition,
205 natural emissions of sulfur are also accounted for, including 12.6 Tg S yr⁻¹ of SO₂ from
206 volcanic eruptions, in the range of 10–13 Tg S yr⁻¹ derived from the Ozone Monitoring
207 Instrument (OMI) measurement (McLinden et al., 2016), and 18.2 Tg S yr⁻¹ of DMS.
208 Figure S2 shows the spatial distribution of SO₂ emissions from each tagged
209 region/sector as well as DMS emissions. Emissions are spatially heterogeneous even
210 within the individual tagged regions. For instance, SO₂ emissions in North America are
211 mainly located in Eastern U.S., and Eastern China accounts for the majority of SO₂
212 emissions from East Asia. In addition, seasonal variations in emissions are quite
213 different among the source regions (Table 1). East Asia, RBU and Europe have
214 seasonal peak emissions in boreal winter due to high residential emissions from
215 heating in this season together with higher SO₂ emission from the energy sector.
216 Southern Africa shows larger emission in boreal summer from biomass burning in this
217 season, while emissions from North America are comparable in winter and summer
218 due to the bulk of SO₂ emissions arising from baseload electric power generation.

219 DMS is emitted over oceans with a boreal winter peak due to phytoplankton blooms
220 over the Southern Ocean. These heterogeneous spatial and temporal distributions of
221 emissions could lead to different influences on air quality and radiative forcing over
222 continents and subcontinents near the source regions.

223 **2.4. Model configurations**

224 The CAM5 simulation is conducted using a meteorological nudging method (Ma
225 et al., 2013; Zhang et al., 2014), with winds nudged to the MERRA reanalysis
226 (Rienecker et al., 2011) every 6 hours. Simulations performed are shown below:

- 227 1) Base simulation: the simulation is integrated for years 2009–2014, with 2009
228 for spin-up and 2010–2014 for analysis.
- 229 2) All reduction simulation: one sensitivity simulation with the same base model
230 configuration but having a uniform 20% reduction in sulfur (SO₂, sulfate, DMS)
231 emissions globally is performed to quantify source attributions of incremental
232 IRF of sulfate.
- 233 3) Source reduction simulations: three sensitivity simulations with the same base
234 model configuration but having a 20% reduction in global DMS emissions and
235 regional sulfur emissions over North America and East Asia, respectively, are
236 performed to validate the decomposition of global incremental IRF into
237 contributions from source regions/sectors using the tagging method.
- 238 4) Preindustrial simulation: one sensitivity simulation with the same base model
239 configuration but anthropogenic SO₂ emissions fixed at 1850 level globally is
240 performed to compare incremental IRF and anthropogenic IRF of sulfate.

241 The 20% is chosen to follow the experiment design in the framework HTAP2.
242 All simulations are performed at 1.9° latitude by 2.5° longitude horizontal grids and
243 30 vertical layers.

244 **3. Model evaluation**

245 To evaluate the model's performance in simulating sulfate with the latest
246 emissions from CEDS inventory, the simulated sulfur concentrations are compared
247 with measurements from regional observation networks. These datasets include the
248 Interagency Monitoring of Protected Visual Environments (IMPROVE), the European
249 Monitoring and Evaluation Programme (EMEP), the East Asian Monitoring Network
250 (EANET), and the China Meteorological Administration Atmosphere Watch Network
251 (CAWNET, Zhang et al., 2012). Sulfate concentrations observed from IMPROVE,
252 EMEP and EANET being used here are from 2010 to 2014, covering the same time
253 period as the simulation, while CAWNET only collected data over 2006–2007. In
254 order to use the CAWNET data to evaluate 2010-2014 simulation results, we decide
255 to scale the observed sulfate mass concentrations using the ratio of CEDS
256 2010-2014 SO₂ emissions to 2006-2007 emissions over China (which is 0.92) for
257 comparison, thus assuming a linear relationship between SO₂ emissions and sulfate
258 concentrations.

259 Figure 2 shows the comparison of modeled annual mean near-surface sulfate
260 concentrations with those from the observational networks. The model successfully
261 reproduces the global spatial distribution of sulfate with high concentrations over East
262 Asia and low concentrations over North America and Europe, as well as the spatial

263 patterns within major continents, for instance, high (low) values over Eastern
264 (Western) U.S. and high (low) sulfate concentrations over Eastern (Western) China.
265 The spatial correlation coefficient between simulated and observed sulfate
266 concentrations globally is +0.86 and is statistically significant at the 95th percentile.
267 Compared to the measurements at the IMPROVE sites over North America, at the
268 EMEP sites over Europe, and at the EANET sites over part of East Asia (only one site
269 in China) and Southeast Asia, the model reproduces sulfate concentrations with
270 biases within $\pm 20\%$. However, the model largely underestimates the simulated sulfate
271 concentrations in China, with normalized mean biases (NMB) of -54% , compared to
272 the CAWNET observations.

273 A few factors could be responsible for the bias between the observed and
274 modeled sulfate concentrations. Underestimation of local SO_2 emissions could result
275 in the simulated low sulfate concentrations (Liu et al., 2012; Wang et al., 2013). Too
276 frequent liquid clouds and too strong wet scavenging at the mid- and high latitudes in
277 CESM model can lead to shorter aerosol lifetime and lower concentrations in the
278 simulation (Wang et al., 2011; Liu et al., 2012; Wang et al., 2013). In addition, the
279 underestimation of emissions from upwind regions or strong wet scavenging of
280 aerosols during transport could be another reason for the simulated low bias (Yang et
281 al., 2017). A too low rate of transformation from SO_2 gas to sulfate particles in the
282 model could also contribute to the low bias in sulfate concentrations (Wang et al.,
283 2016; Li et al., 2017). The bias can also result from the fact that the site
284 measurements are point observations, while the model results are grid-cell average

285 that does not consider subgrid aerosol variations (Qian et al., 2010; R. Wang et al.,
286 2014). In addition, different models show large discrepancies in simulating sulfate
287 over China (Kasoar et al., 2016). The underestimation of sulfate in China can lead to
288 an underestimation of source contribution from East Asia of sulfate concentrations,
289 direct and indirect radiative forcing of sulfate, and forcing efficiencies of sulfate.

290 To evaluate the model results more broadly, we compare the simulated total
291 column burden of SO₂ with that derived from the OMI measurements (Li et al., 2013),
292 as shown in Fig. S3. Both the model results and the OMI satellite data are averaged
293 over 2010–2014. Compared to the OMI SO₂, the spatial distribution of column burden
294 of SO₂ is reproduced in CAM5, with a statistically significant spatial correlation
295 coefficient of +0.57. However, the model largely overestimates the magnitude of SO₂,
296 especially over China where the simulated values are about 8 times larger than OMI
297 data. Outside of China, simulated SO₂ burdens are 3–7 times larger than OMI data
298 over North America, Europe and Southeast Asia. The large difference between SO₂
299 burden and OMI retrievals must be due to either an underestimation of SO₂ in OMI
300 products and/or an overestimation of SO₂ burden in the model results. He et al. (2012)
301 compared in situ measurements with OMI SO₂ burden over central China and
302 reported a negative bias of 50% in OMI data, which probably came from cloud
303 contamination, reduced satellite sensitivity to SO₂ due to aerosols, and spatial
304 sampling bias in the satellite data. It is also worth mentioning that satellite column-SO₂
305 retrievals depend on the vertical distribution of SO₂ assumed in the retrieval algorithm,

306 which could be different from either the modeled SO₂ profile in this study or the actual
307 profile, which would introduce a bias.

308 The simulated near-surface SO₂ concentrations, however, are also
309 underestimated by 25% compared to observations over thirteen sites in China (Gong
310 et al., 2014) shown in Fig. S4a, also suggesting a large bias in satellite retrievals or too
311 much SO₂ simulated in higher altitude. In general, transport is more efficient in the free
312 troposphere. If too much SO₂ is simulated in higher altitude, the [near-surface](#) SO₂
313 concentration is likely to be overestimated over downwind regions. However, the
314 modeled SO₂ concentrations over downwind regions of China are underestimated by
315 45% compared to observations from EANET sites (Fig. S4b). This indicates that bias
316 in the satellite retrievals may be a significant cause of the inconsistency between
317 modeled and satellite-estimated SO₂ burden.

318 A less efficient of transformation from SO₂ to sulfate could also lead to
319 underestimation of sulfate. A recent study by Wang et al. (2016) focusing on the
320 sulfate pollution over China and London found that aqueous oxidation of SO₂ by NO₂
321 was key to an efficient sulfate formation, which has typically been neglected in
322 atmospheric models and is not considered in the CAM5. Another study by Li et al.
323 (2017) found that including an aerosol water (HRSO₂) parameterization in SO₂
324 oxidation in a box model could reproduce the observed rapid sulfate formation in Xi'an
325 over China. More rapid oxidation of SO₂ would reduce SO₂ loss by dry and wet
326 removal and increase sulfate production, which can partly explain the low bias in the
327 simulated sulfate concentrations and high bias in SO₂. In CAM5, 36% of total sulfur

328 converts into column-integrated sulfate over China, similar to 33% in the Community
329 Multiscale Air Quality (CMAQ) model (He et al., 2012). However, it changes to 21% in
330 the bottom model layer (about 992 hPa), indicating that the oxidation of SO₂ may be
331 underestimated near the surface, which most directly affects the comparison to
332 near-surface observations. This appears to be a plausible explanation for the
333 underestimated sulfate concentrations over China and points to a potentially important
334 direction for future model development.

335 Biases in simulated precipitation can also lead to biases in sulfate concentrations.
336 Fig. S5 compares annual mean precipitation from CMAP (Climate Prediction Center's
337 Merged Analysis of Precipitation) and that simulated in this study. Over China, CAM5
338 overestimates precipitation over northern China, which leads to a strong aerosol
339 scavenging and low sulfate concentration over this region.

340 **4. Source attribution of sulfate mass concentrations**

341 Figure 3 shows spatial distributions of modeled fractional contributions to annual
342 near-surface sulfate concentrations. (The absolute concentrations of sulfate are
343 shown in Fig. S6). East Asia, ROW, South Asia and the Middle East contribute 16%,
344 14%, 10% and 7%, respectively, to global annual mean near-surface sulfate
345 concentration, whereas contributions from the other individual source regions are all
346 less than 5%. Natural emissions of volcanic SO₂ and ocean DMS account for 11% and
347 16% of global mean sulfate concentrations. Sulfate concentrations are mostly
348 contributed by local sources in regions with high emissions, such as Eastern U.S.,
349 Southern Africa, South Asia, and Eastern China, where local source contributions are

350 larger than 80%. Over regions with relatively low SO₂ emissions, the near-surface
351 sulfate concentrations are primarily attributed to non-local sources from long-range
352 transport. Natural DMS emissions are the source of 80% of near-surface sulfate
353 concentrations over Southern Hemisphere oceans and 20–60% for Northern
354 Hemisphere oceans. Over downwind ocean regions of East Asia, emissions from
355 DMS only account for 20–40% of near-surface sulfate concentrations, showing a
356 stronger influence of regional transport. Sources from volcanic eruption strongly
357 influence sulfate concentrations over eruption regions. They are responsible for 10–
358 40% of near-surface concentrations over Central America and South America, 40–80%
359 over North Africa and Southeast Asia, but only account for about less than 5% over
360 East Asia and South Asia where anthropogenic emissions dominate.

361 The spatial distribution of sulfate column burden and relative contributions are
362 shown in Figs. S7 and S8, respectively. The global average source attribution of
363 column burden does not differ significantly from that of near-surface concentration.
364 The exception is an increase from 11% to 15% of the relative contribution from VOL to
365 column burden as compared to near-surface concentration due to injection mostly into
366 the free troposphere. The DMS contribution decreases from 16% to 11% to
367 compensate the increase of VOL contribution over oceans. In general, the relative
368 contribution from local source to column burden within a source region is lower than
369 that of near-surface concentration.

370 Figure 4 presents relative contributions of major sources to near-surface sulfate
371 concentrations in neighboring receptor regions along with seasonal mean wind fields

372 at 850 hPa. (Table S1 summarizes a complete list of numbers characterizing the
373 source-receptor relationships.) Transport of sulfate shows different patterns in
374 different seasons, due to the seasonal variability in local precursor emissions, lifetime
375 of sulfate, and meteorology, such as wind fields and precipitation.

376 The export of sulfate from Europe contributes to about 16–20% of near-surface
377 sulfate concentrations over North Africa, RBU and Central Asia in all seasons due to
378 the westerly jet over the eastern European boundary and northerly winds over
379 southern boundary. Sulfate from the Middle East can be effectively transported to the
380 surrounding receptor regions. This export accounts for 15–24% of sulfate
381 concentrations over North Africa, Southern Africa and Central Asia in DJF and SON,
382 and 19% over South Asia in MAM. Sources in the RBU explain about 21–42% of
383 sulfate concentrations over Central Asia, especially in JJA, with northerly winds over
384 north boundary of Central Asia driving transport from this region. Central Asia
385 accounts for 13% of sulfate over the RBU region in DJF when source emissions are
386 the largest. Northerly winds over East Asia in DJF and SON associated with the East
387 Asian winter monsoon transport sulfate from highly polluted Eastern China to
388 Southeast Asia, which accounts for about 50% of near-surface sulfate concentrations
389 over Southeast Asia in these months. The oxidation of SO₂ is expected to peak in JJA
390 because of the high temperature and humidity, and more sunlight. With the help of
391 southerly winds of East Asian summer monsoon, East Asia contributes to 15% of
392 sulfate concentrations over RBU in JJA. Due to the strong westerly jet in MAM,
393 sulfate originating from East Asia has a long-range transport across the North Pacific

394 and accounts for 11% of near-surface sulfate concentrations and 25% of total
395 imported sulfate (without local contributions) over North America. The transport of
396 sulfate from South Asia contributes 11–24% of sulfate in Southeast Asia in DJF and
397 MAM. These results, however, have additional uncertainties due to the SO₂/sulfate
398 bias in the model for East Asia discussed previously.

399 Source-receptor relationships for sulfate column burden are summarized in Table
400 S2. Compared to the near-surface concentrations, the sulfate column burden
401 contributed by local sources is much lower in all the receptor regions due to the more
402 efficient long-range transport of aerosols in the free atmosphere. Annually, the local
403 contribution over North America decreases from 67% for near-surface concentration
404 to 33% for column burden. The contributions of non-local sources from East Asia and
405 South Asia increase from 7% and 1% for near-surface concentration to 24% and 10%
406 for column burden, respectively, to the sulfate over North America. In addition, South
407 Asia contribution to sulfate in East Asia, and East Asia contribution to sulfate in RBU
408 and Europe also significantly increase for column burden compared to near-surface
409 concentrations.

410 Figure 5 shows local contributions (i.e., from sources within the tagged regions)
411 to near-surface sulfate concentrations. Averaged over individual tagged regions,
412 contributions from local sources dominate (i.e., local contributions > 50%) over North
413 America, South America, Europe, Southern Africa, the Middle East, South Asia, and
414 East Asia. Imports dominate near-surface sulfate concentrations (i.e., local
415 contributions < 50%) over the rest of tagged land regions. Within each tagged region,

416 whether local source or import dominates depends on specific locations. For instance,
417 over Eastern China, because of high anthropogenic emissions, local contribution to
418 sulfate concentration is larger than 80%, whereas import from other source regions
419 dominates sulfate over the less economically developed Western China. The same
420 difference can be found between Eastern and Western U.S. of the tagged North
421 America. Over oceans in the Southern Hemisphere, natural sources of DMS
422 contribute the largest to local sulfate concentrations (Fig. 3), whereas long-range
423 transport dominates over the North Pacific in DJF and MAM.

424 Figure 6 presents the aggregate, seasonal relative source contributions to area
425 weighted average near-surface sulfate concentrations over land/ocean in the
426 Northern/Southern Hemisphere. Over land in the Northern Hemisphere, sulfate
427 concentration is mainly attributed to sources from East Asia, South Asia, the Middle
428 East, ROW and volcanic eruption, with relative contributions of 22–29%, 9–16%, 8–
429 14%, 9–11%, and 6–13%, respectively. Over ocean in the Northern Hemisphere,
430 although contribution from ROW, volcanic SO₂ and DMS increase dramatically
431 compared to land, contributions from East Asia and South Asia do not have a large
432 decrease, especially in DJF, MAM and SON when aerosol outflow from Asia is strong
433 (Yu et al., 2012; Yang et al., 2015). Over land in the Southern Hemisphere, mean
434 sulfate concentration is dominated by sources in Southern Africa, having a
435 contribution of 33–43%, followed by 13–25% from South America. Emissions from
436 DMS drive sulfate over ocean in the Southern Hemisphere in all seasons contributing
437 27–63% of sulfate, although Southern Africa contributes 20% of sulfate in JJA.

438 Figure 7 shows seasonal and annual mean regional concentration efficiencies of
439 sulfate from the tagged source regions/sectors, defined as the local contribution to
440 near-surface sulfate concentration divided by the corresponding sulfur emissions
441 from that region. (Table S3 provides the numeric values.) The regional concentration
442 efficiency represents the relationship between local contribution to sulfate
443 concentration and local emission, which is influenced by many factors, such as local
444 production of sulfate from the emitted SO₂, aerosol removal and export. Note that, the
445 receptor region of ROW is used to calculate efficiencies of the VOL and DMS source
446 sectors, which leads to low biases in efficiencies. The efficiencies over the Middle
447 East show high values in almost all seasons due to dry atmospheric conditions
448 favoring long aerosol lifetime, especially in DJF and SON (e.g., Wang et al., 2014;
449 Stjern et al., 2016). The efficiencies are also high over South Asia in DJF and SON,
450 but low in MAM and JJA due to strong wet removal during the South Asian summer
451 monsoon season. North Africa and Central Asia also show high efficiencies resulted
452 from less precipitation. Although East Asia does not have much precipitation in DJF,
453 the efficiency is low because a large amount of sulfate is transported outside East
454 Asia. It suggests that the lifetime of aerosols, mainly driven by wet deposition,
455 together with regional export, is important in determining the local contribution to
456 near-surface concentrations or regional air quality.

457

458 **5. Source attribution of direct and indirect radiative forcing of sulfate**

459 The modeled global annual mean sulfate total DRF here is -0.42 W m^{-2} , with –
460 0.31 W m^{-2} contributed by anthropogenic sulfate and -0.11 W m^{-2} contributed by
461 natural sulfate (e.g., relative to a state with no natural emissions). The DRF of
462 anthropogenic sulfate is $-0.4 \pm 0.2 \text{ W m}^{-2}$ provided in the Fifth Assessment Report of
463 the Intergovernmental Panel on Climate Change (IPCC, 2013). Note that, the DRF of
464 anthropogenic sulfate calculated here is total anthropogenic sulfate, whereas values
465 from IPCC represent changes in anthropogenic sulfate between 1750 and
466 present-day conditions, although this difference is small since 1750 SO_2 emissions
467 are less than 1% of 2010 emissions. Spatial distributions of sulfate DRF, originating
468 from the individual sixteen sources are shown in Fig. S9. The spatial distributions and
469 global contributions of sulfate DRF are similar to those of sulfate column burden (Fig.
470 S7), except that contribution of DMS to global sulfate DRF (18%) is much larger
471 relative to its global column burden (11%). It is because DMS-produced sulfate
472 burden is mostly located between 30°S – 30°N (Fig. S7), where insolation is much
473 stronger than at mid- and high latitudes, leading to stronger DRF over these regions.
474 East Asia is the second largest contributor to global sulfate DRF, contributing 16% of
475 global sulfate DRF, followed by 13% from ROW and 11% from South Asia.

476 Figure 8 shows seasonal and zonal mean DRF of sulfate originating from the
477 tagged regions/sectors and the global total. The meridional distribution of DRF is
478 jointly determined by many factors, e.g. sulfate loading, the insolation, cloud cover,
479 and surface albedo. The total sulfate DRF shows a seasonal pattern that has the
480 maximum DRF over 0° – 10°N in DJF and over 30° – 40°N in JJA, with values between

481 -0.9 and -1.3 W m^{-2} . The global and annual average sulfate DRF has a contribution
482 of -0.074 W m^{-2} from DMS, -0.068 W m^{-2} from East Asia, -0.054 W m^{-2} from ROW, $-$
483 0.047 W m^{-2} from South Asia, -0.035 W m^{-2} from VOL, -0.031 W m^{-2} from the Middle
484 East, -0.023 W m^{-2} from Southern Africa, -0.018 W m^{-2} from Europe, -0.016 W m^{-2}
485 from North America, and a total of -0.057 W m^{-2} from all other regions (Table S4).

486 Figure 9 shows seasonal fractional contributions to sulfate DRF in different
487 latitudinal bands. Over the Southern Hemisphere tropics (30°S –Equator), mid-
488 (60°S – 30°S) and high (90°S – 60°S) latitudes, DMS has the largest contribution to
489 sulfate DRF in all seasons, with contribution about 17–84%. Sources from Southern
490 Africa contribute about 11–20% of sulfate DRF over the Southern Hemisphere tropic
491 and mid-latitudes, followed by about 10% from South America and ROW. Sources
492 from East Asia account for 6–19% of sulfate DRF over the Southern Hemisphere high
493 latitudes. In the Northern Hemisphere, influence from DMS becomes much weaker,
494 but still substantial. Over the Northern Hemisphere tropics, East Asia, South Asia,
495 ROW, and DMS exert equal contributions of 10–20%. East Asia has the largest
496 contribution of 20–30% over the Northern Hemisphere mid- and high-latitudes,
497 followed by South Asia and ROW.

498 Sulfate incremental IRF is estimated by using an additional simulation in which
499 sulfur emissions are reduced by 20% for all regions and sectors. The difference in
500 cloud radiative forcing between the control simulation and this second simulation gives
501 the sulfate incremental IRF of the last 20% of sulfur emissions. Regional incremental
502 IRF contributions are calculated by scaling the total incremental IRF in a grid column

503 by regional source contributions to sulfate mass concentration reduction averaged
504 from the surface layer to 850 hPa, which is the approximate altitude of cloud base.

505 Figure 10 shows regional contributions to sulfate incremental IRF from the tagged
506 source regions/sectors. The sulfate incremental IRF is -0.44 W m^{-2} . The spatial
507 pattern is consistent with that of stratiform clouds since the model only considers
508 aerosol effects on stratiform cloud. The strong negative forcing is mainly over oceans.
509 All source contributions to sulfate incremental IRF from the fourteen tagged source
510 regions are less than -0.04 W m^{-2} , probably due to the polluted conditions over or near
511 land. Particles originating from North America, South America, Southern Africa, and
512 East Asia are also transported to ocean regions, leading to a strong negative forcing
513 there. DMS has the largest contribution, explaining -0.23 W m^{-2} of the global sulfate
514 incremental IRF, because complex cloud adjustments are likely to respond sensitively
515 to small changes in aerosol under clean conditions (Rosenfeld et al., 2014), followed
516 by -0.06 W m^{-2} from volcanic emissions. Note that the regional contribution to
517 incremental IRF is simply calculated by decomposing the total incremental IRF with
518 mass concentrations based on two simulations without and with the reduction in
519 emissions. This assumption could introduce biases considering non-linear relationship
520 between mass concentration and IRF of sulfate.

521 To evaluate this new method for decomposing incremental IRF into different
522 source regions/sector contributions, the IRF for two regions (North America and East
523 Asia) and one sector (DMS) were calculated in a traditional manner using three
524 additional simulations in which SO_2 emissions from North America, East Asia and

525 DMS emissions were reduced by 20%, respectively. The incremental IRF calculated
526 with the two methods are compared in Fig. S10. Although the incremental IRF outside
527 the source regions obtained from the emission perturbation method is noisy, these two
528 methods show similar negative incremental IRF within and near source regions. The
529 20% DMS leads to strong negative IRF over oceans. The 20% emission from North
530 America results in negative IRF over Eastern U.S. and downwind ocean regions. The
531 20% emission in East Asia emissions produces negative IRF over the northwestern
532 Pacific. Globally, DMS, North America and East Asia contribute to $-0.230 (\pm 0.012)$, $-$
533 $0.014 (\pm 0.002)$, and $-0.028 (\pm 0.003) \text{ W m}^{-2}$, respectively, of sulfate incremental IRF
534 from the method with sulfur tagging technique, similar to $-0.248 (\pm 0.020)$, -0.018
535 (± 0.019) , and $-0.028 (\pm 0.018) \text{ W m}^{-2}$, from the individual emission-perturbation
536 simulations. The latter method has larger noise, seen in both the spatial distributions
537 and large uncertainties (standard deviation) of the incremental IRF. The three
538 emission-perturbed simulations produced similar system noise, with a magnitude of
539 $\sim 0.02 \text{ W m}^{-2}$. The incremental IRF signal is larger than the noise around the source
540 regions whereas noise masks the signal in other regions, leading to large uncertainties.
541 However, in the simulation with all source emissions reduced by 20%, the IRF signal
542 overwhelms noise almost everywhere. With the sulfur tagging technique and
543 decomposition method, the noise is also decomposed into smaller pieces which are, in
544 turn, much smaller than the decomposed incremental IRF signal.

545 Table S5 summarizes the DRF and incremental IRF of sulfate over land/ocean in
546 the Northern/Southern Hemisphere contributed by the tagged source regions/sectors.

547 Over the fourteen tagged source regions, the total anthropogenic source region
548 contribution to DRF is $-0.54/-0.18 \text{ W m}^{-2}$ over land in the Northern/Southern
549 Hemisphere, larger than $-0.48/-0.12 \text{ W m}^{-2}$ over ocean due to the larger sulfate
550 burden near sources. Anthropogenic source contributions to incremental IRF are
551 larger over ocean, with values of $-0.23/-0.13 \text{ W m}^{-2}$ compared to $-0.08/-0.10 \text{ W m}^{-2}$
552 over land in the Northern/Southern Hemisphere, because clouds are more
553 susceptible to aerosol changes in clean environment and there are more stratiform
554 clouds over ocean. For natural source sectors, their contributions are larger over
555 oceans for both DRF and incremental IRF. Over land in the Northern Hemisphere,
556 DRF is mainly driven by emissions from East Asia, South Asia, and the Middle East,
557 whereas incremental IRF is dominated by emissions from North America, RBU and
558 East Asia. The difference in major contributing regions for DRF vs. incremental IRF
559 may be due to changes in cloud susceptibility when background aerosol
560 concentrations are different. North America and RBU have more relatively clean
561 areas (Alaska, N. Canada, parts of Siberia) than South Asia and East Asia, and
562 clouds in the cleaner areas are more susceptible to the 20% emissions reductions.
563 The non-linearity in DRF is much weaker, so the high emissions from South Asia and
564 East Asia dominate DRF. Over ocean in the Northern Hemisphere, East Asia also
565 contributes the largest to DRF and it is the second largest contributor to incremental
566 IRF of sulfate following DMS. Over land in the Southern Hemisphere, emissions from
567 Southern Africa and South America control DRF, whereas incremental IRF are
568 largely attributed to sources from South America, DMS, and PAN

569 (Pacific/Australia/New Zealand). Over ocean in the Southern Hemisphere, both
570 sulfate DRF and incremental IRF are dominated by DMS emissions.

571 Figure 11 shows the seasonal and annual global DRF and incremental IRF
572 efficiencies of sulfate. (Table S6 gives values.) Global DRF efficiency of a source
573 region is defined as the global DRF of sulfate originating from the source
574 region/sector divided by the total sulfur emissions from that region/sector. The global
575 DRF efficiency treats the whole globe as a receptor region, as opposed to a specific
576 region in the regional concentration efficiency definition, considering that aerosol
577 climatic impacts are on a global scale whereas air quality impacts are more important
578 on a regional scale. As the DRF is more closely related to sulfate burden, global
579 sulfate burden efficiencies are also provided in Table S7. The global DRF efficiency
580 for total sulfur emissions is $-4.8 \text{ mW m}^{-2} (\text{Tg S yr}^{-1})^{-1}$. The Middle East, North Africa,
581 and Southern Africa present high DRF efficiencies, as a result of both long aerosol
582 lifetime and strong tropical insolation. These source regions also have high global
583 burden efficiencies.

584 The global IRF efficiency of a source region is calculated as the global
585 contribution of sulfate incremental IRF divided by the changes (i.e., 20% reduction) in
586 sulfur emissions in that region. Unlike the DRF efficiencies, IRF efficiencies are
587 higher over or near ocean regions, with a global IRF efficiency of $-5.0 \text{ mW m}^{-2} (\text{Tg S}$
588 $\text{yr}^{-1})^{-1}$ for the global total 20% of sulfur emissions. PAN and DMS have the largest IRF
589 efficiencies because PAN has a relatively clean environment compared to other
590 regions and DMS is emitted over clean oceans. Cloud properties are more

591 susceptible to aerosol perturbations in a more pristine environment. Although the
592 background aerosols in South America are not so low, sulfate originating from this
593 region has a large contribution to sulfate over oceans of the Southern Hemisphere,
594 explaining a large IRF efficiency from that region.

595 In addition to the incremental IRF and efficiency, we also calculated the
596 anthropogenic sulfate IRF and its efficiency between present-day and preindustrial
597 conditions with an additional simulation, in which anthropogenic SO₂ emissions are
598 fixed at the 1850 level, and compared these values with those from the 20% sulfur
599 emission reduction simulation in Table S8. The modeled annual and global mean
600 anthropogenic sulfate IRF here is -0.74 W m^{-2} , which is comparable to $-0.45 \pm 0.5 \text{ W}$
601 m^{-2} of IRF for total anthropogenic aerosols from IPCC (2013). The anthropogenic IRF
602 contributed from individual source regions is about 3–6 times larger than the
603 incremental IRF, in agreement with about 5 times more reduction in SO₂ emissions in
604 the preindustrial simulation than in the 20% sulfur emission reduction simulation. The
605 forcing efficiencies are roughly similar between the incremental and the
606 anthropogenic IRF, indicating a nearly linear relationship between SO₂ emission and
607 sulfate IRF, except for the Middle East and South Asia where concentrated dust and
608 its variability may strongly influence cloud properties and therefore sulfate IRF. Figure
609 S11 shows the anthropogenic sulfate IRF efficiencies that are calculated based on
610 anthropogenic IRF from the present-day and preindustrial condition simulations. The
611 values are similar to the incremental IRF efficiencies, further validating the robust
612 results from the decomposed regional IRF with the sulfur tagging technique.

613 For comparison, Table S8 also includes the incremental DRF calculated with the
614 same simulations for the incremental IRF and the standard anthropogenic DRF
615 between present-day and preindustrial conditions, as well as their efficiencies. The
616 forcing efficiencies are also similar between the incremental and the standard
617 anthropogenic DRF. The IRF and its efficiencies are much higher than those of DRF
618 for sources over or around clean oceanic regions (e.g., DMS, volcanic SO₂,
619 emissions from Australia and South America), but much lower for regions with high
620 emissions (e.g., the Middle East, South Asia).

621

622 **6. Conclusions and discussions**

623 A sulfur tagging technique is implemented in Community Atmosphere Model
624 (CAM) of the Community Earth System Model (CESM) and used in this study to
625 examine source-receptor relationships of sulfate concentrations, DRF and IRF
626 originating from sixteen regions/sectors (North America, Central America, South
627 America, Europe, North Africa, Southern Africa, the Middle East, Southeast Asia,
628 Central Asia, South Asia, East Asia, RBU, PAN, ROW, VOL, and DMS) for 2010–
629 2014. The anthropogenic emissions came from the CEDS inventory developed for
630 the CMIP6.

631 Near-surface sulfate concentrations are mostly contributed by local emissions in
632 regions with high emissions, such as Eastern U.S., Southern Africa, South Asia, and
633 Eastern China, where local source contributions exceed 80%. Over regions with

634 relatively low SO₂ emissions, the near-surface sulfate concentrations are primarily
635 attributed to non-local sources from long-range transport.

636 The source-receptor relationships have strong seasonal variations. The export of
637 sulfate from Europe contributes to 16–20% of near-surface sulfate concentrations
638 over North Africa, RBU and Central Asia in all seasons. Sulfate from the Middle East
639 is effectively transported to the surrounding receptor regions and accounts for 15–24%
640 of sulfate concentrations over North Africa, Southern Africa and Central Asia in DJF
641 and SON, and 19% over South Asia in MAM. Sources in RBU account for 21–42% of
642 sulfate concentrations over Central Asia, with a peak contribution in JJA. Northerly
643 winds over East Asia in DJF and SON associated with East Asian winter monsoon
644 transport sulfate from highly polluted Eastern China to Southeast Asia, accounting for
645 about 50% of near-surface sulfate concentrations over Southeast Asia. East Asia
646 also contributes 15% to the near-surface sulfate over RBU in JJA and 11% over North
647 America in MAM. The transport of sulfate from South Asia contributes 11–24% of
648 near-surface sulfate over Southeast Asia in DJF and MAM. Regional sulfate
649 concentration efficiencies are higher over regions with dry atmospheric conditions
650 and less export, suggesting that the lifetime of aerosols mainly driven by wet
651 deposition, together with regional export, is important in determining the regional air
652 quality.

653 The simulated global total sulfate DRF is -0.42 W m^{-2} , with -0.31 W m^{-2}
654 contributed by anthropogenic sulfate and -0.11 W m^{-2} contributed by natural sulfate.
655 DMS has the largest contribution to the global sulfate DRF, followed by East Asia,

656 ROW and South Asia. In the Southern Hemisphere, DMS contributes 17–84% to the
657 seasonal total sulfate DRF. In the Northern Hemisphere tropics, East Asia, South
658 Asia, ROW, and DMS exert similar contributions of 10–20%. East Asia has the
659 largest contribution of 20–30% over the Northern Hemisphere mid- and high-latitudes,
660 followed by South Asia and ROW.

661 Sulfate incremental IRF is estimated using an additional simulation in which sulfur
662 emissions are reduced by 20%. The difference in cloud radiative forcing between the
663 control simulation and this second simulation gives the sulfate incremental IRF of the
664 last 20% of sulfur emissions, which is -0.44 W m^{-2} globally. DMS has the largest
665 contribution, explaining -0.23 W m^{-2} of the global sulfate incremental IRF, because of
666 the clean marine background conditions, followed by -0.06 W m^{-2} from volcanic
667 emissions. The tagging method, combined with regional decomposition, provides a
668 computationally efficient method of quantifying regional IRF that has a higher signal
669 to noise as compared to regional perturbation simulations.

670 The Middle East, North Africa, and Southern Africa have high global DRF
671 efficiencies, due to both longer aerosol lifetimes (from low precipitation) and strong
672 insolation. Regions in the Southern Hemisphere with low background aerosols have
673 stronger global IRF efficiencies than those over the polluted Northern Hemisphere,
674 because cloud properties are more susceptible to aerosol perturbations in a more
675 pristine environment.

676 Note that, although simulated near-surface sulfate concentrations are in
677 agreement with observed values at the IMPROVE sites over North America and at

678 the EANET sites over part of East Asia and Southeast Asia, the model strongly
679 underestimates sulfate concentrations by –54% in China, compared to site
680 observations from the CAWNET network. Comparison of column-integrated SO₂
681 between model simulation and OMI satellite data shows a possible overestimation of
682 SO₂ in the model. The simulated SO₂ near-surface concentrations, however, are
683 underestimated by 25% compared to observations over thirteen sites in China,
684 suggesting a large bias in satellite retrievals or too much SO₂ simulated at higher
685 altitudes. The model SO₂ concentrations over downwind regions of China are
686 underestimated by 45%, indicating that the transport of SO₂ from China is probably
687 underestimated in the model. A less efficient transformation from SO₂ to sulfate could
688 also lead to the underestimation of sulfate in the model. The underestimation of sulfate
689 over China could lead to the underestimation of contributions from East Asia to remote
690 sulfate concentrations, global DRF and incremental IRF, as well as their efficiencies.

691 Table S9 compares the annual sulfate radiative forcing efficiencies simulated in
692 this study to those in previous multi-model studies (Yu et al., 2013; Bellouin et al.,
693 2016; Stjern et al., 2016). As in the previous studies, the DRF efficiency is calculated
694 as the response of global DRF to a 20% reduction in local emissions divided by the
695 20% of sulfur emissions based on two separate simulations rather than 100% of local
696 emissions in a single simulation (Table S6). The efficiencies based on the 20%
697 emission reduction are very similar to those of the 100% emission reduction,
698 indicating a nearly linear relationship between sulfate DRF and emissions. Compared
699 to Yu et al. (2013) and Stjern et al. (2016), the DRF efficiencies in this study are

700 around the lower bound for all source regions. Another multi-model intercomparison
701 study also reported a lower sulfate DRF simulated in CAM5 compared to other
702 models (Myhre et al., 2013). The difference in DRF efficiencies likely arises from
703 differences in the estimates of aerosol optical properties. With aerosol-cloud
704 interactions included, the total radiative forcing efficiencies in this study are similar to
705 the best estimates provided by Bellouin et al. (2016). The global IRF in CAM5 was
706 also found to be larger than other models in a nine-model intercomparison study,
707 which was attributed to an strong aerosol induced cloud scattering (Zelinka et al.,
708 2014).

709

710

711

712

713 *Data availability.* All the emissions datasets used in this study can be obtained from
714 <https://pcmdi.llnl.gov/projects/input4mips>. The sulfate datasets are available from
715 <http://vista.cira.colostate.edu/IMPROVE/> for IMPROVE sites, <http://www.eanet.asia>
716 for EANET sites, and <http://www.emep.int> for EMEP sites. The OMI satellite-derived
717 total column burden of SO₂ can be downloaded from
718 http://disc.sci.gsfc.nasa.gov/Aura/data-holdings/OMI/omso2e_v003.shtml. The
719 CESM model is publically available at <http://www.cesm.ucar.edu/models/cesm1.2/>.
720 Our model results can be made available through the National Energy Research
721 Scientific Computing Center (NERSC) servers upon request.

723 *Competing interests.* The authors declare that they have no conflict of interest.

724

725 *Acknowledgments.* This research was supported by the National Aeronautics and

726 Space Administration's Atmospheric Composition: Modeling and Analysis Program

727 (ACMAP), award NNH15AZ64I. We also acknowledge support from the

728 U.S. Department of Energy (DOE), Office of Science, Biological and

729 Environmental Research. The Pacific Northwest National Laboratory is

730 operated for DOE by Battelle Memorial Institute under contract

731 DE-AC05-76RLO1830. The CESM project was supported by the National Science

732 Foundation and the DOE Office of Science. The National Energy Research Scientific

733 Computing Center (NERSC) provided computational resources.

1007 **Figure 1.** (a) Tagged source regions (NAM: North America, CAM: Central America,
1008 SAM: South America, EUR: Europe, NAF: North Africa, SAF: Southern Africa, MDE:
1009 the Middle East, SEA: Southeast Asia, CAS: Central Asia, SAS: South Asia, EAS:
1010 East Asia, RBU: Russia/Belarus/Ukraine, PAN: Pacific/Australia/New Zealand and
1011 ROW: rest of the world) and (b) the respective percentage contributions to global
1012 annual mean combustion SO₂ emissions (anthropogenic + biomass burning) from the
1013 individual source regions.

1014

1015 **Figure 2.** Spatial distribution (left panel) and scatter plot (right) between the simulated
1016 and observed annual mean near-surface sulfate concentrations ($\mu\text{g m}^{-3}$) over years
1017 2010–2014. Observations are from IMPROVE (up pointing triangle), EMEP (square),
1018 EANET (down pointing triangle) for years 2010–2014, and CAWNET (circle) for years
1019 2006–2007, which are scaled to 2010–2014 based on the ratio of CEDS 2010-2014
1020 SO₂ emissions to 2006-2007 emissions over China (which is 0.92). Solid lines mark
1021 the 1:1 ratio and dashed lines mark the 1:2 and 2:1 ratio. Normalized mean bias
1022 (NMB) and correlation coefficient (R) between observation and simulation are shown
1023 on the right panel. $\text{NMB} = 100\% \times \sum(M_i - O_i) / \sum O_i$, where M_i and O_i are the
1024 modeled and observed values at site i , respectively.

1025

1026 **Figure 3.** Spatial distribution of relative contributions (%) to annual mean
1027 near-surface sulfate concentrations from each of the tagged source regions/sectors.

1028 Relative contributions to global averaged sulfate from individual source
1029 regions/sectors is shown at the bottom right of each panel.

1030

1031 **Figure 4.** Relative contributions of non-local sources to seasonal near-surface sulfate
1032 concentrations (left panels) and wind fields over 850 hPa (right panels). Arrows with
1033 numbers show contributions (%) of a source region to sulfate over a receptor region.
1034 Only relative concentrations larger than 10% are shown.

1035

1036 **Figure 5.** Relative contributions (%) of local emissions (inside the tagged regions) to
1037 near-surface sulfate concentrations. Contributions from natural source sectors are
1038 added to ROW here. Contributions less than 50% are shown in cold colors and those
1039 larger than 50% are shown in warm colors.

1040

1041 **Figure 6.** Relative contributions (%) to near-surface sulfate concentrations averaged
1042 over land and ocean of the Northern and Southern Hemisphere from emissions in the
1043 sixteen tagged source regions/sectors.

1044

1045 **Figure 7.** Seasonal and annual mean regional concentration efficiency of sulfate (μg
1046 $\text{m}^{-3} (\text{Tg S yr}^{-1})^{-1}$) of the sixteen tagged source regions/sectors. The efficiency is
1047 defined as the local contribution to near-surface sulfate concentration divided by the
1048 corresponding sulfur emissions from that region (seasonal emissions multiplied by 4).
1049 Error bars indicate 1- σ of mean values during years 2010–2014. The receptor region
1050 of ROW is used to calculate efficiency of VOL and DMS.

Figure 8. Contributions to zonal mean sulfate direct radiative forcing ($W m^{-2}$) from emissions of the tagged regions/sectors shown in colors (left Y axis) and from global total emissions shown in black (right Y axis). Only regions with maximum of zonal mean sulfate direct radiative forcing stronger than $-0.1 W m^{-2}$ are shown here.

Figure 9. Relative contributions (%) from emissions in the sixteen tagged regions/sectors to sulfate direct radiative forcing over the Southern Hemisphere high-latitudes ($90^{\circ}S-60^{\circ}S$), Southern Hemisphere mid-latitudes ($60^{\circ}S-30^{\circ}S$), Southern Hemisphere tropics ($30^{\circ}S-Equator$), Northern Hemisphere tropics ($Equator-30^{\circ}N$), Northern Hemisphere mid-latitudes ($30^{\circ}N-60^{\circ}N$), and Northern Hemisphere high-latitudes ($60^{\circ}N-90^{\circ}N$).

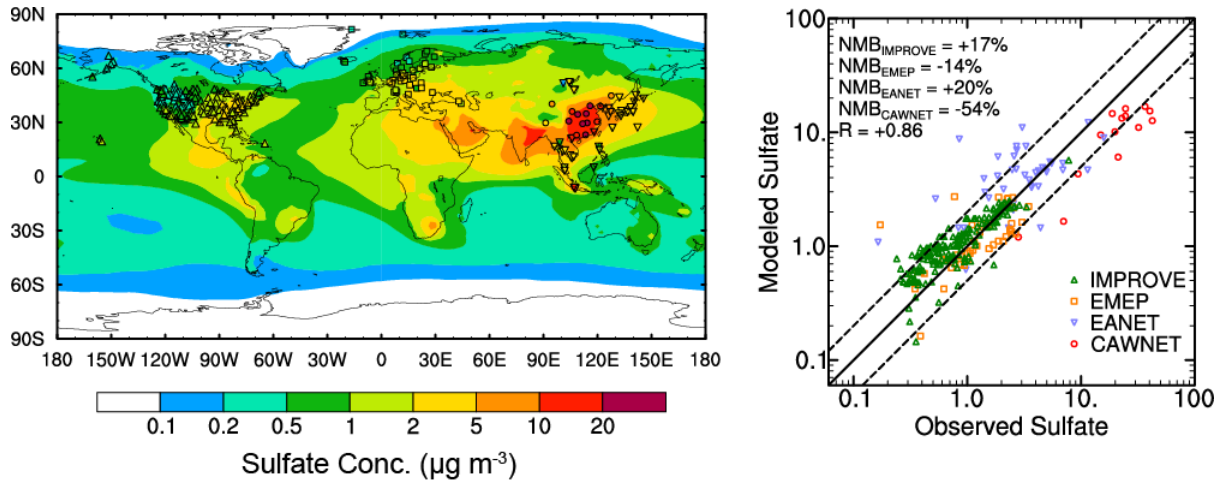

Figure 10. Spatial distribution of responses of annual mean indirect radiative forcing of sulfate (IRF, $W m^{-2}$) to a 20% reduction in sulfur emissions (standard simulation – simulation with 20% emission reduction). Regional contributions are calculated as a scaled total incremental IRF in each grid cell by the ratio of source contribution to total sulfate mass concentration reduction averaged from the surface layer to 850 hPa. Regional mean contributions to global incremental IRF of sulfate are shown at the bottom right of each panel.

1072 **Figure 11.** Seasonal and annual mean global sulfate (a) direct and (b) indirect
1073 radiative forcing efficiency ($\text{mW m}^{-2} (\text{Tg S yr}^{-1})^{-1}$) of the sixteen tagged source
1074 regions/sectors. The sulfate radiative efficiency is defined as the global sulfate
1075 radiative forcing divided by the corresponding scaled annual sulfur emission
1076 (seasonal emission multiplied by 4). Error bars indicate 1- σ of mean values during
1077 years 2010–2014.
