Abstract. Recent studies have found inland concentrations of reactive chlorine species to be higher than expected, suggesting that atmospheric chlorine chemistry is more extensive than previously thought. Chlorine radicals can interact with HO_x radicals and nitrogen oxides (NO_x) to alter the oxidative capacity of the atmosphere. They are known to rapidly oxidize a wide range of volatile organic compounds (VOC) found in the atmosphere, yet little is known about secondary organic aerosol (SOA) formation from chlorine-initiated photo-oxidation and its atmospheric implications. Environmental chamber experiments were carried out under low-NO_x conditions with isoprene and chlorine as primary VOC and oxidant sources. Upon complete isoprene consumption, observed SOA yields ranged from 8 % to 36 %, decreasing with extended photo-oxidation and SOA aging. A High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer was used to determine the molecular composition of gas-phase species using iodide-water and hydronium-water ionization. Ions consistent with isoprene-derived epoxydiol (IEPOX) and other common OH-isoprene oxidation products were observed, evident of secondary OH production and resulting chemistry from Cl-initiated reactions.

1 Introduction

Studies have shown that long-term exposure to fine particulate matter (PM), also known as aerosol, is linked to increases in mortality and cardiorespiratory diseases (Dockery et al., 1993; Pope et al., 2006). Short term exposure to aerosol could also induce stress response and cytotoxicity in cells (de Bruijne et al., 2009; Ebersviller et al., 2012; Hawley et al., 2014). Equilibrium partitioning of oxidized, semi-volatile organic compounds (Pankow, 1994), collectively referred to as secondary organic aerosol (SOA), contributes 20–90 % to the global fine aerosol budget (Jimenez et al., 2009; Kanakidou et al., 2005). The majority of SOA originates from oxidation of biogenic volatile organic compounds (BVOCs), which account for ~90% of annual non-methane hydrocarbon emissions (Goldstein and Galbally, 2007; Guenther et al., 2012), among which isoprene has the highest emission rate at ~600 Tg/yr (Guenther et al., 2006). Isoprene SOA formation initiated by ozone, hydroxyl, and nitrate radicals has been studied extensively and is estimated to account for 6–30 Tg/yr of the global aerosol budget (Brégonzio-Rozier et al., 2015; Claeys, 2004; Guenther et al., 2006; Kroll et al., 2006; Lin et al., 2012; Surratt et al., 2006, 2010; Zhao et al., 2015). Meanwhile, little is known about SOA from chlorine-initiated oxidation of isoprene.

20
25

The concentration of chlorine radicals is approximately one order of magnitude lower compared to OH radicals under ambient conditions (Faxon and Allen, 2013), but due to its high reactivity towards numerous VOCs, chlorine radicals could contribute significantly as a primary oxidant under certain circumstances (Riedel et al., 2012; Riva et al., 2015; Young et al., 2014). Hydrogen-abstraction and chlorine-addition to alkenes produce peroxy and chloroperoxy radicals, respectively, that could lead to formation of semi-volatile oxidized products. Studies have shown that chlorine-initiated oxidation of alpha-pinene (Cai and Griffin, 2006; Ofner et al., 2013), toluene (Cai et al., 2008; Huang et al., 2014; Karlsson et al., 2001), and polycyclic aromatic hydrocarbons (PAHs, Riva et al., 2015) lead to SOA formation, with close to unity SOA yield reported for select PAHs (Riva et al., 2015). Reactive chlorine species could also enhance OH-radical propagation (Young et al., 2014), nocturnal NO_x recycling (Riedel et al., 2012; Thornton et al., 2010), and ozone production (Tanaka et al., 2003), further increasing the oxidative capacity of the atmosphere. Recent studies show that air quality models severely under-predict the abundance of inland reactive chlorine species (Faxon and Allen, 2013; Faxon et al., 2015; Riedel et al., 2012; Thornton et al., 2010), suggesting that chlorine chemistry may be more extensive than previously thought.

Chlorine-initiated oxidation of isoprene could either proceed via the dominant (85 %) chlorine addition pathway, much like OH-isoprene reactions, or proceed via a minor (15 %) hydrogen-abstraction pathway (Fantechi et al., 1998; Lei and Zhang, 2000; Nordmeyer et al., 1997; Orlando et al., 2003). Major gas-phase products include methyl vinyl ketone (MVK), methacrolein (MACR), chloroacetone, chloroacetaldehyde, hydrochloric acid, and isomers of 3-methyl-3-butene-2-one (CMBO), a unique tracer for atmospheric chlorine chemistry (Nordmeyer et al., 1997; Riemer et al., 2008; Tanaka et al., 2003). The rate constant of the isoprene-chlorine reaction at 25°C ($2.64\text{--}5.50 \times 10^{-10}$ molecules⁻¹ cm³) (Fantechi et al., 1998; Orlando et al., 2003; Ragains and FinlaysonPitts, 1997) is much faster than the rate constant of the isoprene-OH reaction (1.00×10^{-10} molecules⁻¹ cm³) (Atkinson and Arey, 2003), suggesting that isoprene-chlorine chemistry could compete with isoprene-OH chemistry under certain conditions. Moreover, reactions between chlorine and isoprene or isoprene-derived SOA could serve as a reactive chlorine sink in the atmosphere, as has been proposed for reactions between chlorine and biogenic SOA (Ofner et al., 2012). To our knowledge, SOA formation from chlorine-initiated oxidation of isoprene has not been reported in literature. To address this significant knowledge gap, we conducted environmental chamber studies using chlorine radicals as the primary oxidant source for isoprene oxidation under low NO_x conditions, which could dominate in remote coastal regions. We report SOA composition, yields and select gas-phase products.

2 Methods

2.1 Environmental Chamber Experiments

Experiments were performed at 25° C under low relative humidity (RH < 10%) and low NO_x (<5 ppb) conditions in a 12 m³ temperature-controlled Teflon[®] chamber lined with UVA lights. Chamber characteristics were described elsewhere (Bean and Hildebrandt Ruiz, 2016). Temperature, RH, concentration of ozone, NO, NO₂, and NO_x were continuously monitored. The chamber was flushed with dry clean air at a flowrate exceeding 100 liters per minute (LPM) for at least 12 hours before each

experiment. Between experiments, “blank experiments” were conducted in which seed particles, ozone, and chlorine gas (Cl_2 Airgas, 106 ppm in N_2) were injected into the chamber at high concentrations and UV lights were turned on to remove any residual organics.

For each experiment, microliters of isoprene (Acros Organics, 98% stabilized) were transferred into a glass sampling tube (Kimble-Chase, 250 ml), which was then flushed with zero air into the chamber. Two Cl_2 injection methods were used: For “initial case” experiments, all Cl_2 was injected in the dark and allowed to mix with isoprene prior to photo-oxidation. For “continuous case” experiments, Cl_2 was injected continuously with UV lights on at 0.1 LPM with an additional 0.9 LPM clean air dilution flow, equivalent to ~ 0.88 ppb/min Cl_2 into the chamber. Depositional particle wall loss was constrained using dried, monomodal, and polydisperse ammonium sulfate seed particles introduced prior to photo-oxidation.

10 2.2 Instrumentation

A High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (Aerodyne Research Inc., “CIMS”) was used to measure gas-phase organic compounds via proton transfer, charge exchange, or clustering with chemical ionization (CI) reagent ions, with humidified ultra-high purity nitrogen as the carrier gas. Hydronium-water cluster ($[\text{H}_2\text{O}]_n\text{H}_3\text{O}^+$) ionization detected isoprene and select moderately oxidized species. Iodide-water cluster ($[\text{H}_2\text{O}]_n\text{I}^-$) ionization detected select highly oxidized and acidic species (Aljawhary et al., 2013; Lee et al., 2014). Detailed theory and operation of the CIMS are discussed elsewhere (Aljawhary et al., 2013; Bertram et al., 2011; Lee et al., 2014; Yatavelli et al., 2012).

An Aerosol Chemical Speciation Monitor (Aerodyne Research Inc., “ACSM”) was used to determine the bulk chemical composition of submicron, non-refractory aerosol species (Ng et al., 2011). Analytes are flash-vaporized at 600°C , ionized via electron impact ionization (EI) (Ng et al., 2011), and then measured by a quadrupole mass spectrometer. Background-corrected (“difference”) mass spectra are obtained by subtracting filtered (“closed”) from unfiltered (“open”) measurements (Ng et al., 2011). A standard fragmentation table is used to speciate difference mass spectra (Allan et al., 2004). Calibration is performed with 300 nm size-selected ammonium nitrate and ammonium sulfate aerosol to determine the response factor for particulate nitrate and the relative ionization efficiencies (RIE) for sulfate and ammonium; these values are needed to convert ion intensities to mass concentrations (Ng et al., 2011). Particle volume and size distributions were measured using a Scanning Electrical Mobility Spectrometer (Brechtel, SEMS Model 2002) consisting of a Differential Mobility Analyzer and a butanol Condensation Particle Counter. SEMS sheath and sample flowrates were set to 5 and 0.35 LPM, respectively, covering a 10–1000 nm sizing range.

2.3 Data Analysis

Suspended particles are lost to the Teflon® chamber wall over time, for which numerous correction methods have been proposed (Carter et al., 2005; Hildebrandt et al., 2009; Ng et al., 2007; Pathak et al., 2007; Pierce et al., 2008; Verheggen and Mozurkewich, 2006). Recent studies also report loss of organic vapors to Teflon surfaces (Kokkola et al., 2014; Krechmer et al., 2016; Loza et al., 2010; Matsunaga and Ziemann, 2010; Zhang et al., 2015). Assuming internal mixing of particles and

that organic vapor can condense onto suspended and wall-deposited particles alike, we corrected for particle wall loss and the loss of organic vapors onto wall-deposited particles using the organic-to-sulfate ratio (Hildebrandt et al., 2009),

$$C_{OA}(t) = \frac{C_{OA}^{sus}(t)}{C_{seed}^{sus}(t)} C_{seed}^{sus}(t = 0), \quad (1)$$

where $C_{OA}^{sus}(t)$ is the suspended organic aerosol (OA) concentration, which was zero at the start of each experiment, $C_{seed}^{sus}(t)$ is the suspended ammonium sulfate seed particle concentration, $C_{seed}^{sus}(t = 0)$ is the suspended seed particle mass concentration at the start of photo-oxidation, and $C_{OA}(t)$ is the corrected OA concentration. Note that Eq. (1) does not account for loss of organic vapors to clean Teflon surfaces, which could be significant for SVOCs (Krechmer et al., 2016).

SOA yield, Y , is calculated as,

$$Y = \frac{C_{OA}}{\Delta VOC}, \quad (2)$$

where ΔVOC is the amount of VOC consumed. Based on absorptive equilibrium partitioning theory (Odum Jay et al., 1996; Pankow, 1994), the volatility basis set (VBS) framework (Donahue et al., 2006) states that

$$Y = \xi = \sum_i \alpha_i \xi_i; C_i = \alpha_i \Delta VOC; \xi_i = \left(1 + \frac{C_i^*}{C_{OA}}\right)^{-1}; C_{OA} = \sum_i C_i \xi_i, \quad (3)$$

where C_i^* is the effective saturation concentration of the surrogate compound in VBS bin i in $\mu\text{g m}^{-3}$; α_i , C_i , ξ_i are the total yield, total mass concentration, and the condensed phase mass fraction of bin i , respectively. By rearranging Eq. (3), we can derive an expression for the minimum VOC consumption required for SOA formation (see section S1),

$$(\Delta VOC_{min})^{-1} = \sum_1^n \frac{\alpha_i}{C_i^*}, \quad (4)$$

where ΔVOC_{min} is low if low-volatility compounds dominate the aerosol phase. When aerosol volatility is low and aerosol loading is high, the condensed phase mass fraction approaches 1, where the “maximum” SOA yield (Griffin et al., 1999) according to Eq. (2) and Eq. (3) is

$$Y_{max} = \sum_1^n \alpha_i \quad (5)$$

The extent of SOA oxidation is often depicted using f_{44} and f_{43} , which represent the fractional contribution to the total organic ion signal from ion fragments at mass-to-charge (m/z) 44 (mostly CO_2^+ , a proxy for doubly-oxidized compounds) and at m/z 43 (mostly $\text{C}_2\text{H}_3\text{O}^+$, a proxy for singly-oxidized compounds), respectively (Chan et al., 2010; Chhabra et al., 2011). Based on empirical correlations, the oxygen-to-carbon ratio (O:C), the hydrogen-to-carbon ratio (H:C), and the oxidation state

of carbon (\overline{OS}_c) can be estimated from f_{44} alone as summarized in section S2 (Canagaratna et al., 2015; Donahue et al., 2012; Heald et al., 2010; Kroll et al., 2011).

High resolution mass spectra fitting of CIMS data was performed using the software Tofware V2.5.7 (Tofwerk) in Igor Pro V6.37 (Wavemetrics Inc.). CIMS sensitivity correction utilized the Active Chemical Ionization Mass Spectroscopy (ACIMS) formula (de Gouw and Warneke, 2007), normalizing all product ion signals against dominant reagent ion signals, $[\text{H}_2\text{O}]_n\text{H}_3\text{O}^+$ and $[\text{H}_2\text{O}]_n\text{I}^-$. For most experiments conducted, the reagent signals were at least five times greater than the summed product signals, equivalent to less than 10 % overcorrection by ACIMS compared to more rigorous methods such as Parallel-ACIMS, which accounts for reagent ion depletion (see section S3 for a more detailed discussion). Because the CIMS cannot distinguish between isomers and because of the lack of calibration standards, gas-phase data presented here are normalized by the maximum signals for qualitative interpretations only.

3 Results and Discussion

3.1 SOA Formation, Ageing, and Composition

Table 1 summarizes the experimental conditions and results. Figure 1 compares wall loss-corrected SOA time series from two experiments with similar precursor concentrations. In the continuous chlorine experiment (C2), isoprene gradually reacted away during chlorine injection; SOA concentration steadily increased until isoprene was depleted, at which point SOA concentration began to decay, likely due to vapor wall loss (Boyd et al., 2015; Krechmer et al., 2016) and oxidative fragmentation (Kroll et al., 2011). The initial chlorine experiment (A4) exhibited similar trends, though the initial SOA decay rate was very fast, likely due to rapid oxidation and fragmentation of reaction products, and loss of early generation low-volatility products that are especially susceptible towards vapor wall loss effects (Boyd et al., 2015). It should be noted that little SOA formation delay was observed in all experiments. ΔVOC_{min} from Eq. (4) is therefore small, suggesting that the initial oxidation products responsible for SOA formation have very low volatility. Prompt SOA formation was also observed in previous work for chlorine-initiated oxidation of α -pinene (Ofner et al., 2013), as well as for chlorine-initiated homogenous nucleation of toluene SOA (Huang et al., 2012). Formation of low volatility early generation products may be a common feature of chlorine-initiated oxidation. Outside of the initial period, some vapor wall loss was observed, although oxidative fragmentation appeared to be the main cause of SOA mass decrease (see section S2 and Fig. S1).

Figure 2 shows that SOA oxidation state, represented by f_{44} , depended on the initial isoprene concentration and was unaffected by the oxidant injection method. Because isoprene is more reactive towards chlorine radicals than its oxidation products, such as MVK and MACR (Orlando et al., 2003), isoprene could scavenge radicals and delay SOA aging. Additionally, increased OA mass loading could absorb less oxidized and more volatile compounds into the particle-phase, lowering the observed SOA oxidation state at higher initial isoprene concentrations. Estimated \overline{OS}_c of chlorine-isoprene SOA increased from -0.5 to over 1 during experiment C1, characteristic of the evolution of semi-volatile oxygenated OA (SV-OOA) to low-volatility oxygenated OA (LV-OOA) (Kroll et al., 2011). Oxidation of chlorine-isoprene SOA formed under low NO_x

follows a similar trajectory as OH-isoprene SOA formed under higher NO_x , which is considerably more oxidized than OH-isoprene SOA formed under low NO_x (Chhabra et al., 2011), as shown in Figure 3. The oxidizing capacity of chlorine radicals has also been demonstrated for select biogenic SOA derived from α -pinene, catechol, and guaiacol, where halogenation led to significant SOA aging, formation of high molecular weight compounds, and particle growth (Ofner et al., 2012). High reactivity of chlorine radicals towards isoprene and its reaction products meant that extensive SOA processing could be easily achieved within laboratory timescales.

3.2 Particulate Organic Chloride

Chlorine addition to the double bond is the dominant (~85%) isoprene-chlorine reaction pathway (Fan and Zhang, 2004; Ragains and FinlaysonPitts, 1997). Formation of semi-volatile and low-volatility chlorinated organic compounds could be expected, but quantification proved to be difficult. As shown in Fig. 4 for Exp. H1, significant particulate chloride formation (over 9 % of total SOA mass) was initially observed, which then decreased to near background levels. In other experiments, particulate chloride concentrations were near the detection limit. The low measured chloride concentration was likely due to incomplete vaporization of chlorinated compounds during the sample (“open”) period, resulting in particulate matter vaporization during the filter (“closed”) period and overestimation of background signals. Furthermore, our analysis shows that while the difference signal of a fast-desorbing chloride ion fragment (HCl^+) correlates well with OA, the difference signal of a slow-desorbing ion fragment (Cl^+) anti-correlates with OA (Fig. S7). The background Cl^+ signal was consistently higher than the sample Cl^+ signal, except when the sample chloride concentration increased significantly faster than background, as was the case for Exp. H1, a high-concentration experiment. Our results show that the particulate chloride observed was likely organic chloride. The presence of organic chloride aerosol has been observed previously in SOA from chlorine-initiated oxidation of α -pinene (Ofner et al., 2013), in SOA which was post processed by halogenation (Ofner et al., 2012), as well as in new particle formation from 1,8-cineol and limonene over simulated salt lakes (Kamilli et al., 2015) using ion cyclotron-Fourier transform/mass spectroscopy. To date, this is the only reported study of organic chloride measurement using an ACSM. A more detailed discussion of organic chloride detection with the ACSM can be found in section S4.

Low abundance has been cited as the reason for highly variable measurements of ambient chloride using ACSM and similar instruments (Crenn et al., 2015). Overall, our results indicate that the standard operating procedure of the ACSM and similar instrumentation may systematically underestimate chloride concentration. To better quantify chloride, the filtered measurement period could be extended to better capture the true background. Higher vaporizer temperatures could be applied to desorb low-volatility species more efficiently, but doing so could also change the fragmentation profile. Another idea would be to only use fast-desorbing chloride (HCl^+ ions) for quantification: For SOA from chlorine-initiated oxidation of isoprene under low NO_x , the average (HCl^+)-to-organics ratio was 0.072 ± 0.009 (Fig. S8).

3.3 SOA Yield

It is customary to present SOA yield as a function of OA loading. From Eq. (2), when the VOC precursor has been depleted, all subsequent yield Y varies linearly with C_{OA} along a slope of $(\Delta VOC_0)^{-1}$, the inverse of the initial VOC concentration. Post VOC depletion, SOA mass may further increase as multi-generation oxidation products partition to the particle phase, but SOA mass will eventually decrease due to fragmentation (Kroll et al., 2011). In theory, all VOC-oxidant mixtures whose ΔVOC_{min} is less than VOC_0 eventually fall somewhere on the same, pre-defined yield “line” with slope $(\Delta VOC_0)^{-1}$, and will converge (to Cartesian origin) over time as fragmentation becomes dominant. This pre-defined yield curve is thus non-unique and depends only on VOC_0 . Incorporating data collected after VOC depletion, whether from the same experiment or different experiments with similar initial VOC_0 values, biases the VBS fitting parameters towards the pre-defined yield curve (see section S5). Therefore, 1-dimensional VBS fitting is not sufficient to describe SOA formation and oxidation post VOC depletion, as numerous studies have also pointed out (Kroll et al., 2007; Liu et al., 2016; Xu et al., 2014). A two-dimensional model would be more appropriate in these cases (Chuang and Donahue, 2016; Donahue et al., 2012; Murphy et al., 2012).

Considering the different oxidation conditions examined in this study, varying initial isoprene concentration, chlorine concentration, and duration of oxidation, we did not perform 1-D VBS fitting on the collective dataset. Instead, the highest observed SOA yields from each experiment are reported in Table 1 and compared with literature values (Brégonzio-Rozier et al., 2015; Koo et al., 2014; Liu et al., 2016; Xu et al., 2014) in Fig. 5. Maximum SOA yields were lower for continuous cases, likely because there was less suspended absorbing mass to retain initial low-volatility products or to compete with vapor wall loss. It also took longer for continuous cases to reach maximum SOA concentrations, as shown in Fig. 1; the effects of vapor wall loss and oxidative fragmentation seemed to be more pronounced. Highest SOA yields observed for initial cases (A2–A5) were on average 23.7 ± 3.5 %. For continuous cases (C1–C4), the average was 9.5 ± 1.3 %, similar to yields reported for OH-oxidation by recent publications (Liu et al., 2016; Xu et al., 2014). Recall that the f_{44} vs f_{43} patterns observed were also similar for chlorine-isoprene and OH-isoprene SOA, as shown in Fig. 3. This suggests that OH- and chlorine-initiated oxidation of isoprene may result in SOA of similar bulk vapor pressure and oxidation state. This is also suggested by gas-phase measurements as explained below.

3.4 Gas-phase products: Overlaps with OH chemistry

Using $(H_2O)_nH_3O^+$ CIMS, we observed ions consistent with isoprene [$C_5H_8^+$ and $(C_5H_8)H^+$], methacrolein (MACR)/methyl vinyl ketone (MVK) [$(C_4H_6O)H^+$], isomers of 3-methyl-3-butene-2-one (“CMBO”) [$(C_5H_7OCl)H^+$], chloroacetone [$(C_3H_5OCl)H^+$], and other gas-phase oxidation products, as shown in Fig. 6. CMBO and MVK/MACR were among the earliest oxidation products, which were likely further oxidized to produce SOA, as shown in Figure 6a. MVK and MACR are also key intermediary products in OH-isoprene reactions from $NO + RO_2$ and $RO_2 + RO_2$ reaction pathways (Kroll et al., 2006), where MACR is a known SOA precursor (Brégonzio-Rozier et al., 2015; Xu et al., 2014), which could contribute to some similarities between OH-isoprene and chlorine-isoprene SOA. Multiple generations of chlorinated C_5 compounds were also observed in

the gas-phase, as shown in Fig. 6a and 7a, possibly from continued oxidation of CMBO and chlorination of 2-methyl-3-buten-2-ol (MBO), which further demonstrates that semi-volatile and low volatility organic chlorides should be present. CMBO has long been identified as a unique gas-phase marker for isoprene-chlorine oxidation (Nordmeyer et al., 1997; Riemer et al., 2008; Tanaka et al., 2003). Degradation of CMBO by OH is implemented in some air quality models, though only with inferred
5 reaction rates (Tanaka and Allen, 2001). The degradation of CMBO and its role as a potential SOA precursor could have important implications for estimating atmospheric chlorine activity and warrant future investigation.

The formation of CMBO also produces HO₂ hydroperoxy radicals (Orlando et al., 2003; Ragains and FinlaysonPitts, 1997), serving as a source of secondary OH radicals. Other unidentified HO_x production pathways could also be present. Evidence of secondary OH radical production has been reported for NO₃-oxidation of isoprene (Kwan et al., 2012; Schwantes et al., 2015),
10 for chlorine-initiated oxidation of methylnaphthalenes and naphthalene under low-NO_x (Riva et al., 2015; Wang et al., 2005) and for chlorine-initiated oxidation of toluene under high NO_x (Huang et al., 2012). Figure 7a shows the accumulation of ClOH observed using (H₂O)I⁻ CIMS during the SOA growth period, where HO_x radicals produced from chlorine-isoprene oxidation could react with excess chlorine. Production of OH is also possible from reactions between NO and HO₂ radicals, which would be more pronounced under high NO_x conditions. No NO_x was added to our experiments, and measured concentrations were
15 below 5 ppb, mostly in the form of NO₂. Because isoprene is not detected using (H₂O)I⁻ CIMS, we use the SOA trend as a common reference. It can be seen in Fig. 1 and 6a that isoprene depletion roughly coincides with the SOA concentration peak. This explains the reversal from ClOH production to ClOH decay following the SOA concentration peak shown in Fig. 7a, when HO_x radical production from isoprene-chlorine oxidation (e.g. formation of CMBO) ceased due to isoprene depletion. Accumulated ClOH was then gradually photolyzed under UV. In the absence of a primary oxidant source, such as when
20 chlorine injection stopped in Exp. C3, ClOH could provide residual OH and chlorine radicals under UV, as shown in Fig. 7a. Under dark, dry, and low-NO_x conditions, ClOH remains stable as a temporary radical reservoir, as shown in Fig. 7a during the period when UV lights were turned off.

Secondary OH chemistry may have also contributed to SOA formation. Ions consistent with isoprene-derived hydroxyl hydroperoxides (ISOPOOH) or isoprene-derived epoxydiols (IEPOX) were observed in both CIMS modes, as shown in Fig.
25 6b and 7b. Reactive uptake and oxidation of IEPOX has been reported to contribute significantly to SOA mass during isoprene OH-oxidation (Bates et al., 2014; Paulot et al., 2009; Surratt et al., 2010), especially under acidic or humid conditions (Lewandowski et al., 2015; Nguyen et al., 2014). Figure 6b shows that (C₅H₁₀O₃)H⁺ ions correlated well with SOA growth. However, there are several ways to produce (C₅H₁₀O₃)H⁺ ions in addition to direct protonation, such as clustering or ligand exchange between C₅H₈O₂ (e.g. methyl methacrylate) and (H₂O)_nH₃O⁺ reagent ions, as well as fragmentation of
30 (C₅H₁₁O₃Cl)H⁺ product ions. As seen in Fig. 6b, the qualitative (C₅H₁₀O₃)H⁺ trend is similar to that of both (C₅H₈O₂)H⁺ and (C₅H₁₁O₃Cl)H⁺. Furthermore, ions that would be consistent with IEPOX-oxidation products, such as (C₅H₈O₃)H⁺ were observed to precede the formation of (C₅H₁₀O₃)H⁺. In contrast, (H₂O)I⁻ CIMS measurements show distinct trends for C₅H₁₀O₃ (detected as [(C₅H₁₀O₃)I⁻]) and C₅H₈O₂ (detected as [(C₅H₈O₂)I⁻]) in Fig. 7b. While (C₅H₈O₂)I⁻ correlated well with SOA growth and decay, as (C₅H₈O₂)H⁺ and (C₅H₁₀O₃)H⁺ did in Fig. 6a, (C₅H₁₀O₃)I⁻ resembled an intermediary species and a SOA

precursor, consistent with the role of IEPOX during OH-oxidation of isoprene. This suggests that IEPOX was observed only with (H₂O)⁺ CIMS while its oxidation products were observed by both (H₂O)_nH₃O⁺ and (H₂O)⁺ CIMS. Without any information on the chemical structure, it is also possible that (C₅H₁₀O₃)⁺ is the fragment of some unidentified parent ion(s) or that it is an IEPOX isomer produced from non-OH-reaction pathways. Moreover, photooxidative degradation of chlorinated organic compounds could produce products that resemble OH-oxidation products like C₅H₁₀O₃. A similar observation has been reported for chlorine-initiation oxidation of α -pinene, where the SOA appeared less like halogenated organic aerosols as oxidation continued (Ofner et al., 2013). Regardless, it is evident that SOA formation from chlorine-initiated and OH-initiated oxidation of isoprene proceeds via multi-generational oxidation chemistries involving similar, if not identical, key gas-phase products.

10 4 Conclusions

Chlorine-initiated oxidation of isoprene under low NO_x was investigated inside an environmental chamber. Chlorine was injected either in bulk or continuously in low amounts to simulate fast and slow oxidation conditions; prompt SOA formation was observed in both cases, indicative of low volatility initial product formation. Average wall loss-corrected SOA yield was 9.5 ± 1.3 % for continuous chlorine injection experiments and 23.7 ± 3.5 % for initial injection experiments; the differences resulted from loss of initial low volatility products and organic vapor to the chamber wall, and from oxidative fragmentation of SOA. 1-D VBS fitting should not include yield data collected post VOC depletion. The effects of SOA aging must be described explicitly and separately from initial SOA formation.

The extent of SOA oxidation was similar to that of SOA formed from OH-oxidation of isoprene under high NO_x reported in the literature. Chloride fragments at *m/z* 35 were found to desorb slowly and to interfere with chloride quantification using standard operating and data analysis procedures. We propose alternative methods for improved organic chloride quantification including extended filter sampling and the use of “fast” desorbing chloride fragments (at *m/z* 36) for quantifying chloride, which accounted for approximately 6.7 % of total SOA mass in these experiments. Measurements by HR-ToF-CIMS show evidence of chlorine-initiated secondary OH chemistry and continued oxidation of gas-phase products by chlorine and OH radicals.

SOA formation from chlorine-initiated oxidation of isoprene is reported for the first time. The high isoprene-chlorine SOA yields suggest that, despite comparatively low ambient abundance, chlorine radicals could have a notable contribution to overall SOA formation. The chlorine-addition dominated oxidation pathway, presence of particulate chloride, and difficulties associated with particulate chloride quantification suggest that the prevalence of particulate organic chloride in the ambient atmosphere is likely underestimated. Similarities between chlorine-isoprene and OH-isoprene oxidation products suggest that air quality models may be able to lump the treatment of SOA produced from chlorine- and OH- initiated oxidation of isoprene.

Table 1. Summary of Experimental Conditions and Results

Exp. ^a	Isoprene (ppb) ^b	Chlorine (ppb) ^c	VOC:Cl ₂	Cl ₂ Inj. ^d	Ini Seed SA ($\mu\text{m}^2 \text{cm}^{-3}$) ^e	Max OA ($\mu\text{g m}^{-3}$) ^f	Yield
A1	24	40	0.59	Ini	1510	15	0.230
A2	40	88	0.45	Ini	905	32	0.289
A3	82	115	0.71	Ini	811	47	0.207
A4	120	177	0.68	Ini	1328	84	0.253
A5	160	231	0.69	Ini	1769	91	0.205
C1	40	94	0.42	Cont	947	10	0.092
C2	120	180	0.67	Cont	881	37	0.111
C3	240	272	0.88	Cont	774	64	0.096
C4	300	246	1.22	Cont	1431	67	0.080
C5 ^g	72	122	0.59	Cont	N/A	N/A	N/A
H1	180	359	0.50	Ini	775	180	0.360
H2 ^h	244	681	0.48	Ini	1047	N/A	N/A

^a“A”: Initial chlorine injection experiments. “C”: Continuous chlorine injection experiments. “H”: High aerosol loading ($>100 \mu\text{g m}^{-3}$) initial chlorine injection experiments. Q-ACSM scan speed for Exp. H1 (500 ms amu^{-1}) was different from other experiments (200 ms amu^{-1})

^bInitial isoprene concentration

5 ^c Amount of chlorine injected initially (for A1–A5 and H1–H2) or cumulative chlorine injected (for C1–C5)

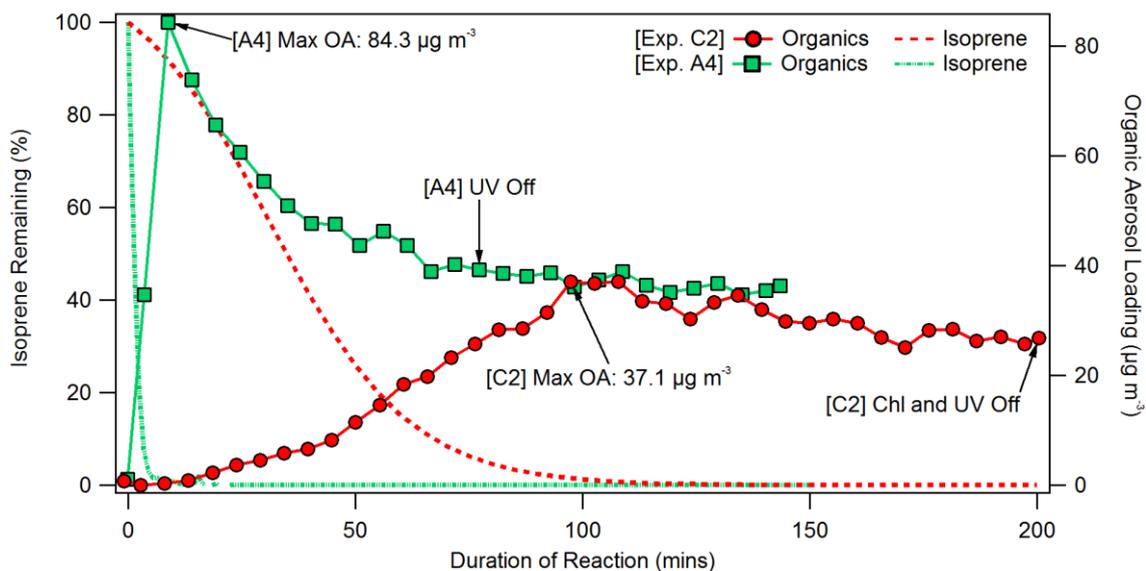

^dChlorine injection method. “Ini” for initial injection; “Cont” for continuous chlorine injection

^eTotal initial surface area of ammonium sulfate seed aerosol

^fHighest, particle wall-loss-corrected OA concentration observed

^gNo SEMS data available

10 ^h UV was turned off at T = 5 mins, see section S4

5 **Figure 1:** Comparison of SOA formation during continuous (C2) and initial (A4) chlorine injection experiments with similar precursor concentrations. SOA concentration is wall-loss corrected and averaged over five-minute intervals. Isoprene concentration is tracked using $[\text{H}_2\text{O}]_n\text{H}_3\text{O}^+$ CIMS and averaged over one-minute intervals.

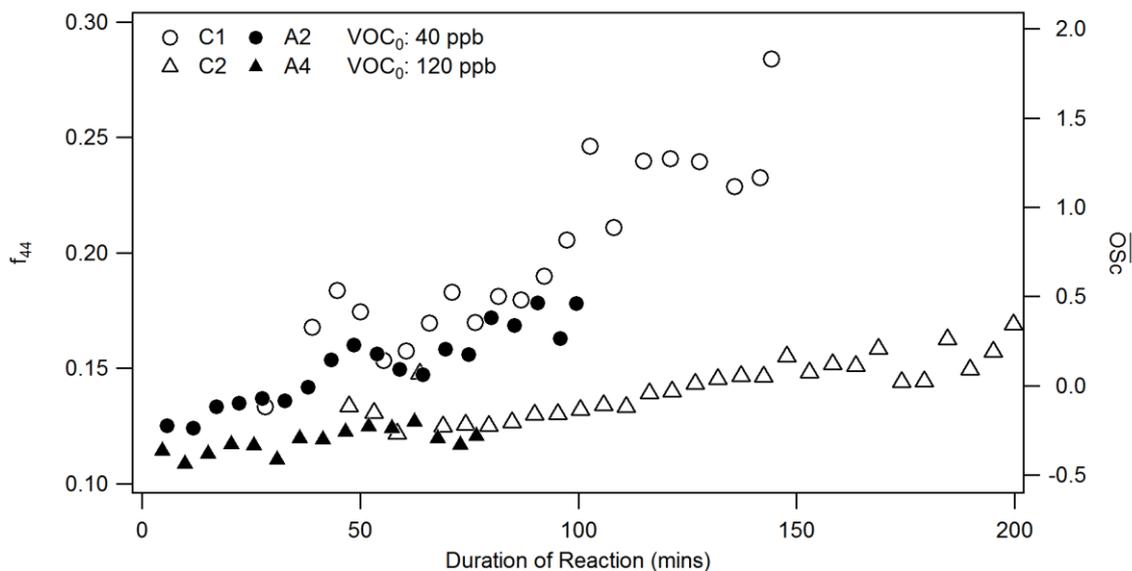

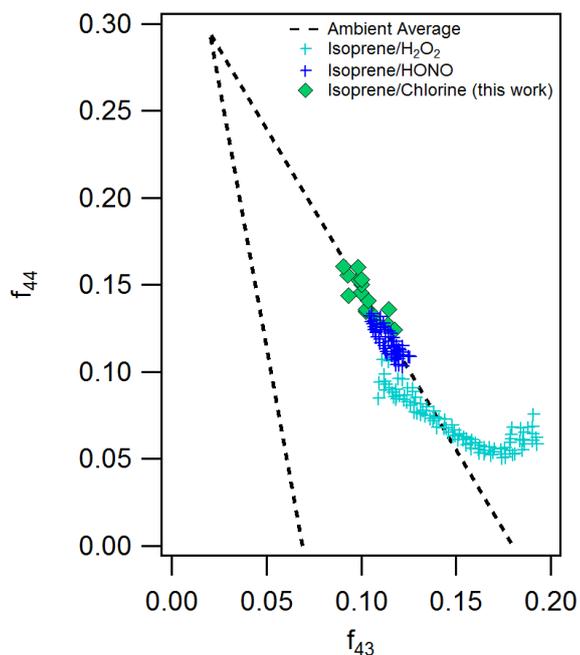

Figure 2: Comparison of SOA aging between two pairs (C1 and A2; C2 and A4) of initial and continuous chlorine injection experiments. The trend of f_{44} is consistent for each pair, regardless of chlorine injection method used. Higher initial isoprene concentration resulted in less oxidized organic aerosol (lower f_{44}). \overline{OS}_c is estimated based on f_{44} (see section S2).

5 **Figure 3:** Oxidation state of SOA generated from chlorine-initiated oxidation (Exp. C3, five-minute averages) compared to OH-oxidation of isoprene under low- and high-NO_x (Chhabra et al., 2011). Area enclosed by the dashed lines represent typical ambient OA measurements (Ng et al., 2010).

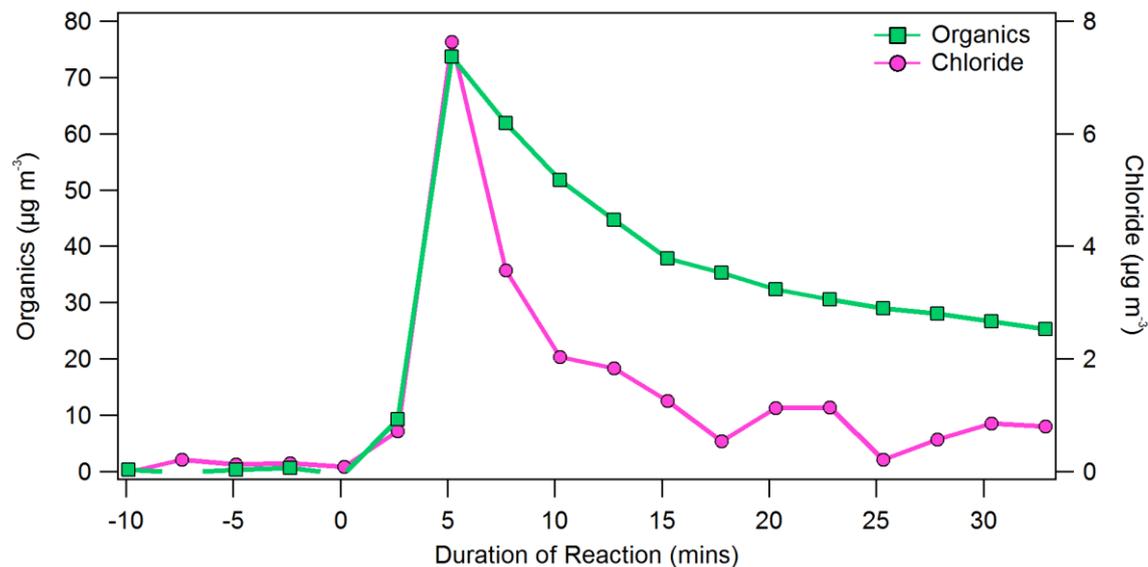

Figure 4: The raw organics and chloride measurements for Exp. H1. UV was turned on at $T = 0$. Apparent chloride concentration rapidly decreased to near-background levels while significant suspended OA mass remained. This rapid decrease is likely a measurement artifact due to build-up of chloride on the vaporizer surface, see section 3.2 and S4.

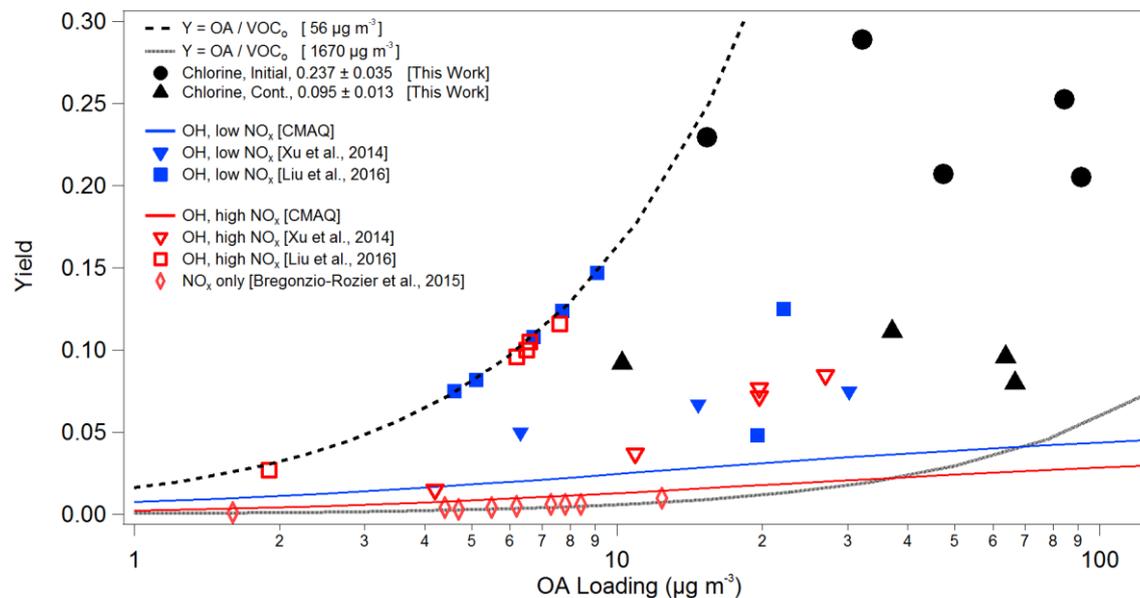

Figure 5: Comparison of observed isoprene-chlorine SOA yield with recent literature values (Brégonzio-Rozier et al., 2015; Liu et al., 2016; Xu et al., 2014). Dashed lines illustrate the concept of a “pre-defined” yield curve as discussed in the text. The yield used in CMAQ was reproduced using cited VBS parameters (Koo et al., 2014).

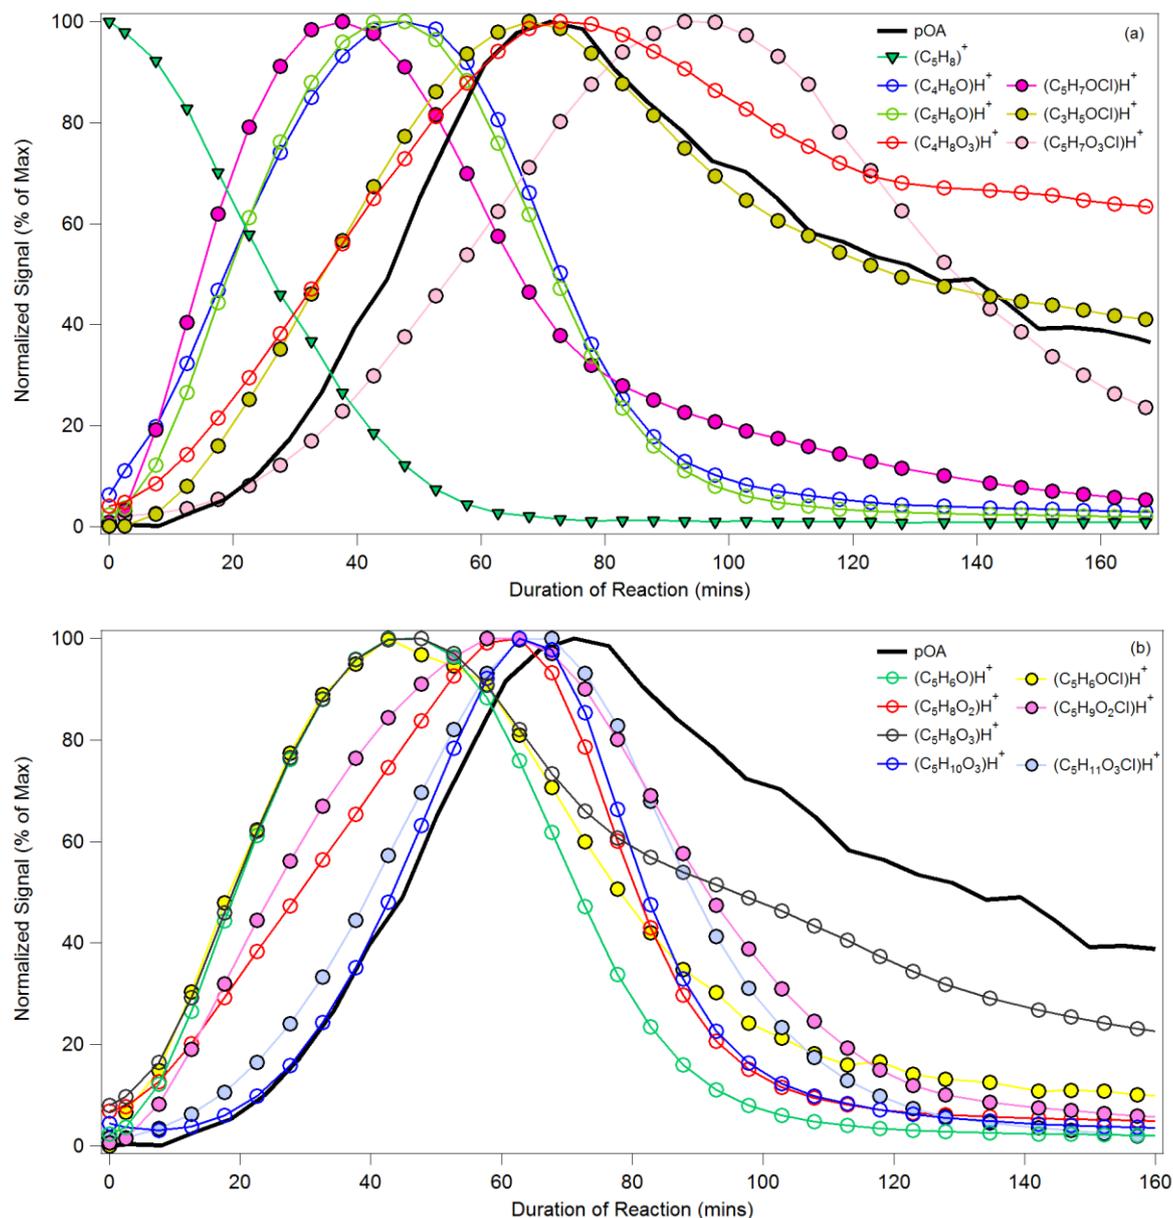

Figure 6: Observation of select gas-phase species using $(\text{H}_2\text{O})_n\text{H}_3\text{O}^+$ -CIMS plotted alongside SOA concentration for Exp. C5. Suspended particle concentration is shown. Ion signal for each individual species was normalized to its maximum value. Five minute averages are shown (a) Isoprene was completely depleted by the time maximum OA concentration was reached; multi-generational oxidation and chlorinate were clearly observed. (b) Observation of ions potentially resembling IEPOX, or $\text{C}_5\text{H}_{10}\text{O}_3$. Potential oxidation product ion $(\text{C}_5\text{H}_8\text{O}_3)^+\text{H}^+$ and interfering ions, $(\text{C}_5\text{H}_8\text{O}_2)^+\text{H}^+$ and $(\text{C}_5\text{H}_{11}\text{O}_3\text{Cl})^+\text{H}^+$ are also shown.

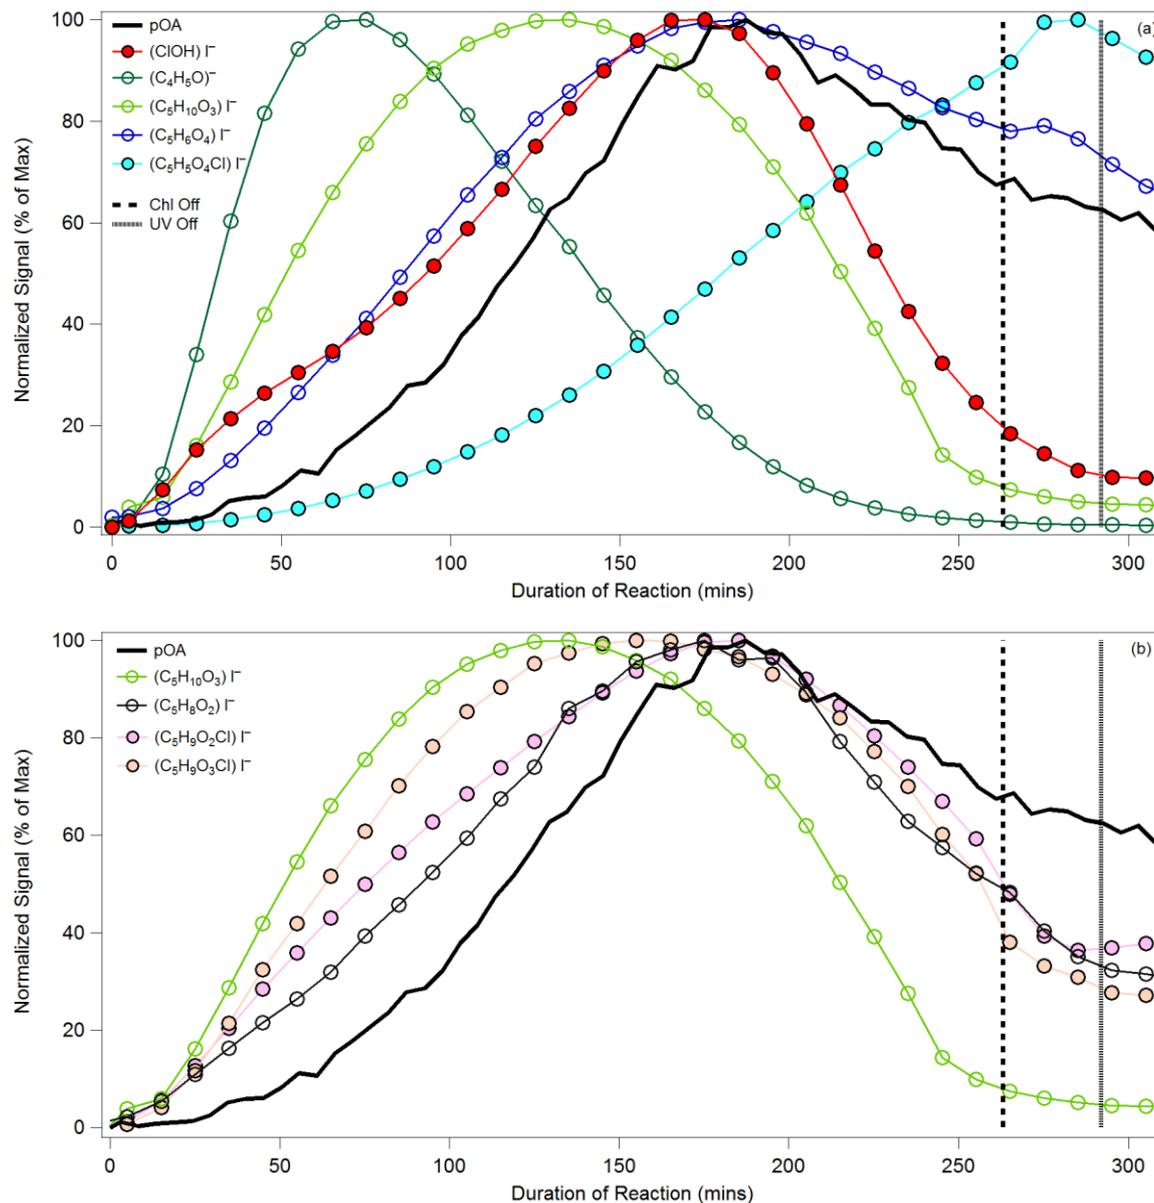

Figure 7: Observation of select gas-phase products using $(\text{H}_2\text{O})\text{I}^-$ CIMS from Exp. C3. Chlorine injection stopped at $T = 263$ mins and UV lights were turned off at $T = 292$ mins. Ten-minute averages of normalized CIMS ion signals and five-minute averages of normalized, suspended OA concentrations are shown. Note that Exp. C3 (Fig. 7) and Exp. C5 (Fig. 6) have different precursor concentrations, hence the difference in the time required to achieve maximum OA concentration. (a) Multi-generational oxidation accompanying SOA formation; ClOH trend suggests OH radical production from isoprene oxidation (b) Observation of ions consistent with IEPOX; potential interfering ion trends were distinct from that of $(\text{C}_5\text{H}_8\text{O}_3)\text{I}^-$.
