28

29 **Abstract**

30 Evolution of droplet size distribution (DSD) due to mixing between cloudy and dry
31 volumes is investigated for different values of the cloud fraction and for different initial DSD
32 shapes. The analysis is performed using a diffusion-evaporation model which describes time-
33 dependent processes of turbulent diffusion and droplet evaporation within a mixing volume.
34 Time evolution of the DSD characteristics such as droplet concentration, LWC and mean
35 volume radii is analyzed. The mixing diagrams are plotted for the final mixing stages. It is
36 shown that the difference between the mixing diagrams for homogeneous and inhomogeneous
37 mixing is insignificant and decreases with an increase in the DSD width. The dependencies of
38 normalized cube of the mean volume radius on the cloud fraction were compared with those
39 on normalized droplet concentration and found to be quite different. In case the normalized
40 droplet concentration is used, mixing diagrams do not show any significant dependence on
41 relative humidity in the dry volume.

42 The main conclusion of the study is that traditional mixing diagrams cannot serve as a
43 reliable tool for analysis of mixing type.

44

45 **Keywords:** turbulent mixing, droplet evaporation, DSD evolution, mixing diagram

46

47 **1. Introduction**

48 The effects of mixing of cloudy air with surrounding dry air on cloud microphysics are still
49 the focus of many studies (see overview by Devenish et al., 2012). Processes of mixing are
50 investigated in observations (Yum et al., 2015; Bera et al., 2016a,b), Large Eddy Simulations
51 (Andrejczuk et al., 2009; Khain et al., 2017) and Direct Numerical Simulations (Kumar et al.,
52 2014, 2017). Processes of mixing and their effects on droplet size distributions were recently
53 investigated in a set of theoretical studies (Yang et al., 2016; Korolev et al., 2016 (hereafter,
54 Pt1); Pinsky et al., 2016 a,b).

55 The Pt1 presented analysis of conventional (classical) concept of mixing and introduced the
56 main parameters characterizing homogeneous and extremely inhomogeneous mixing. In the
57 classical concept two volumes, cloudy and droplet free one, mix within an unmovable adiabatic
58 mixing volume. At a monodisperse initial droplet size distribution (DSD), homogeneous mixing
59 leads to a decrease in droplet size and droplet mass content, while the number of droplets
60 remains unchanged. Extremely inhomogeneous mixing is characterized by decreasing the
61 number of droplets due to full evaporation of some fraction of droplets penetrating the initially
62 dry air volume while the DSD shape in the cloud volume remains unchanged. As a result of
63 extremely inhomogeneous mixing, droplet number decreases while the mean volume radii
64 remain unchanged. At a polydisperse DSDs, the extreme homogeneous mixing is characterized
65 by proportional changes in DSD for all droplet radii (Pt1). Since widely used mixing diagrams
66 describe the final equilibrium stage of mixing within the mixing volume they do not contain
67 information about changes in microphysical quantities in the course of mixing.

68 Pinsky et al. (2016a, hereafter Pt2) analyzed the time evolution of initially monodisperse
69 and polydisperse DSD during homogeneous mixing. It was shown that result of mixing
70 strongly depends on the shape of the initial DSD. At a wide DSD, evaporation of droplets
71 (first of all, of the smallest ones) is not accompanied by a decrease in the mean volume or
72 effective radius. Moreover, the values of the radii may even increase over time. This result

73 indicates that the widely used criterion of separation of mixing types based on the behavior of
74 the mean volume radius during mixing is not generally relevant and may be wrong in
75 application to real clouds.

76 Pinsky et.al. (2016b, hereafter Pt3) introduced a diffusion-evaporation model which
77 describes evolution DSDs and all the microphysical variables due to two simultaneously
78 occurring processes: turbulent diffusion and droplet evaporation. Mixing between two equal
79 volumes of subsaturated and cloudy air was analyzed, i.e. it was assumed that the cloud
80 volume fraction $\mu = 1/2$. The initial DSD in the cloudy volume was assumed monodisperse.
81 These simplified assumptions allowed to reduce the turbulent mixing equations to two-
82 parametric ones. The first parameter is the Damköhler number, Da , which is the ratio of the
83 characteristic mixing time to the characteristic phase relaxation time. The second parameter is
84 the potential evaporation parameter R characterizing the ratio between the amount of water
85 vapor needed to saturate the initially dry volume and the amount of available liquid water in
86 the cloudy volume.

87 Within the $Da - R$ space, in addition to the two extreme mixing types defined in the
88 classical concept, two more mixing regimes were distinguished, namely, intermediate and
89 inhomogeneous mixing. It was shown that any type of mixing leads to formation of a tail of
90 small droplets, i.e. to DSD broadening. It was also shown that the relative humidity in the
91 initially dry volume rapidly increases due to both water vapor diffusion and evaporation of
92 penetrating droplets. As a result, the mean volume and effective radii in the initially dry
93 volume rapidly approach the values typical of cloudy volume. At the same time, the liquid
94 water content (LWC) remains significantly lower than that in the cloudy volume during much
95 longer time than required for the effective droplet radius to grow.

96 In the present study (Pt4) we continue investigating the turbulent mixing between an
97 initially droplet free volume (referred to as dry volume) and a cloudy volume. The focus of
98 the study is investigation of DSD temporal evolution and analysis of the final equilibrium

99 DSD. In comparison to Pt3, the problem analyzed in this study is more sophisticated in
100 several aspects:

101 • The dependences of different mixing characteristics on cloud volume fraction $0 \leq \mu \leq 1$
102 are analyzed. In this case the equations of turbulent mixing cannot be reduced to the two-
103 parametric problem as it was done in Pt3.

104 • The initial DSDs in cloud volume are polydisperse. We use both narrow and wide
105 initial DSD described by Gamma distributions with different sets of parameters. The DSD are
106 the same as those used in Pt2. Mechanisms of formation of wide DSDs in clouds including
107 DSDs in undiluted cloud cores were investigated in several studies [e.g., Khain et al., 2000;
108 Pinky and Khain, 2002; Segal et al., 2004; Prabha et al., 2011]. These studies show the DSD
109 broadening is caused by in-cloud nucleation of droplets within clouds as well as by collisions
110 between cloud droplets. It was shown that DSDs in adiabatic volumes can be wide and first
111 raindrops or drizzle drop arise namely in non-diluted adiabatic cloud parcels [Khain et al.,
112 2013; Magaritz-Ronen et al., 2016]. We use both narrow and wide DSDs in the form of
113 Gamma distribution with typical parameters used in different cloud resolving models. The
114 DSDs that are used as initial ones in cloudy volumes could be formed also under influence of
115 mixing during their previous history. The mechanisms of the formation of initial DSD are not
116 of interest in the study since that do not affect the analysis.

117 • The equation for supersaturation, used in this study, is valid at low humidity in the
118 initially dry volume and is more general and compared with that used in Pt3, which makes the
119 DSD calculations more accurate.

120 At the same time, some simplifications used in Pt3 are retained in this study. The vertical
121 movement of the entire mixing volume is neglected; collisions between droplets and droplet
122 sedimentation are not allowed. Also, we consider a 1D diffusion-evaporation problem. We
123 neglect the changes of temperature in the course of mixing, which is possibly a less significant

124 simplification. All these simplifications allow to reveal the effects of turbulent mixing and
 125 evaporation on DSD evolution.

126

127 **2. Formulation of the problem and model design**

128 In this study, the process of mixing is investigated basing on the solution of 1D diffusion-
 129 evaporation equation (see also Pt3). According to this equation, evaporation of droplets due to
 130 negative supersaturation in the mixing volume takes place simultaneously with turbulent
 131 mixing. Since droplets within the volume are under different negative supersaturation values
 132 until the final equilibrium is reached, the modeled mixing is inhomogeneous. The droplets can
 133 evaporate either partially or totally. The evaporation leads to a decrease in droplet sizes and in
 134 droplet concentration.

135 Like in Pt3, the process of turbulent diffusion is described by a 1D equation of turbulent
 136 diffusion. The equation does not describe formation of separate turbulent filaments. Instead, it
 137 describes averaged effects of turbulent vortices of different scales by modeling of turbulent
 138 diffusion, characterized by a typical value of turbulent diffusion coefficient K . The mixing is
 139 assumed to be driven by isotropic turbulence at scales within the inertial sub-range where
 140 Richardson's law is valid. In this case, turbulent coefficient is evaluated as in Monin and
 141 Yaglom (1975):

$$142 \quad K(L) = C\varepsilon^{1/3}L^{4/3} \quad (1)$$

143 In Eq. (1) ε is the turbulent kinetic energy dissipation rate and $C = 0.2$ is a constant (Monin
 144 and Yaglom, 1975), Boffetta and Sokolov (2002). Eq. (1) means that we consider the effects
 145 of turbulent diffusion at scales much larger than the Kolmogorov microscale, i.e. the effects of
 146 molecular diffusion are neglected. In the simulations, we use $L = 40 \text{ m}$ and $\varepsilon = 20 \text{ cm}^2 \text{ s}^{-3}$. It
 147 means that in the present study mixing is performed by vortices smaller than several tens of
 148 meters which agrees with measurements in warm Cu (Gerber et al. 2008). The value of
 149 turbulent kinetic energy dissipation rate chosen is also typical for small Cu (e.g. Gerber et al.

150 2008). These parameters correspond to the values of Da of several hundred. The model allows
 151 utilization of other values of L and ε typical of other cloud type (say, deep convective
 152 clouds) which can change results quantitatively, but not qualitatively.

153

154 *Geometry of mixing and the initial conditions*

155 The conceptual scheme presenting mixing geometry and the initial conditions used in the
 156 following analysis are shown in **Figure 1**.

157

158 **Fig 1 here**

159

160 At $t=0$ the mixing volume of length L is divided into two volumes: the cloud volume of
 161 length μL (Fig.1, left) and the dry volume of length $(1-\mu)L$ (Fig.1, right), where $0 \leq \mu \leq 1$
 162 is the cloud volume fraction. The entire volume is assumed closed, i.e. adiabatic. At $t=0$ the
 163 cloud volume is assumed saturated, so the supersaturation $S_1=0$. This volume is also
 164 characterized by the initial distribution of the square of the droplet radii $g_1(\sigma)$, where $\sigma = r^2$.

165 The initial liquid water mixing ratio in the cloudy volume is equal to

166 $q_{w1} = \frac{4\pi\rho_w}{3\rho_a} \int_0^\infty \sigma^{3/2} g_1(\sigma) d\sigma$. The integral of $g_1(\sigma)$ over σ is equal to the initial droplet

167 concentration in the cloud volume $N_1 = \int_0^\infty g_1(\sigma) d\sigma$. The initial droplet concentration in the

168 dry volume is $N_2=0$, the initial negative supersaturation in this volume is $S_2 < 0$ and the

169 initial liquid water mixing ratio $q_{w2}=0$. Therefore, the initial profiles of these quantities

170 along the x -axis are step functions:

171

$$172 \quad N(x,0) = \begin{cases} N_1 & \text{if } 0 \leq x < \mu L \\ 0 & \text{if } \mu L \leq x < L \end{cases} \quad (2a)$$

$$173 \quad S(x, 0) = \begin{cases} 0 & \text{if } 0 \leq x < \mu L \\ S_2 & \text{if } \mu L \leq x < L \end{cases} \quad (2b)$$

$$174 \quad q_w(x, 0) = \begin{cases} q_{w1} & \text{if } 0 \leq x < \mu L \\ 0 & \text{if } \mu L \leq x < L \end{cases} \quad (2c)$$

175

176 The initial profile of droplet concentration is shown in Fig. 1b. This is the simplest
 177 inhomogeneous mixing scheme, wherein mixing takes place only in the x -direction, and the
 178 vertical velocity is neglected.

179 Since the total volume is adiabatic, the fluxes of different quantities through the left and
 180 right boundaries at any time instance are equal to zero, i.e.

181

$$182 \quad \frac{\partial N(0, t)}{\partial x} = \frac{\partial N(L, t)}{\partial x} = 0; \quad \frac{\partial q_w(0, t)}{\partial x} = \frac{\partial q_w(L, t)}{\partial x} = 0; \quad \frac{\partial q_v(0, t)}{\partial x} = \frac{\partial q_v(L, t)}{\partial x} = 0 \quad (3)$$

183 where q_v is the water vapor mixing ratio.

184 To investigate of mixing process for different initial DSD, we assume that DSD in the cloud
 185 volume can be represented by a Gamma distribution:

$$186 \quad f(r, t = 0) = \frac{N_0}{\Gamma(\alpha)\beta} \left(\frac{r}{\beta}\right)^{\alpha-1} \exp\left(-\frac{r}{\beta}\right) \quad (4)$$

187 where N_0 is an intercept parameter, α is a shape parameter and β is a slope parameter of
 188 distribution. The DSD $f(r)$ relates to distribution $g_1(\sigma)$ as $f(r) = 2rg_1(\sigma)$. We performed
 189 simulations with both initially wide and narrow DSDs. The width of DSD is determined by a
 190 set of parameters. The parameters of the initial Gamma distributions used in this study are
 191 presented in **Table 1**. Parameters of the distributions are chosen in such a way that the modal
 192 radii of DSD and the values of LWC are the same for both distributions. These distributions
 193 were used in Pt2 for analysis of homogeneous mixing.

194

195 **Table 1 here**

196

197

198 **Conservative quantity** $\Gamma(x,t)$

199 The supersaturation equation for an adiabatic immovable volume can be written in the

200 form $\frac{1}{S+1} \frac{dS}{dt} = -A_2 \frac{dq_w}{dt}$, where S is supersaturation over water, and the coefficient201 $A_2 = \frac{1}{q_v} + \frac{L_w^2}{c_p R_v T^2}$ is slightly dependent on temperature (Korolev and Mazin, 2003) (notations202 of other variables are presented in **Appendix**). In our analysis we consider A_2 to be a

203 constant. As follows from the supersaturation equation, the quantity

204

205
$$\Gamma(x,t) = \ln[S(x,t)+1] + A_2 q_w(x,t) \quad (5)$$

206

207 is a conservative quantity, i.e. it is invariant with respect to phase transitions. In Eq. (5),

208 $|S(x,t)|$ can be comparable with unity by the order of magnitude. The conservative quantity209 $\Gamma(x,t)$ obeys the following equation for turbulent diffusion

210

211
$$\frac{\partial \Gamma(x,t)}{\partial t} = K \frac{\partial^2 \Gamma(x,t)}{\partial x^2} \quad (6)$$

212

213 with the adiabatic (no flux) condition at the left and right boundaries $\frac{\partial \Gamma(0,t)}{\partial x} = \frac{\partial \Gamma(L,t)}{\partial x} = 0$ 214 and the initial profile at $t = 0$

215

216
$$\Gamma(x,0) = \begin{cases} A_2 q_{w1} & \text{if } 0 \leq x < \mu L \\ \ln[S_2 + 1] & \text{if } \mu L \leq x < L \end{cases} \quad (7)$$

217

218 From Eq. (7) it follows that $\Gamma(x,0)$ is positive in the cloud volume and negative in the
 219 initially dry volume. The mean value of function $\Gamma(x,0)$ can be written as follows:

220

$$221 \quad \bar{\Gamma} = \frac{1}{L} \int_0^L \Gamma(x,0) dx = \frac{A_2 q_{w1}}{L} \int_0^{\mu L} dx + \frac{\ln[S_2 + 1]}{L} \int_{\mu L}^L dx = \mu A_2 q_{w1} + (1 - \mu) \ln[S_2 + 1] \quad (8)$$

222

223 $\bar{\Gamma}$ can be either positive or negative. In the latter case a complete evaporation of droplets in the
 224 course of mixing takes place.

225 The solution of Eq. (6) with the initial condition (7) is (Polyanin et al., 2004):

$$226 \quad \Gamma(x,t) = \sum_{n=0}^{\infty} a_n \exp\left(-\frac{Kn^2 \pi^2 t}{L^2}\right) \cos\left(\frac{n\pi x}{L}\right) =$$

$$\mu A_2 q_{w1} + (1 - \mu) \ln[S_2 + 1] -$$

$$2(\ln[S_2 + 1] - A_2 q_{w1}) \sum_{n=1}^{\infty} \frac{\sin(n\pi\mu)}{n\pi} \exp\left(-\frac{Kn^2 \pi^2 t}{L^2}\right) \cos\left(\frac{n\pi x}{L}\right) \quad (9)$$

227 One can see that function $\Gamma(x,t)$ depends on three independent parameters $A_2 q_{w1}$, S_2 and μ .

228 This function does not depend on the shape of the initial DSD in the cloud volume. In the final
 229 state when $t \rightarrow \infty$, $\Gamma(x,t)$ is :

$$230 \quad \Gamma(t = \infty) = \mu A_2 q_{w1} + (1 - \mu) \ln[S_2 + 1] \quad (10)$$

231 Therefore, $\Gamma(t = \infty)$ depends on the cloud fraction and the initial values of liquid water
 232 mixing ratio in the cloud volume and the relative humidity in initially dry volume.

233 The final equilibrium values of supersaturation $S(x,\infty)$ and liquid water mixing ratio

234 $q_w(x,\infty)$ can be calculated using Eq. (5). The case $\Gamma(t = \infty) > 0$ corresponds to the

235 equilibrium state with $S(x,\infty) = 0$ and $q_w(x,\infty) = \mu q_{w1} + (1 - \mu) \frac{\ln[S_2 + 1]}{A_2}$, when droplets

236 remain, but do not evaporate any longer.

237 The case $\Gamma(t=\infty) < 0$ corresponds to the equilibrium state with $q_w(x, \infty) = 0$ and
 238 $S(x, \infty) = (1 + S_2)^{1-\mu} \exp(\mu A_2 q_{w1}) - 1$. In this equilibrium state droplets are totally evaporated,
 239 and volume remains subsaturated $S(x, \infty) < 0$. At given q_{w1} and S_2 , there is a critical value of
 240 the cloud fraction μ_{cr} which separates these two possible final equilibrium states. This critical
 241 value corresponds to $\Gamma(t=\infty) = 0$ and can be calculated from Eq. (10) as:

242

$$243 \quad \mu_{cr} = \frac{\ln[S_2 + 1]}{\ln[S_2 + 1] - A_2 q_{w1}} \quad (11)$$

244

245 Another expression for μ_{cr} was formulated in Pt1.

246 The examples of spatial-temporal variations of function $\Gamma(x, t)$ for different cloud
 247 fractions and initial RH=80% are shown in **Figure 2**.

248

249 **Fig 2 here**

250

251 Upper panels $\mu = 0.1$ correspond to the case of final total droplet evaporation and negative
 252 final function Γ , whereas the middle and bottom rows $\mu = 0.5$ and $\mu = 0.9$ illustrate partial
 253 evaporation cases when the total mixing volume reaches saturation. It is interesting that the
 254 time required for the final equilibrium state to be reached practically does not depend on the
 255 cloud fraction, being ~ 180 seconds for the illustrated cases. The cases $\mu = 0.1$ and $\mu = 0.9$
 256 demonstrate a strong non-symmetric spatial variability of $\Gamma(x)$ function during the first 50
 257 seconds. At $\mu = 0.5$, a nearly full compensation between saturation deficit in the dry volume
 258 and available liquid water in the cloud volume takes place if at the equilibrium state
 259 $S(x, \infty) = q_w(x, \infty) = \Gamma(x, \infty) = 0$. However, the compensation at $\mu = 0.5$ is not full because of
 260 the nonlinearity of Γ in Eq. (5).

261

262 ***Diffusion-evaporation equation for DSD***

263 To formulate the diffusion-evaporation equation we use a simplified equation for droplet
 264 evaporation (Pruppacher and Klett, 1997), in which the curvature term and the chemical
 265 composition term are omitted

$$266 \quad \frac{d\sigma}{dt} = \frac{2S}{F} \quad (12)$$

267 where $F = \frac{\rho_w L_w^2}{k_a R_v T^2} + \frac{\rho_w R_v T}{e_w(T) D} = \text{const}$ (Notations of other variables are presented in Appendix.)

268 The solution of Eq. (12) is

$$269 \quad \sigma(t) = \frac{2}{F} \int_0^t S(t') dt' + \sigma_0 \quad (13)$$

270 Eq. (13) means that in the course of evaporation, distribution $g(\sigma)$ shifts to the left without
 271 changing its shape. The diffusion-evaporation equation for function $g(x, t, \sigma)$ can be written
 272 in the form

273

$$274 \quad \frac{\partial g}{\partial t} = K \frac{\partial^2 g}{\partial x^2} + \frac{\partial}{\partial \sigma} \left(\frac{d\sigma}{dt} g \right) \quad (14)$$

275 Combining Eqs. (12) and (14) yields

$$276 \quad \frac{\partial g(x, t, \sigma)}{\partial t} = K \frac{\partial^2 g(x, t, \sigma)}{\partial x^2} + \frac{2S}{F} \frac{\partial g(x, t, \sigma)}{\partial \sigma} \quad (15)$$

277

278 Eq. (15) is similar to the diffusion-evaporation equation for size distribution function used in
 279 Pt 3. The first term on the right hand side of Eq. (15) describes the effect of turbulent
 280 diffusion, while the second term describes the changes of size distribution due to droplet
 281 evaporation. To close this equation, one can use Eq. (5) written as

282

283 $S(x,t) = \exp[\Gamma(x,t) - A_2 q_w(x,t)] - 1,$ (16)

284

285 and the equation for liquid water mixing ratio

286

287 $q_w(x,t) = \frac{4\pi\rho_w}{3\rho_a} \int_0^\infty \sigma^{3/2} g(x,t,\sigma) d\sigma$ (17)

288 The equation system (15-17) for distribution $g(x,t,\sigma)$ should be solved under the following

289 initial condition

290 $g(x,0,\sigma) = \begin{cases} g_1(\sigma) & \text{if } 0 \leq x < \mu L \\ 0 & \text{if } \mu L \leq x < L \end{cases}$ (18)

291 and using the Neumann boundary conditions

292

293 $\frac{\partial g(0,t,\sigma)}{\partial x} = \frac{\partial g(L,t,\sigma)}{\partial x} = 0$ (19)

294

295 These equations were solved numerically on a linear grid of droplet radii r_j being within

296 the range 0-50 μm , where $j = 1 \dots 50$ are the bin numbers. The number of grid points along the

297 x -axis was set equal to 81. In numerical calculations, the “evaporation term” in Eq. (15) was

298 approximated as

299 $\frac{2S}{F} \frac{\partial g(x,t,\sigma)}{\partial \sigma} \approx \frac{g\left(x,t,\sigma + \frac{2S}{F} \Delta t\right) - g(x,t,\sigma)}{\Delta t}.$ (20)

300

301 A shift and subsequent remapping of DSD using the method proposed by Kovetz and Olund’s

302 (1969) were implemented to solve Eq. (20) with the help of MATLAB solver PDEPE. After

303 calculation of $g(x,t,\sigma_j)$ function, DSD $f(x,t,r_j)$ was calculated using the relationship

304 $f(x,t,r_j) = 2r_j g(x,t,\sigma_j).$

305

306 **3. Spatial-temporal variations of DSD and of DSD parameters**

307 Mixing may take a significant time. Cloud microphysical parameters measured in *in-situ*
 308 observations correspond to different stages of this transient mixing process. During mixing,
 309 DSDs and its parameters change substantially, which makes it reasonable to analyze these
 310 time changes.

311 **Figure 3** shows time evolution of initially narrow DSD in the centers of the cloudy volume
 312 and of the initially dry volume. The values of DSD in the initially cloudy volume decrease
 313 while there are no significant changes in the DSD shape. At $\mu = 0.7$, the modal droplet
 314 radius remains unchanged during mixing staying equal to $10 \mu m$. At $\mu = 0.3$ the effect of
 315 droplet diffusion on DSD is stronger, and mixing leads not only to a decrease in the DSD
 316 values, but also to a decrease in the modal droplet radius in the cloudy volume. At both
 317 $\mu = 0.3$ and $\mu = 0.7$, mixing leads to broadening of the initial DSD due to the appearance of
 318 the tail of small droplets. **The tail of small droplets is especially pronounced in the initially dry**
 319 **volume due to maximum evaporation of penetrated droplets.**

320 The rate of the DSD growth in the initially dry volume, depends on the value of the cloud
 321 fraction. At a low cloud fraction, the **droplet concentration and droplet mass** remain
 322 substantially lower for the main period of mixing process than that in the cloudy volume. At
 323 the same time, the modal DSD radius increases reaching 80% of its maximum value already
 324 within the first 5 s. This is due to the fast increase in the relative humidity during mixing, so
 325 large droplets penetrating the initially dry volume do not decrease in size anyhow significantly
 326 determining the values of modal, mean volume and effective radii. Thus, we see two stages of
 327 DSD evolution within the initially dry volumes: at the first stage penetrated droplets evaporate
 328 totally or partially forming the tail of small droplets. The formation of the tail of smallest
 329 droplets does not lead to a significant changes of the size of the largest droplets. Note that
 330 according to equation of diffusion growth/evaporation in of sub-saturation conditions, the rate

331 of droplet radii decreases inverse proportionally to the droplet radius. It means that if, say,
332 radius of a $2 \mu\text{m}$ droplet decreases twice during a certain time instance, the radius of $20 \mu\text{m}$
333 droplet will decrease by less than $0.1 \mu\text{m}$, i.e. remains approximately unchanged. At this
334 stage diffusion of water vapor from cloudy volume and evaporation of penetrating droplets
335 lead to a rapid growth of relative humidity RH. This growth of RH decreases evaporation rate
336 of droplets penetrating initially dry volume later. At the second stage mixing leads to the
337 increase in the droplet number due to droplet diffusion from cloudy volume. Since, RH is
338 high, this diffusion is not accompanied by significant change droplet sizes, so DSD grows
339 similarly at all radii.

340

341 **Figure 3 here**

342

343 At the initially wide DSD (**Figure 4**), the modal radii of the DSD do not change. It means
344 that at the initial RH= 80%, mixing and evaporation lead to a fast saturation of the initially dry
345 volume, after which the peak radius remains unchanged in this volume. **In the initially cloud**
346 **volume RH remains close to 100% so the DSD decrease is related to dilution by initially dry**
347 **air.**

348

349 **Figure 4 here**

350

351 It is interesting that at $\mu=0.3$, the maximum value of the DSD maximum in the initially dry
352 volume is reached during the transition period (Fig.4, at $t=80\text{s}$), and then decreases toward the
353 equilibrium state. This behavior is caused by the competition between the diffusion and
354 droplet evaporation.

355 **Figure 5** shows spatial dependences of droplet concentration, LWC and the mean volume
356 radius within the mixing volume at different time instances at narrow initial DSD. At small

357 values of the cloud fraction, diffusion of water vapor and droplets, as well as droplet
 358 evaporation lead to a fast decrease in droplet concentration and in LWC in the initially cloud
 359 volume. The mean volume radius in this volume decreases by about 15% in the course of
 360 mixing. It is natural that at large cloud fraction, droplet concentration and LWC in the initially
 361 cloudy volume decrease slowly, while these quantities in the initially dry volume increase
 362 rapidly. At both small and large cloud fractions, the mean volume radius in the initially dry
 363 volume grows rapidly during the mixing toward its values in the initially cloudy volumes,
 364 even if droplet concentration and LWC remain much lower than in the adjacent cloud volume.

365

366 **Figure 5 here**

367

368 **Figure 6** shows the spatial dependences of droplet concentration, LWC and the mean
 369 volume radius within the mixing volume at different time instances at wide initial DSD.

370

371

372 **Figure 6 here**

373

374

375 A specific feature of mixing at a wide DSD is the increase in the mean volume radius, so the

376 ratio $\frac{r_v}{r_{v0}} > 1$. In the course of mixing, the mean volume radius maximum is reached in the

377 initially dry volumes. This result can be attributed to the fact that in this volume smaller

378 droplets fully evaporate, so the concentration of large droplets increases with respect to

379 concentration of smaller droplets (Fig. 4, right column). Scattering diagrams plotted using *in-*

380 *situ* observations often contain points or groups of points with $\frac{r_v}{r_{v0}} > 1$ (or $\frac{r_e}{r_{e0}} > 1$, where r_e is

381 effective radius) within wide range of normalized droplet concentration (e.g., Burnet and

382 Brenguier, 2007; Krueger et al., 2006, Gerber et al., 2008). The result obtained in the present
 383 study shows that the behavior of $\frac{r_v}{r_{v0}}$ with time in the course of mixing may depend of the
 384 DSD shape in the initially cloud volume that determines relationship between concentrations
 385 of small and large droplets in course of mixing. Of course, the DSD shape is only one possible
 386 reason of appearance of points with $\frac{r_v}{r_{v0}} > 1$ on the scattering diagram.

387 We see that the transition to the final equilibrium state within the volume with the spatial
 388 scale of 40 m is about 5 min (Fig. 8), which is a comparatively long period of time compared
 389 to the characteristic times of other microphysical processes, including droplet evaporation.
 390 During this time the DSD changes substantially, especially at small cloud fraction. The mean
 391 volume radius in the initially dry volume increases much faster than LWC. As a result, mean
 392 volume radius in such volume rapidly reaches the values typical of cloudy air, while LWC
 393 still remains substantially lower than in the cloudy volume. Despite some DSD broadening,
 394 the final DSDs in the mixing volume resemble those in the initially cloud volumes. The main
 395 effect of mixing is lowering the DSD values as the cloud fraction decreases.

396

397 **4. Equilibrium state and mixing diagram**

398 This study reconsiders the classical theory of mixing diagrams. In the classical theory
 399 two volumes (cloudy and droplet free) mix with each other within a given unmovable mixing
 400 volume (see review by Korolev et al., 2016). Mixing diagrams are typically plotted for times
 401 when all variables become uniform within the mixing volume, i.e when the equilibrium state
 402 is reached. We plot the mixing diagram using the same simplifications used in the plotting
 403 classical mixing diagrams, namely: no vertical motions and no collisions are assumed. These
 404 assumptions allow to reveal better the microphysical effects of turbulent mixing. It is widely
 405 assumed that the mixing type is determined by the Damkohler number that depends only on
 406 drop relaxation time and mixing time. No averaged vertical velocity and no collision rate are

407 included into this criterion.

408 We extend the theory, however, in several important aspects concerning microphysical
 409 effects: a) we consider time dependent process of mixing and b) initial droplet size
 410 distributions are assumed polydisperse.

411 Mixing considered in the present study always leads to the equilibrium state. As was
 412 explained above, two equilibrium states are possible. The first one is characterized by the total
 413 evaporation of cloud droplets $q_w(x, \infty) = 0$, whereas the second one occurs if the air in the
 414 mixing volume becomes saturated, i.e. when $S(x, \infty) = 0$. At the given initial values of q_{w1} in
 415 the cloud volume and of S_2 in the initially dry volume, there always exists the cloud fraction
 416 μ_{cr} (Eq. 11) separating these two states.

417

418 **4.1. The process of achieving the equilibrium state**

419 **Figure 7** shows the dependences of the time required to reach the equilibrium on the cloud
 420 fraction, at different initial relative humidity values in the dry volume and two initial DSDs
 421 (the parameters are presented in Tab.1). The characteristic time is defined here as the time
 422 from the beginning of mixing to the time instance when inequality $\delta = \frac{\bar{N}(t) - \bar{N}(\infty)}{\bar{N}(0) - \bar{N}(\infty)} < 0.01$
 423 becomes valid. The mean droplet concentration is calculated by averaging along x -axes

424 $(\bar{N}(t) = \frac{1}{L} \int_0^L N(x, t) dx)$. In case of a total evaporation, $\bar{N}(\infty) = 0$.

425

426 **Figure 7 here**

427

428 Each curve in Fig. 7 consists of two branches. The left branches correspond to the total
 429 evaporation regime, while the right branches correspond to the partial evaporation at
 430 equilibrium. The maximum time corresponds to the situation when the available amount of

431 liquid water is approximately equal to the saturation deficit. A similar result was obtained in
 432 Pt1 and Pt2 for homogeneous mixing. The maximum values of the characteristic time are
 433 about 4 min for a mixing volume of 40 m in length. The right branches show that the
 434 characteristic time decreases with increasing cloud fraction. Despite some differences in the
 435 curve slopes, the characteristic times for wide and narrow DSD are quite similar.

436 **Figure 8** shows dependences of normalized cube of the mean volume radius on the cloud
 437 fraction at different time instances for two values of x : $x=0$ (solid lines) corresponds to the
 438 initially cloudy volume, and $x=L$ (dashed line) corresponds to the initially dry volume. The
 439 figure is plotted for the narrow DSD for two values of RH_2 : 60% and 95%. Despite the fact
 440 that the diffusion-evaporation equation allows simulating using any initial RH, we do not
 441 consider in our examples the cases of very low RH of dry volume. It is because at very low
 442 RH, say, $RH=20\%$, the cloud fraction should exceed 0.8 to prevent total droplet evaporation
 443 in the equilibrium state (at $LWC=1$ g/kg). At the same time, we are interested in the
 444 equilibrium state at which droplets exist. Note that at the lateral edges of warm Cu a shell of
 445 humid air arises around cloud, so RH of the entrained air should be high enough (e.g. Gerber
 446 et al., 2008).

447

448 **Figure 8 here**

449

450 The curve plotted for the time instance of 300 s corresponds to the equilibrium state (hereafter
 451 the equilibrium curve). The curves above the equilibrium curve correspond to the initially
 452 cloudy volume, and the curves below the equilibrium curve correspond to the initially dry
 453 volume. One can see how curves of both types approach the same final state. During the

454 mixing the curves move over the $\left(\frac{r_v}{r_{v0}}\right)^3 - \mu$ plane toward the equilibrium curve. As a result,

455 the curves plotted in Fig.8, corresponding to different time instances of the mixing, together
 456 cover the entire area of the panels.

457 During this movement the distance from the curves to the horizontal line $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ changes,
 458 and the curves slopes increase. In our case of $L = 40$ m, the mixing remains inhomogeneous
 459 the during entire mixing process, so the change in the distance from the curves to the
 460 horizontal line $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ characterizes the temporal changes over the mixing process, but not
 461 a change in mixing type.

462 It is noteworthy in this relation that scattering diagrams plotted using *in-situ* observations
 463 reflect mixing between different multiple volumes at different stages of the mixing process.
 464 Accordingly, points in the scattering diagrams can be far from the equilibrium location. Fig. 8
 465 indicates, therefore, that scattering diagrams show snapshots of transient mixing process when
 466 the distance from points in the diagrams to line $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ characterize the stage of the
 467 mixing process, but not the mixing type.

468 The dependences of normalized cube of the mean volume radius on the cloud fraction at
 469 different time instances at wide DSD also indicate approaching to the equilibrium curve,
 470 while all the curves correspond to $\left(\frac{r_v}{r_{v0}}\right)^3 > 1$ (not shown).

471 Note that in several studies normalized effective radius is used for plotting scattering and
 472 mixing diagrams, but not mean volume radius (Gerber et al. 2008; Freud et al., 2011).
 473 Comparison of scattering and mixing diagrams in the study plotted using mean volume and
 474 effective radii did not reveal any significant differences (not shown).

475

476 **4.2. Mixing diagrams**

477 Using the diffusion-evaporation equations (15-17) we calculated the equilibrium DSD for
 478 different initial relative humidity values and different cloud fractions. Each calculation was
 479 performed for both narrow and wide initial DSD (parameters shown in Tab.1). These
 480 equilibrium DSD were used to calculate mixing diagrams showing dependences of normalized
 481 cube of the effective radius on the cloud fraction.

482 The corresponding mixing diagrams for homogeneous mixing case were also calculated
 483 for comparison. To this effect, the supersaturation and DSD in both the cloud and the dry
 484 volumes were aligned, taking into account the cloud fraction value μ . The alignment led to
 485 the following initial values of supersaturation and DSD within the mixing volume:

486

$$487 \quad S_0 = (1 - \mu)S_2; \quad g_0(\sigma) = \mu g_1(\sigma) \quad (21)$$

488

489 Upon the alignment, time evolution values of DSD under homogeneous evaporation in an
 490 adiabatic immovable parcel were calculated until the equilibrium state was reached. These
 491 equilibrium DSD were used to calculate mixing diagrams for homogeneous mixing. To do
 492 this, we used the parcel model proposed by Korolev (1995) that describes evaporation by
 493 means of equations with temperature-dependent parameters. **Figure 9** shows the mixing
 494 diagrams plotted for initial narrow and wide DSD cases.

495

496 **Figure 9 here**

497

498

499 While all the curves in the mixing diagram for narrow DSD are below the straight line

500 $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$, the curves for wide DSD are above this line. The explanation of this effect is given

501 in Section 3 (Fig. 6). The curves plotted for homogeneous and inhomogeneous mixing

502 demonstrate an important feature. Namely, at given values of RH and q_{w1} in the initially dry
 503 volume, the values μ_{cr} of the cloud fraction at which all the droplets evaporate are
 504 approximately the same for any type of mixing. This condition is the consequence of the mass
 505 conservation law determined by Eq. (11) and does not depend of the initial DSD shape. In
 506 standard mixing diagrams (e.g. Lehmann et al., 2009; Gerber et al., 2008; Freud et al., 2011),
 507 the horizontal straight line $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ (or $\left(\frac{r_e}{r_{e0}}\right)^3 = 1$) is typically plotted for the entire range of
 508 the cloud fraction [0...1], while the curves corresponding to homogeneous mixing are plotted
 509 for different RH within the range $[\mu_{cr}(RH_2)...1]$. As a result, the high difference between
 510 extremely inhomogeneous and homogeneous mixing types is clearly seen at low RH and at
 511 small cloud fractions. The condition that μ_{cr} is the same for different mixing types indicates
 512 that the mixing diagrams may look nearly similar for $\mu > \mu_{cr}$. It means that the range of the
 513 cloud fractions required for comparison of diagrams aimed at determination of a mixing type
 514 shortens as RH_2 values in the surrounding air decrease.

515 The comparison of the left and the right panels in Fig. 9 shows that the differences
 516 between the diagrams for homogeneous and inhomogeneous mixing types are more
 517 pronounced for initially narrow DSD. The maximum difference should take place for
 518 monodisperse DSD considered in in Pt1, Pt2 and Pt3. Within the range of $\mu > \mu_{cr}$, the
 519 distance between the curves corresponding to different mixing regimes is small even for
 520 narrow DSD and low RH_2 . The lower difference is related to the fact that at high RH_2 the
 521 curves in the mixing diagrams are close to the horizontal straight line in both regimes, while at
 522 low RH_2 , μ_{cr} is small and both curves should drop to zero in the vicinity of $\mu = \mu_{cr}$.

523 As regards the wide DSD case, the difference between the curves corresponding to
 524 different mixing type is negligible (Fig. 9, right)

525

526 4.3. Effect of the relative humidity

527 In measurements carried out at cloud boundaries and in cloud simulations, the cloud
 528 fraction is not known, therefore it is widely accepted to use normalized droplet concentration
 529 instead of the cloud fraction (Burnet and Brenguier, 2007; Gerber et al., 2008; Lehmann et al.,
 530 2009). Droplet concentration is normalized by the maximum value along the airplane traverse.
 531 The difference between the cloud fraction and normalized droplet concentration is obvious:
 532 the cloud fraction is a parameter given as the initial condition. At the same time, normalized
 533 droplet concentration changes with time and space due to complete evaporation of some
 534 droplet fraction. **Figure 10** shows dependencies of normalized droplet concentration on the
 535 cloud fraction at the equilibrium final state of mixing. One can see a substantial deviation
 536 from 1:1 linear dependence, especially at low RH. As we know, droplet concentration
 537 decreases in the course of both homogeneous and inhomogeneous mixing if the initial DSD
 538 are polydisperse. The fraction of totally evaporating droplets increases with decreasing RH_2 .
 539 As expected, droplet concentration in homogeneous mixing is higher than that in
 540 inhomogeneous mixing. The difference between droplet concentrations at wide DSD is lower
 541 than at narrow DSD.

542

543 **Fig. 10 here**

544

545 **Figure 11** shows the dependencies $\left(\frac{r_v}{r_{v0}}\right)^3$ on normalized droplet concentration for narrow
 546 and wide DSD in inhomogeneous mixing. The normalization by droplet concentration in the
 547 initially cloud volume at $t=0$ was used. Taking into account the dependences of normalized
 548 droplet concentration on the cloud fraction μ (Fig. 10), one can get the curves shown in Fig.
 549 11 which actually coincide at different RH_2 . The lack of the sensitivity to RH_2 can be
 550 attributed to the fact that a decrease in RH leads to a decrease in normalized droplet

551 concentration, so the curves corresponding to low RH in Fig. 9 shift to the left when the
 552 normalized droplet concentration is used instead of μ . The shape of the dependences in Fig
 553 11 (right) is explained by an increase in the mean volume radius with decreasing droplet
 554 concentration.

555

556 **Fig 11 here**

557

558 Thus, the mixing diagrams plotted in the plane $\left(\frac{r_v}{r_{v0}}\right)^3$ vs normalized droplet
 559 concentration do not depend on the relative humidity of the surrounding dry air. This result
 560 indicates an additional difficulty in distinguishing between mixing types based on scattering
 561 diagrams plotted using *in-situ* data in these axes. The concentration of observed points in
 562 these scattering diagrams close to the line $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ is often interpreted as an indication of
 563 homogeneous mixing, but at high RH in the surrounding air (Gerber et al., 2008; Lehmann et
 564 al., 2009). High values of RH in the penetrating air volumes are usually explained by
 565 formation of a layer of moist air around the cloud boundary (Gerber et al., 2008, Knight and
 566 Miller, 1998).

567 The reference values of droplet concentration and the effective radius used for
 568 normalization in the present study are taken as the initial values in the cloud volume before it
 569 mixes with the neighbouring dry volume. In real *in-situ* measurements the reference values of
 570 these quantities are typically chosen in a less diluted cloud volume along the airplane traverse.
 571 This reference volume may be quite remote from the particular mixing volume. It can lead to
 572 a shift of the mixing diagram with respect to the $\left(\frac{r_v}{r_{v0}}\right)^3 = 1$ line, as well as to a large variation

573 in mixing diagram shapes, unrelated, however, to the mixing type (e.g., Lehmann et al.,
574 2009).

575

576 **5. Discussion and conclusion**

577 This study extends the analysis of mixing performed in Pt3 where the diffusion-
578 evaporation equation served as the basis, the initial DSD were assumed monodisperse and
579 the cloud fraction was chosen as $\mu = 1/2$. In the present study, the analysis focuses on the
580 temporal and spatial evolution of initially polydisperse DSD and investigates mixing diagrams
581 obtained for narrow and wide initial DSD within a wide range of the cloud fraction values (0.1
582 - 0.95). It is shown that results of mixing and the structure of mixing diagrams depend on the
583 initial DSD shape. This finding indicates that mixing is a multi-parametrical problem that
584 cannot be determined by a single parameter (e.g. the Damköhler number as often assumed) or
585 even by two parameters (the Damköhler number and the potential evaporation parameters as
586 assumed in Pt3). The temporal changes of DSD and their moments during mixing are
587 calculated. Although DSD broaden, they tend to remain similar to the original DSD. The main
588 changes come from the cloud air dilution by the dry air, which leads to a decrease in droplet
589 concentration for all droplet sizes. The changes of DSD and its shape are minimum in the
590 initially cloud volumes, especially at significant cloud fractions. The droplet radii
591 corresponding to the DSD peak do not change anyhow significantly. In the initially dry
592 volumes, mixing and evaporation of penetrated droplets leads to a rapid increase in RH.
593 Consequently, large droplets penetrating these volumes do not change their sizes significantly.
594 As a result, the mean volume radius in these volumes rapidly increases and reaches the values
595 typical of cloud volumes, while LWC remains lower than in the cloud volume for most of the
596 mixing time. At narrow DSD, the mean volume (and effective) radius remains smaller than
597 that in the initially cloud volume. At wide DSD, the mean volume (and effective) radius may
598 become larger than that in the initial DSD. This increase in the effective radius is attributed to

599 the fact that evaporation of smaller droplets leads to the increase in the fraction of larger
 600 droplets in the DSD. In this study, and in Pt3 it is shown that mixing leads to DSD
 601 broadening. This contrasts with the classical theory, when initially monodisperse DSDs
 602 remain monodisperse in course of mixing. This problem is analyzed in detail in Pt 3. Note
 603 that in real clouds DSD there are many mechanism leading to DSDs broadening (e.g. Pinsky
 604 and Khain 2002).

605 Dependences of normalized cube of the mean volume radius on the cloud fraction
 606 $(r_v / r_{v0})^3$ as a function of μ at different time instances form the set of curves filling the entire
 607 $(r_v / r_{v0})^3 - \mu$ plane. Therefore, both the slope and the distance of these curves in respect to
 608 the horizontal line $(r_v / r_{v0})^3 = 1$ change with time. It means that this distance characterizes
 609 the temporal changes in the course of mixing, but not the mixing type (which remains
 610 inhomogeneous during the entire mixing time). The mixing process is comparatively long
 611 (several minutes), so the final equilibrium stage is hardly achievable in real clouds.

612 It is highly significant that the critical values of the cloud fraction μ_{cr} corresponding to
 613 total droplet evaporation are the same for any mixing type. It means that the curves in a
 614 mixing diagram corresponding to homogeneous and inhomogeneous mixing types should be
 615 compared only within the range of $\mu > \mu_{cr}$. The range width of $\mu > \mu_{cr}$ decreases with
 616 decreasing relative humidity in the initially dry volume. Taking into account significant
 617 scattering of observed points, this condition greatly hampers the problem of how to
 618 distinguish between mixing types,

619 Another important result of the study is that mixing diagrams for homogeneous and
 620 inhomogeneous mixing plotted for polydisperse DSD do not differ much. The largest
 621 difference takes place for initially narrow DSD (the maximum difference takes place for
 622 initially monodisperse DSD), but even in this case the difference is not large enough to
 623 reliably distinguish mixing type, owing the significant scatter of observed data. At wide DSD,

624 this difference between mixing diagrams for homogeneous and inhomogeneous becomes
625 negligibly small.

626 The cloud fraction μ is a predefined parameter and is not determined from observations.
627 Consequently, in the analysis of *in-situ* measurements the normalized droplet concentration is
628 typically used instead of the cloud fraction. However, there is a significant difference
629 between the cloud fraction prescribed a priori and the normalized droplet concentration that
630 changes due to total evaporation of some fraction of droplets. We have shown that the
631 utilization of normalized droplet concentration in mixing diagrams is not equivalent to the
632 utilization of the cloud fraction. The important conclusion is that when mixing diagrams are
633 plotted using the normalized concentration, the sensitivity to RH disappears. This conclusion
634 is valid even when RH in the initially dry volume is as low as 60%. This conclusion clearly
635 contradicts the wide-spread assumption that mixing types can be easily distinguished in
636 mixing diagrams in case of low relative humidity of the surrounding air.

637 In the present study as well as in Pt3 and modeling studies performed by Andrejczuk et al.
638 (2006, 2009), Khain et al. (2017) it is shown that time needed to establishing of equilibrium
639 either quite long or even never reached. It means that the scattering diagrams observed in situ are
640 just snapshots of the transient mixing process. In order to show how different are the equilibrium
641 and intermediate states we investigate the transition to such equilibrium assuming that the mixing
642 volume remains adiabatic (i.e. isolated) during the entire period of mixing. This is, of course, a
643 serious simplification made to compare the results with those predicted by classical concept.
644 Another simplification of the model is the neglecting the intermittency in the process of mixing
645 that takes place in real clouds.

646 To sum up, our general conclusion is that the simplifications underlying the classical
647 concept of mixing are too crude, making it impossible to use scattering diagrams for
648 comprehensive analysis of mixing and especially for determination of mixing types. At the

649 same time, scattering diagrams may contain useful information concerning intensity of
 650 mixing, the DSD width and other parameters of DSDs (see Khain et al., 2017).
