Abstract

Aerosol pollution in eastern China is an unfortunate consequence of the region's rapid economic and industrial growth. Here, sunphotometer measurements from seven sites in the Yangtze River Delta (YRD) from 2011 to 2015 were used to characterize the climatology of aerosol microphysical and optical properties, calculate direct aerosol radiative forcing (DARF), and classify the aerosols based on size and absorption. Bimodal size distributions were found throughout the year, but larger volumes and effective radii of fine-mode particles occurred in June and September due to hygroscopic growth and/or cloud processing. Increases in the fine-mode in June and September caused $AOD_{440nm} > 1.00$ at most sites, and annual mean AOD_{440nm} values of 0.71-0.76 were found at the urban sites and 0.68 at the rural site. Unlike north China, the $AOD_{440\ nm}$ was lower in July and August (~0.40–0.60) than in January and February (0.71–0.89) due to particle dispersion associated with subtropical anticyclones in summer. Low volumes and large bandwidths of both fine- and coarse-mode aerosol size distributions occurred in July and August because of biomass burning. Single scattering albedos at 440 nm ($SSA_{440\ nm}$) from 0.91 to 0.94, indicated particles with relatively strong to moderate absorption. Strongly absorbing particles from biomass burning with a significant SSA wavelength dependence were found in July and August at most sites while coarse particles in March to May were mineral dust. Absorbing aerosols were distributed more-or-less homogeneously throughout the region with absorption aerosol optical depths at 440 nm ~0.04-0.06, but inter-site differences in the absorption Angström exponent indicate a degree of spatial heterogeneity in particle composition. The DARF was -93 ± 44 to -79 ± 39 W/m^2 at the Earth's surface and ~ -40 W/m^2 at the top of the atmosphere (for the solar zenith angle range of 50 to 80 degrees) under cloud free conditions, which indicates cooling at the surface and top of the atmosphere. The fine-mode composed a major contribution of the absorbing particles in the classification scheme based on SSA, fine mode fraction, and extinction Angström exponent. This study contributes to our understanding of aerosols and regional climate/air quality, and the results will be useful for validating satellite retrievals and for improving climate models and remote sensing algorithms.

1. Introduction

Aerosols can have important effects on the Earth's climate over regional to global scales, but there are still uncertainties in the strengths and significance of these impacts (Hansen et al.2000; Solomon et al., 2007; Schwartz and Andreae, 1996). Aerosols affect the radiative balance of the Earth–atmosphere system by directly scattering and absorbing solar radiation (Charlson et al., 1992; Ackerman and Toon, 1981), and they can affect climate indirectly through aerosol–cloud interactions (Twomey et al., 1984; Albrecht et al., 1989; Li et al., 2016).

The physical and optical properties of aerosol particles determine their radiative effects, and information on these properties can be used to predict and assess global and regional changes in the Earth's climate (Eck et al., 2005; Myhre et al., 2009; IPCC, 2013; Panicker et al., 2013). Long-term, ground-based observations have contributed greatly to our understanding of the spatial variations in aerosols and their effects on the Earth's climate (Holben et al., 2001; Kaufman et al., 2002; Sanap and Pandithurai, 2014; Li et al., 2016). Ground-based monitoring networks have been established worldwide—for instance, AERONET (Aerosol Robotic Network) (Holben et al.,1998; Goloub et al., 2007), SKYNET (SKYrad Network) (Takamura et al., 2004), EARLINET (European aerosol Lidar network) (Pappalardo et al., 2014) and the GAW-PFR Network (Global Atmosphere Watch Programmer-Precision Filter Radiometers) (Wehrli, 2002; Estelles et al., 2012). In China, CARSNET (the China Aerosol Remote Sensing NETwork) and CSHNET (the Chinese Sun Hazemeter Network) were established to obtain data on aerosol optical characteristics (Che et al., 2009a, 2015b; Xin et al., 2007). High-frequency, ground-based measurements of aerosol optical properties made at these stations have improved our understanding of the sources, transport, and diurnal variations of air pollutants, and they have provide insights into the aerosols' effects on climate. Ground-based observations are also useful for the validation of satellite retrievals (Holben et al., 2017; Xie et al., 2011).

Most of the ground-based studies of the optical properties of aerosols in China have been conducted in urban regions that have been undergoing rapid economic development. Those

92 sites typically have had high aerosol loadings and in many cases serious environmental

93 problems (Cheng et al., 2015; Pan et al., 2010; Xia et al., 2013; Wang et al., 2015; Che et al.,

94 2015a). Detailed information on aerosol optical depth (AOD), the types of aerosols, and

95 especially the size and absorption properties of ambient populations over a wide sampling of

96 regions is needed to understand the effects of aerosols on the Earth's climate and the

97 environment (Giles et al., 2011; Che et al., 2009b; Wang et al., 2010; Zhu et al., 2014). In

98 particular, the aerosol direct radiative forcing is sensitive to the aerosol radiation absorptivity

99 (Haywood and Shine, 1995). Therefore, it is important to understand the connections between

100 the aerosol types and absorption properties because that information can be used for

101 comparisons and validation of chemical transport models and satellites (Lee et al., 2010).

102 The Yangtze River Delta (YRD) region in eastern China has recently undergone rapid

103 economic growth, and the loadings of aerosols in the region can be very high during heavy

104 pollution episodes (Fu et al., 2008; Zhang et al., 2009). Studies of aerosol optical properties in

105 eastern China have contributed to our understanding of local air quality and regional climate

106 impacts (Duan and Mao, 2007; Pan et al., 2010; Ding et al., 2016). In the YRD, investigations

107 of aerosol optical properties have been conducted in Nanjing, Hefei, Shanghai, Shouxian and

108 Taihu (Zhuang et al. 2014; Li et al., 2015; Wang et al., 2015; He et al., 2012; Lee et al., 2010;

109 Cheng et al., 2015; Xia et al., 2007). Those studies mostly involved sampling at single sites

110 ~100 km apart from one other without synchronous observations, and many have been of

111 relatively short duration, and so there remains a need for more extensive ground-based

112 measurements.

113 For the present study, sampling was conducted over a period of several years to better

114 characterize the climatology of the aerosol microphysical and optical properties, including

115 aerosol absorptivity, and to improve estimates of direct aerosol radiative forcing. For these

116 studies, sun photometer measurements were made at 3 min intervals from 2011 to 2015 at

117 seven CARSNET sites (one densely populated urban site, five urban center sites in smaller

118 cities, and one rural site) ~10–40 km apart in the YRD. The dense network of ground-based

119 sun- and sky-scanning spectral radiometers improves the temporal and spatial coverage of the

data, and that has enabled us to capture small-scale variations in the aerosols. The results not only contribute to our understanding of regional climate and local air quality impacts, but they also will be useful for validation of satellite data and improving the performance of models and remote sensing algorithms in the future.

This paper is organized as follows: Section 2 describes the sites, the methods used for retrieving the aerosol optical properties and their uncertainties, and the calculation of aerosol direct radiative forcing from the retrieved aerosol optical parameters. Section 3 presents the aerosol microphysical properties, optical properties, and calculations of direct radiative forcing. The aerosol type classification is also presented based on the aerosol optical parameters. Then a brief discussion is made about the analysis of this study. Section 4 is the conclusions.

2. Site descriptions, measurements and methods

Figure 1 shows the locations of the seven CARSNET sites of the YRD, and detailed information on the sites is included in Table 1. Hangzhou is a densely populated urban site with a heavy vehicular traffic, and it is affected by various types of anthropogenic emissions. LinAn, Fuyang, Jiande, Xiaoshan and Tonglu are urban center sites in smaller cities, and they are all affected to varying degrees by anthropogenic activities, especially pollutants from industries and agriculture. The rural site of ChunAn has a small population, and there are few industrial sources nearby so the effects from local or regional pollution are relatively small.
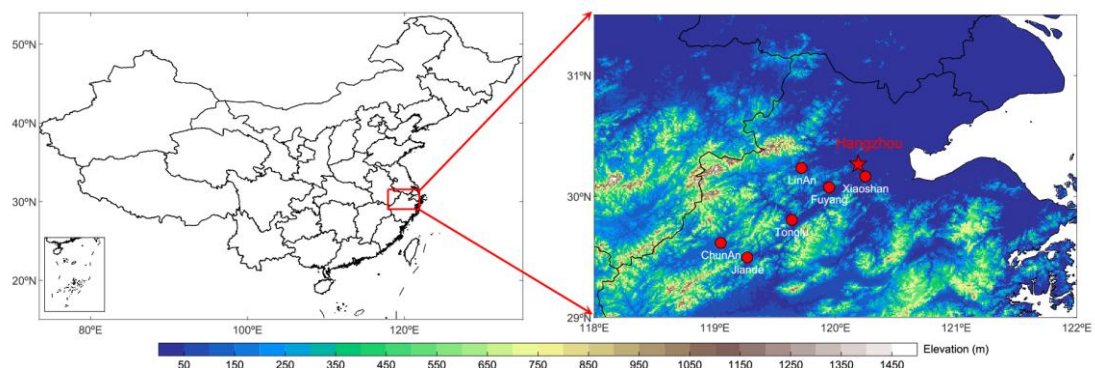

Figure 1. Locations and elevations of the seven CARSNET sites in the Yangtze River Delta.

Sun photometers (CE-318, Cimel Electronique, Paris, France) were installed at each of

5

the seven sites and operated from 2011 to 2015. These instruments were standardized and calibrated using CARSNET reference instruments (Che et al., 2009a), which in turn were periodically calibrated at Izaña, Tenerife, Spain in conjunction with the AERONET program. The cloud-screened AODs (based on the work of Smirnov et al. 2000) at 340, 380, 440, 500, 670, 870, 1020 and 1640 nm with uncertainties less than 0.01 (Eck et al., 1999) were obtained using ASTPwin software (Cimel Electronique). The water vapor expressed as precipitable water in the column was derived from the 940 nm channel with uncertainties less than 10% (Eck et al., 1999). Daily averages and statistical analysis were calculated for days on which instantaneous AOD measurements were made more than ten times (Che et al., 2015b). The extinction Angström exponent values (EAE) were calculated from AOD values at 440 and 870 nm.

Aerosol microphysical properties were retrieved from the almucantar sky irradiance measurements in conjunction with measured spectral AOD, following the methods of Dubovik and King (2000) and Dubovik et al. (2002, 2006). The dataset contained information on (1) volume size distributions in 22 size bins for particle radii 0.05–15 µm; (2) fine and coarse mode aerosol effective radii; and (3) aerosol optical properties—including the wavelength dependent single-scattering albedo (SSA), the complex refractive index, the absorption AOD (AAOD), and the absorption Angström exponent (AAE). For the retrieval process, the surface albedo (SA) was interpolated/extrapolated to 440, 670, 870, and 1020 nm from the daily Moderate Resolution Imaging Spectroradiometer (MODIS) surface reflectance product of MCD43C3 (https://ladsweb.modaps.eosdis.nasa.gov/). Following the procedures of Dubovik et al. (2002, 2006), all particles smaller than 0.6 µm were considered fine mode particles while those larger than 0.6 µm were considered coarse mode. And the effective radii for the total ($Reff_t$), fine ($Reff_{fine}$) and coarse ($Reff_{coarse}$) mode aerosols are calculated as follows:

$$R_{eff} = \frac{\int_{r_{min}}^{r_{max}} r^3 \frac{dN(r)}{dlnr} dlnr}{\int_{r_{min}}^{r_{max}} r^2 \frac{dN(r)}{dlnr} dlnr} \tag{1}$$

Where r_{min} is 0.05, 0.05, and 0.6 µm and r_{max} is 15, 0.6, and 15 µm for the total, fine and coarse mode aerosols, respectively.

168   The inversion algorithm used for calculating the aerosol volume distribution (dV/ln$r$)

169   assumed a homogeneous distribution of non-spherical aerosol particles as in the work of

170   Dubovik (2006); this approach has been widely applied in studies of many different areas of

171   the world. The SSA was retrieved using only $AOD_{440nm} > 0.40$ measurements to avoid the

172   large uncertainties inherent in low AOD retrievals (Dubovik et al. 2002, 2006). Real and

173   imaginary parts of refractive index at 440, 675, 870, and 1020 nm were constrained to the

174   ranges of 1.33–1.60 and 0.0005–0.50, respectively (Dubovik and King, 2000; Che et al.,

175   2015b). The AOD, AAOD, and AAE are related to one another as shown in equations (2) and

176   (3):

$$AAOD(\lambda) = [1 - SSA(\lambda)] \times AOD(\lambda) \qquad (2)$$

$$AAE = -d\ln[AAOD(\lambda)]/d\ln(\lambda) \qquad (3)$$

179   The inversion algorithms mentioned above have been used for AERONET and CARSNET,

180   and the accuracies of the volume size distribution were 15-25% for 0.1 µm $\leq$ r $\leq$ 7.0 µm and

181   25-100% for r < 0.1 µm and r >7µm. The accuracies for both AOD and AAOD are ~0.01. The

182   errors for the total, fine and coarse mode SSA are about 0.030, 0.037 and 0.085, respectively.

183   The imaginary and real parts of the complex refractive index for the AOD at 440 nm > 0.40 and

184   a solar zenith angle > 50° have errors of ~0.0025–0.0042 and 0.04, respectively (Dubovik et

185   al., 2000; Li et al., 2015a).

186   The direct aerosol radiative forcing (DARF) values in units of W/m^2 were calculated using

187   the radiative transfer module in the AERONET inversion (García et al., 2008; 2012) under the

188   assumption of cloud-free conditions. The DARF (ΔF) is defined as the difference in the net

189   shortwave radiative fluxes between the two energy levels including and excluding aerosol

190   effects at the Earth's surface (bottom of the atmosphere, BOA) and the top of the atmosphere

191   (TOA) in equations (4) and (5) as follows:

$$\Delta F_{TOA} = F_{TOA}^{\uparrow 0} - F_{TOA}^{\uparrow} \qquad (4)$$

$$\Delta F_{BOA} = F_{BOA}^{\downarrow} - F_{BOA}^{\downarrow 0} \qquad (5)$$

194   where F and F^0 represent the broadband fluxes with and without aerosols at BOA and TOA,

195   respectively. The arrows in these equations indicate the direction of the fluxes for the

196   downward and upward cases. Defined this way, a negative value for ΔF indicates aerosol

197   cooling effects while positive values imply warming, both at the BOA and the TOA.

198   In the radiative transfer module used here, the flux calculations accounted for absorption

199   and multiple scattering effects using the Discrete Ordinates (DISORT) approach (Stamnes et

200   al., 1988; Nakajima and Tanaka, 1988). The solar broadband fluxes from 0.2 to 4.0 μm were

201   simulated by using information on aerosol properties (size distribution, spectral AOD, SSA,

202   and phase function) obtained from the ground-based measurements. The spectral refractive

203   indices (both real and imaginary parts) were interpolated/extrapolated from the values

204   retrieved at four distinct wavelengths (440, 670, 870, 1020 nm) from the ground-based sun

205   photometers. Likewise, the spectral dependence of surface reflectance was

206   interpolated/extrapolated from surface albedo values used in the aerosol property retrieval

207   process for the same wavelengths.

208   The integrated effects of atmospheric aerosol scattering and absorption, gaseous

209   absorption, and molecular scattering and underlying surface reflection effects were evaluated

210   using the Global Atmospheric ModEl (GAME) code (Dubuisson et al., 1996; Roger et al., 2006).

211   In the GAME code, gaseous absorption (mainly H_2O, CO_2, and O_3), is calculated from the

212   correlated k-distribution (Lacis and Oinas, 1991). The instantaneous column water vapor

213   content was retrieved by the absorption differential method from the 0.94 mm channel

214   (Smirnov et al., 2004). The total ozone content was taken from monthly climatology values

215   based on the Total Ozone Mapping Spectrometer (TOMS) measurements. The GAME model

216   accounts for spectral gaseous absorption; that is, ozone in the ultraviolet-visible spectral range

217   (0.20–0.35 μm and 0.5–0.7 μm) and water vapor in the shortwave infrared spectrum (0.8–3.0

218   μm).

219   The flux calculations were performed for a multi-layered atmosphere with the US standard

220   1976 atmosphere model for gaseous distributions and single fixed aerosol vertical distribution

221   (exponential with an aerosol height of 1 km) (Gacia et al., 2008). As these authors have

222 pointed out, solar fluxes calculated using the module described above show excellent

223 agreement with ground-based measurements of solar radiation (slope of 0.98 ± 0.00 and bias

224 of -5.32 ± 1.00 W/m^2) with a correlation of 99%. There is a small overestimation of +9 ± 12

225 Wm^{-2} of the observed solar radiation at the surface in global terms, and this corresponds to a

226 relative error of +2.1 ± 3.0%. The differences range from +14 ± 10 Wm^{-2} to +6 ± 13 Wm^{-2} for

227 urban-industrial and biomass burning aerosols, respectively. The errors are expected to be of

228 the same magnitude at the TOA, since the same methodology and inputs are used at both

229 levels (gaseous and aerosol distribution, radiative model, etc).

230 **3. Results and discussion**

231 **3.1 Aerosol microphysical properties: particle radius and volume size distributions**

232   Figure 2 shows the monthly aerosol size distribution (dV/dln$r$) for all seven sites in the

233 YRD. The annual mean values for the effective radii of the total particles (R$_{efft}$) were ~0.30 μm,

234 and the average annual volume was ~0.18 μm^3/μm^2 (Table 1). The fine-mode effective radii

235 averaged ~0.16 μm in the YRD with a fractional volume of 0.10–0.11 μm^3/μm^2 while the

236 coarse-mode average effective radii were ~2.2 μm with a fractional volume ~0.08 μm^3/μm^2.

237 These results show that there was a larger contribution of fine-mode particles to the aerosol

238 volume compared with the coarse mode at all sites. The total and fine-mode aerosol volumes

239 and effective radii showed small differences from the densely populated urban site (Hangzhou),

240 to the urban center sites in smaller cities (Xiaoshan, Fuyang, LinAn, Tonglu, Jiande) or the

241 rural site (ChunAn), and this reflects a generally homogeneous distribution of the aerosol in the

242 YRD. The coarse-mode aerosol volumes also showed small differences among site, but the

243 range of effective radii was greater, possibly due in part to the lower retrieval accuracy for

244 coarse particles compared with the fine-mode.

245   Higher volumes and larger effective radii of the fine-mode were observed in June and

246 September at most sites, and again there were relatively small differences among sites; the

247 exception was Xiaoshan where the month-to-month differences in these variables were less

248 pronounced (Fig. 2). The increases in submicron particles during the summer may have been

9

caused in part by the hygroscopicity of the aerosols. In this regard, Saha et al. (2004) reported the volume of accumulation mode particles increased faster than the coarse-mode under high relative humidity conditions. At our sites, the precipitation in June and September was greater than in the other months because of the "Meiyu flood period" and the "typhoon and autumn rain period", respectively. Indeed, the major aerosol components, which include sulfate, nitrate, ammonium, and organic compounds, can cause severe haze-fog events during high relative humidity conditions. Fine particles containing sulfate, nitrate, and ammonium are hygroscopic, and their sizes are strongly affected by the relative humidity (Fu et al., 2008; Shen et al., 2015; Li et al., 2015b; Huang et al., 2016). Additionally, broad fine-mode distributions may result from the occurrence of fog or low-altitude cloud dissipation events (Eck et al. 2012; Li et al., 2010, 2014). Eck et al. (2012) also pointed out that a large range of fine-mode aerosol sizes may result from cloud processing, and that also could contribute to a shoulder of larger size particles in the accumulation mode, especially in regions where sulfate and other water-soluble aerosols exist. Another interesting observation is that the fine-mode aerosol volume in July was relatively low at all sites, and is coincident with lower relative humidity in July (~60%) compared with that in June (~80%) in the YRD. Therefore, the hygroscopic effects on fine particles in July evidently are not as obvious as in June or September.

High volumes for coarse-mode aerosol occurred in March to May at all sites, and this suggests that more large particles occurred in spring than in the other seasons. The most likely explanation for this is the presence of mineral dust in the YRD region at that time of year. High PM_{10} mass concentrations of Hangzhou during 2012-2015 showed 78.5 ± 15.4, 84.7 ± 11.3, and 83.6 ± 15.5 μg/m^3 in March, April, and May, respectively (see the supplement), which is consistent to the results of relative large coarse-mode aerosol volumes in this study. As Cao et al. (2009) pointed out, fugitive dust can account for about one-third of PM_{10} mass concentration in Hangzhou, and that mainly came from re-suspended road dust and construction soil. The long-range transportation of dust in spring from northern/northwestern China could also contribute to the high coarse-mode aerosol volume. For instance, Fu et al. (2014) and Sun et al. (2017) found that dust particles could be transported long distances, and the impacts were apparent in the YRD. Low volumes and large bandwidths of coarse-mode

278   aerosol were found in July and August at all sites, and that may have been due to the wet

279   removal of coarse particles by the heavy precipitation in June. In July and August, strong

280   convection associated with subtropical anticyclone can disperse the aerosol. These results

281   also are consistent with previous reports showing minimum PM_{10} concentrations in summer of

282   the YRD region (Cao et al., 2009). It was found the PM_{10} mass concentrations of Hangzhou

283   during 2012-2015 were relative low with values 53.2 ± 6.8, and 56.7 ± 4.4 $\mu g/m^3$ in July and

284   August, respectively (see the supplement) Sun et al. (2013) found that aerosol size

285   distributions can broaden under unstable weather conditions, and in July and August, the

286   Weather in the YRD can become unstable due to the high temperatures, and this could be

287   another factor that contributed to the large bandwidth of both fine- and coarse-mode particles

288   in our study. However, these possible connections should be re-visited in the future.
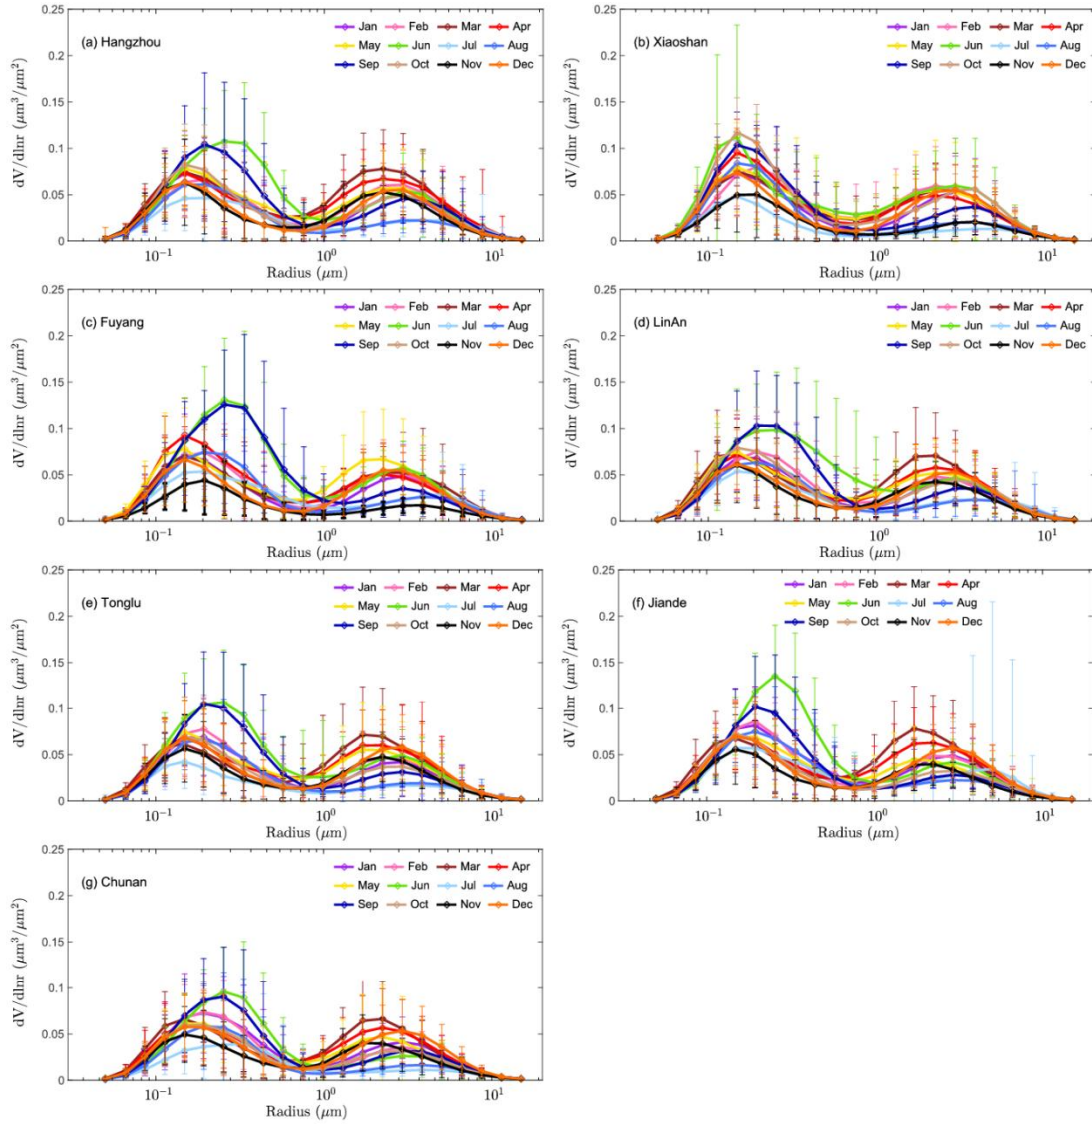

Figure 2.Temporal variations in the aerosol volume-size distributions at (a) Hangzhou, (b) Xiaoshan, (c) Fuyang, (d) LinAn, (e) Tonglu, (f) Jiande and (g) ChunAn.

3.2 Aerosol optical properties: AOD and EAE

The arithmetic mean annual values for AOD_{440nm} at the six urban sites (Hangzhou, Xiaoshan, Fuyang, LinAn, Tonglu, Jiande) were 0.71-0.76 and 0.68 at the rural site of ChunAn (Table 1). The difference in AOD between urban and rural sites was <10%, and this indicates there were widespread anthropogenic impacts on the aerosol populations in the YRD and that the high particle concentrations extend beyond the local to the regional scale. Nonetheless, the AOD_{440nm} generally decreased from the east coast to inland areas towards the west (0.76

12

at Hangzhou, 0.73 at LinAn, 0.71 at Jiande, and 0.68 at ChunAn), and this can be explained by stronger anthropogenic impacts in the more urbanized east. The high AOD_{440nm} at Hangzhou was likely the result of the greater industrial activity and higher population density in the eastern part of that metropolitan region; both of those factors could lead to larger aerosol emissions compared with the less populated urban and rural sites. The coarse-mode AOD values were just ~0.06 to 0.08, and ratios of the fine-mode $AOD_{440\ nm}$ to the total $AOD_{440\ nm}$ varies from 0.89-0.91 at the sites, and therefore, fine-mode particles clearly were the main contributors to light extinction in the region. The less coarse mode fraction of total aerosol extinction (~10%) indicated that the contribution of coarse particles to aerosol loading in the YRD region is not as obvious as in other north/northeast China region (Zhang et al., 2012).

Table1.Geographical location and annual arithmetic mean optical parameters for aerosols from seven sites in the Yangtze River Delta.

318

319   Unlike one peak $AOD_{440\ nm}$ distribution found in June–August over northern and
320   northeastern China (Che et al., 2015), the monthly averaged AODs at 440 nm at all seven
321   sites showed two peaks, one in June and the other in September (Fig.3) with mean values of
322   ~1.26 ± 0.50 (FMF ~ 0.93) and ~1.03 ± 0.57 (FMF ~ 0.95), respectively. Low $AOD_{440\ nm}$
323   values of ~0.40 - 0.60 were found in July and August throughout the region, and these low
324   values are consistent with the discussion above concerning aerosol microphysical
325   characteristics. That is, hygroscopic effects and/or cloud processing of fine-mode aerosol
326   particles caused greater extinction in June and September compared with July and August.
327   Zhang et al. (2015) reported the hygroscopic particles under high relative humidity conditions
328   could cause strong aerosol light scattering in the Yangtze River Delta. Other meteorological
329   factors also may have played a role in the variations in $AOD_{440\ nm}$ during summer because in
330   July and August, subtropical high-pressure systems prevail, and the planetary boundary layer
331   (PBLH) at Hangzhou is deep, ~1.5–2.0 km (Sun et al., 2017). The large PBLH associated with
332   subtropical anticyclone favor aerosol dispersion, and this can help explain the relatively low
333   aerosol extinction observed in July and August. In January and February, high $AOD_{440\ nm}$
334   values (0.71-0.89) were observed at all sites, and this can be attributed to emissions from
335   residential heating and the stability of the atmosphere, which can cause the near surface
336   accumulation of aerosol particles. The high $AOD_{440\ nm}$ values in winter also are consistent with
337   studies by Cao et al. (2009) who reported that the PM_{10} mass concentrations at Hangzhou
338   were highest in winter. According to the PM_{10} mass concentration measurements during
339   2012-2015 at Hangzhou, it was found that the PM_{10} mass concentrations was about 82.2 ± 9.5,
340   59.1 ± 6.0, 82.8 ± 13.9, and 92.3 ± 14.3 μg/m^3 in spring, summer, autumn, and winter,
341   respectively (see the supplement).

342   The extinction Angström exponent (EAE = -$d$ln[EAOD($λ$)]/$d$ln($λ$)) can be regarded as an
343   indicator of aerosol size; that is, $EAE_{440\ nm-870\ nm}$ > 1.00 typically indicates that the aerosol
344   particles are small. The mean extinction Angström exponent at all seven CARSNET sites was
345   higher than 1.20 throughout the year (Table 1), which means that small particles were
346   predominant. This finding is consistent with the reported dominance of small particles from
347   anthropogenic emissions and agricultural activity in the region (Tan et al., 2009).

348
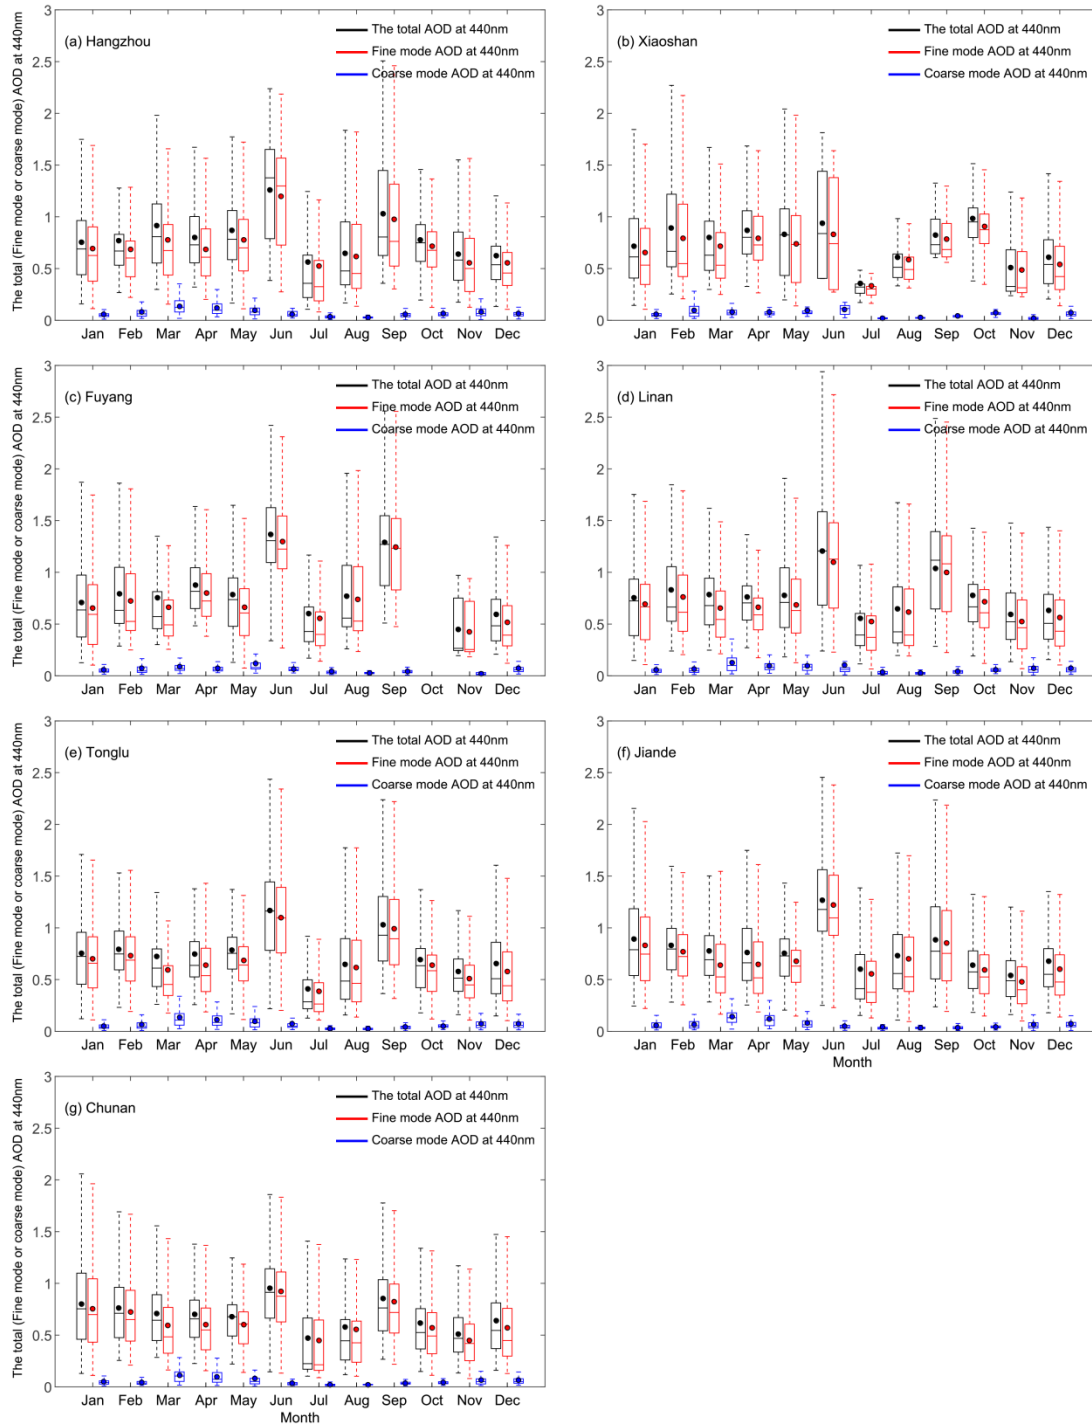

Figure 3. Variations in the total, fine- and coarse-mode $AOD_{440\ nm}$ at (a) Hangzhou, (b) Xiaoshan, (c) Fuyang, (d) LinAn, (e) Tonglu, (f) Jiande and (g) ChunAn. The boxes represent the 25th to 75th percentiles of the distributions while the dots and solid lines within each box represent the means and medians, respectively.
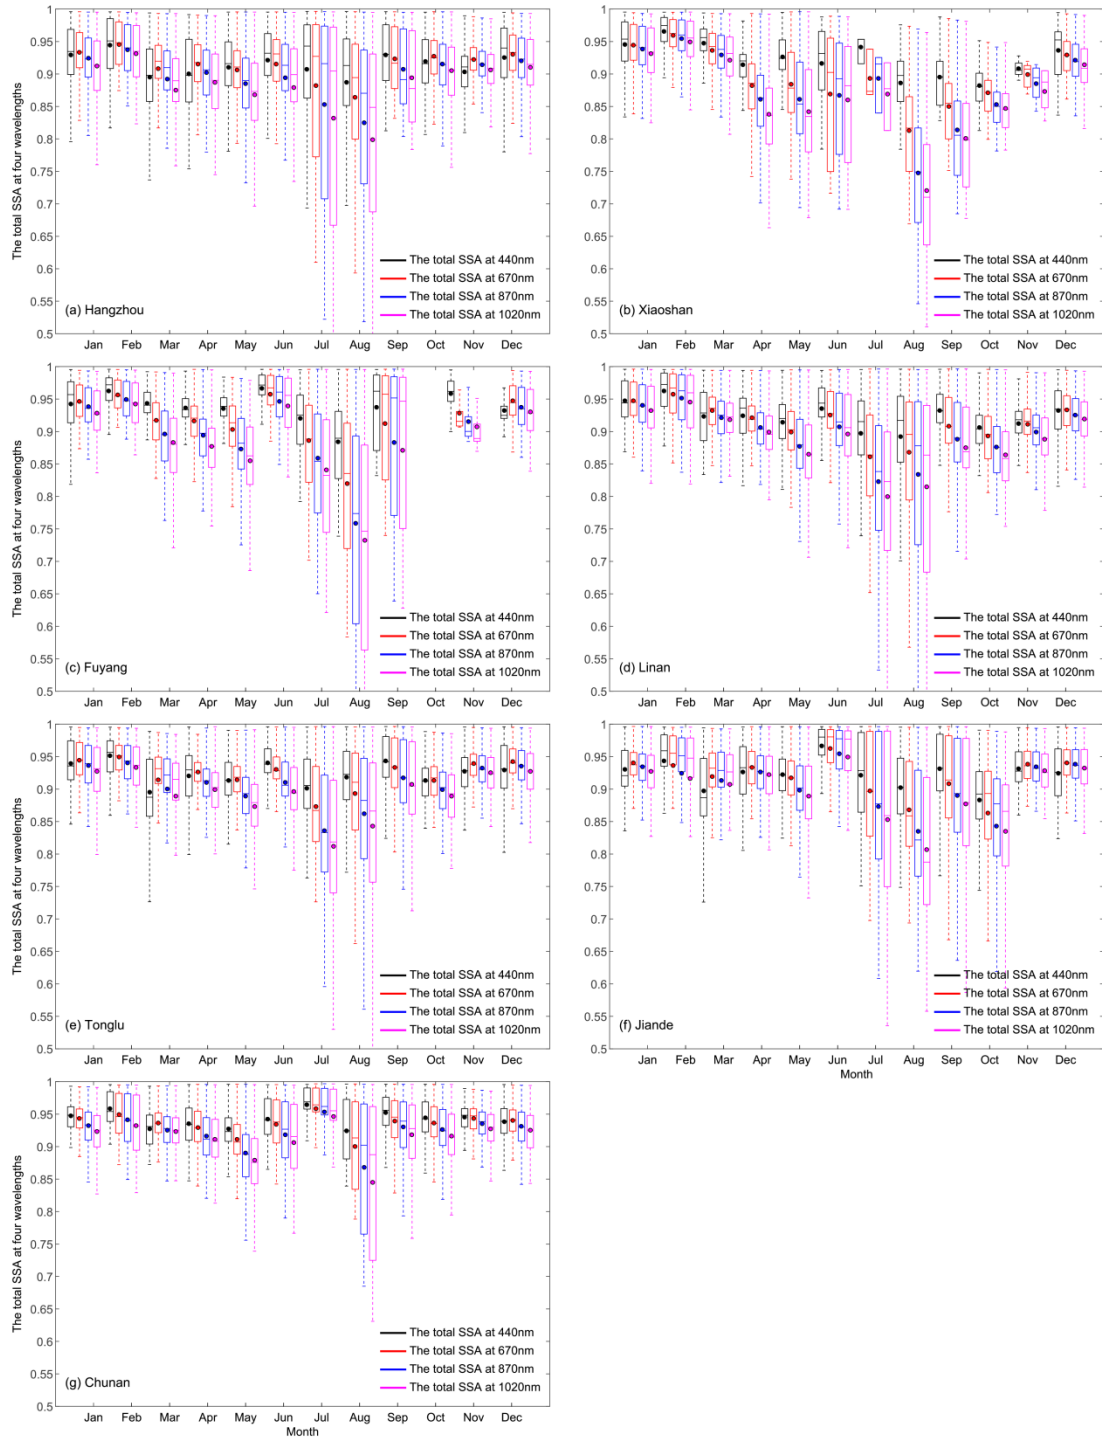

3.3 Aerosol optical properties: single-scattering albedo

354   The SSAs at 440 nm at our seven sites in YRD region varied from 0.91 to 0.94 (Table 1),

355   and boxplots of the monthly SSAs at wavelengths of 440, 670, 870 and 1020 nm are shown in

356   Figure 4. Eck et al. (2005) reported that the SSAs at 440 nm from AERONET retrievals were

357   confined to a relatively narrow range of values globally from ~0.82 to 0.98. Therefore, the SSA

358   values in this study may be explained by moderately to strongly absorbing aerosols from

359   industrial emissions and other anthropogenic sources. The $SSA_{440\ nm}$ at Hangzhou site was

360   0.91 ± 0.06, which is lower than that at the rural ChunAn site (0.94 ± 0.03). As Dubovik et al.

361   (2000, 2002, 2006) reported, the SSA depends on two factors—particle size and composition.

362   From Table 1, one can see that the differences in effective radii for total, fine and coarse mode

363   particles between Hangzhou and ChunAn are quite small, and therefore, the differences in

364   SSAs between the two sites can best be explained by differences in composition. Furthermore,

365   the differences in SSAs between these sites indicate that there was a higher percentage of

366   absorbing aerosols at urban site than the rural one.

367   The SSAs for seven sites showed significant month-to-month variations. The increased

368   scattering (light-absorbing) effects seen in June can be attributed to hygroscopic growth, which

369   can modify aerosol properties greatly (Xia et al., 2007). The presence of light-absorbing dust

370   aerosols in spring and absorbing aerosols from biomass burning in August were probably

371   responsible for the differences in SSA values observed between those months because of the

372   distinct differences in the intensive optical properties of dust and biomass burning products

373   (Yang et al., 2009). At Hangzhou, the monthly average SSA values at 440 nm were relatively

374   high in February (~0.94 ± 0.05) and June (~0.92 ± 0.06) and more moderate in March (~0.90 ±

375   0.06) and August (~0.89 ± 0.09). In comparison, the differences in monthly SSA values at the

376   rural ChunAn site were smaller, only varying from 0.92 to 0.95. We conclude from the temporal

377   patterns of the SSAs that the types of aerosols at the urban/suburban sites were more variable

378   than at the rural sites.

379   The SSA wavelength dependence is a function of the specific absorption/scattering

380   properties of different aerosol types (Sokolik and Toon, 1999; Eck et al., 2010). The SSA for

381   mineral dust particles typically shows a strong wavelength dependence from 440 to 1020 nm

382   with a low value at 440 nm due to iron oxide absorption (Cheng et al., 2006; Dubovik et al.,

383   2002). In spring, especially in March, the SSA was obviously lower at shorter wavelengths than

384   at the longer ones, and this implies absorption by dust particles. This conclusion is consistent

385   with the discussion above concerning the impact of dust on aerosol size distributions. In

386   addition, there was a significant decrease in SSA at shorter wavelengths in July and August at

387   most sites, and this supports the presence of aerosol particles with strong absorption,

388   especially at infrared wavelengths. The decreases in those months can be explained by

389   strongly absorbing aerosols from biomass burning or possibly industrial emissions. As Ding et

390   al. (2013a, b) and Wang and Zhang (2008) have reported, plumes from agricultural burning

391   typically contain light-absorbing carbonaceous aerosols, and these pollutants can seriously

392   impair air quality. Indeed, aerosols from biomass burning were more than likely responsible for

393   the low in SSAs found in our study during July and August.

394

Figure 4. Variations in the single scattering albedo at 440, 670, 870, and 1020 nm at (a) Hangzhou, (b) Xiaoshan, (c) Fuyang, (d) LinAn, (e) Tonglu, (f) Jiande and (g) ChunAn. See Figure 3 for an explanation of the symbols.

3.4 Aerosol optical properties: AAOD and AAE

399   The AAODs at 440 nm at the seven sites were similar ~ 0.04-0.06 (Fig. 5a and Table 1),

400   and therefore, absorbing aerosols apparently were widely distributed throughout the YRD.

401   There were large uncertainties in the $AAOD_{440\ nm}$, however; in fact, the standard deviations

402   (0.03 to 0.05) were comparable to the means, and this reflects the large temporal variability in

403   absorbing aerosol particle loadings. The average $AAOD_{440\ nm}$ at Hangzhou was about 0.02

404   higher than that at ChunAn, and this shows that the relative proportion of absorbing particles at

405   the urban area was larger than at the rural site, presumably due to greater anthropogenic

406   emissions. From Fig. 5, one can see that the monthly $AAOD_{440\ nm}$ at the urban sites from

407   March to November usually exceeded 0.05, which implies there were more absorbing species

408   in spring and autumn compared with winter (December to February) when the $AAOD_{440\ nm}$

409   tended to be lower, < 0.05. This result suggests that the relative abundances of light-absorbing

410   particles were lower in winter compared with other seasons, and this is different from many

411   regions in northern China where the AAODs are highest in winter due to the emission of

412   absorbing particles from residential heating and other sources (Zhao et al., 2015). At the

413   ChunAn, the variations in AAODs were smoother than the more heavily impacted urban sites,

414   and the monthly mean AAODs at ChunAn were < 0.05 throughout the year.

415   The AAE can be viewed as an indicator of the type of dominant absorbing aerosol

416   particles, which include black carbon, organic matter, and mineral dust (Giles et al., 2012).

417   Generally, an AAE < 1 indicates mixing, coating, and coagulation of black carbon with organic

418   and inorganic materials; an AAE close to 1 indicates absorbing black carbon aerosols from the

419   fossil fuel burning; and an AAE >1.10 indicates absorbing aerosols mainly from the biomass

420   burning or mineral dust (Russell et al., 2010; Bergstrom et al., 2007; Lack and Cappa, 2010).

421   The annual mean AAEs at Hangzhou, Xiaoshan, Fuyang, LinAn, Tonglu, Jiande and ChunAn

422   were 1.13 ± 0.46, 0.88 ± 0.42, 0.85 ± 0.43, 0.98 ± 0.35, 1.11 ± 0.49, 1.16 ± 0.44 and 0.93 ±

423   0.31, respectively (Table 1), and for discussion purposes, the seven sites were grouped into

424   three categories based on their average AAEs. The mean AAE values at Xiaoshan and

425   Fuyang were < 1.00, which suggests that coated black carbon particles dominated at these

426   two sites. However, this also could be due to measurement uncertainties due to smaller

427   numbers of samples from those sites or to slightly larger values of the imaginary part of the

428 refractive index at longer wavelengths for certain particles (Bergstrom et al., 2007). There

429 would need to more observations to confirm the low AAEs at these two sites.

430 The AAE values ~1.00 at LinAn and ChunAn indicate that the absorbing aerosol

431 population was mainly composed of black carbon from fossil fuel burning. LinAn has a more

432 developed economy compared with Tonglu and Jiande, and in comparison, LinAn has many

433 more motor vehicles and is more heavily impacted by industrial emissions and fossil fuel

434 combustion. In contrast, the ChunAn site is located in the Qiandao Lake National Water

435 Resources Protection Zone where biomass burning and industrial activities are banned. Thus,

436 emissions from motor vehicles are probably the main source of absorbing carbon aerosols at

437 ChunAn. Finally, the AAE values at Hangzhou, Tonglu and Jiande were > 1.10, indicating a

438 predominance of light-absorbing aerosols from either biomass burning or mineral dust.

439 Hangzhou has a population of ~10 million and more than one million vehicles, and the city can

440 be impacted by fugitive dust and biomass burning emissions (Cao et al., 2009). Tonglu and

441 Jiande have small economies compared with Hangzhou, but there is more agricultural

442 production near those two sites, and they can be impacted by biomass burning. These

443 inter-site differences in the AAEs reflect a degree of spatial heterogeneity in the

444 distributions of absorbing aerosols even though the AODs were relatively similar, and these

445 differences likely result from the many types of emission sources that can impact the sites.
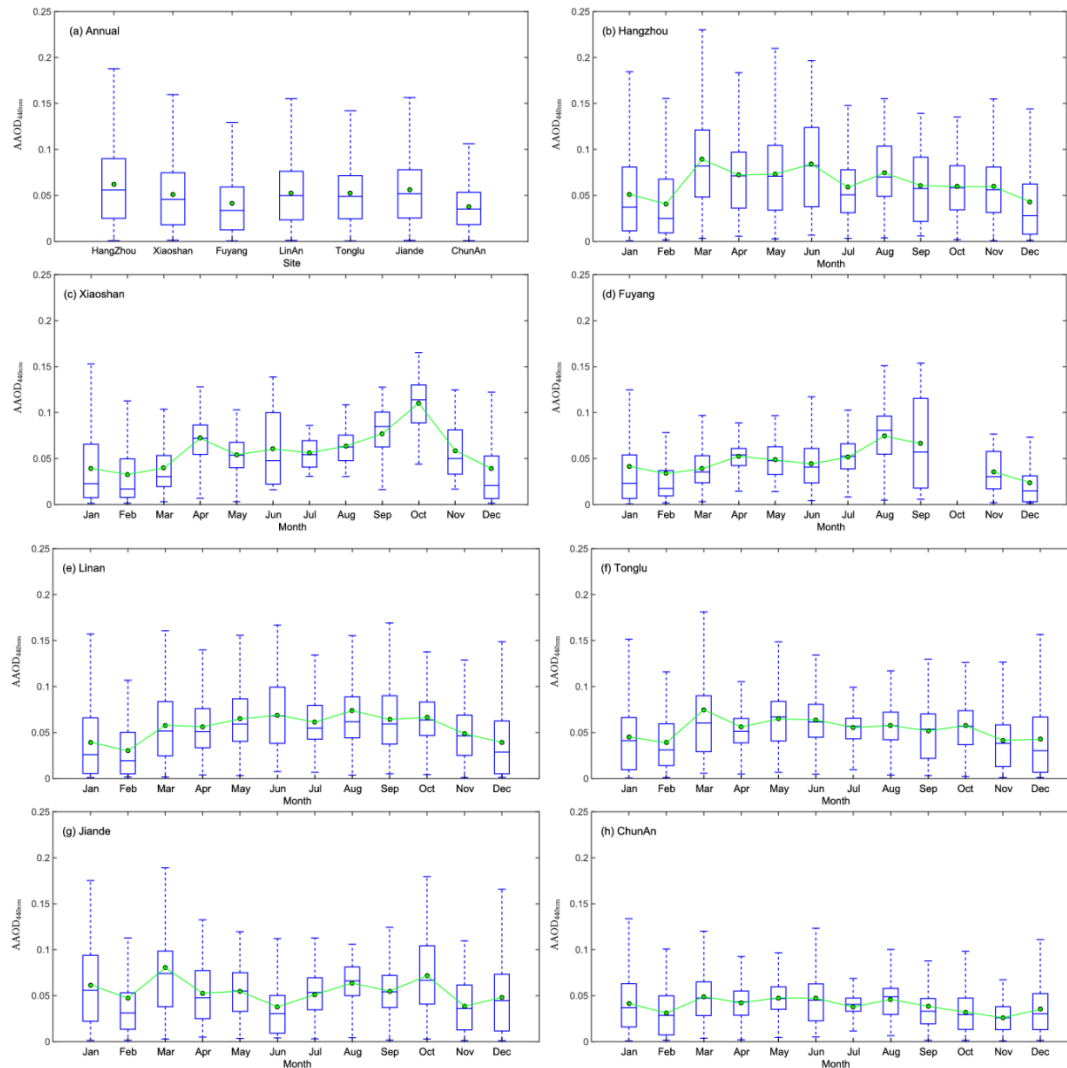

Figure 5. (a) Annual average absorption aerosol optical depths at 440 nm (AAOD$_{440\ nm}$) at the CARSNET sites and month-to-month variations in AAOD$_{440\ nm}$ at (b) Hangzhou, (c) Xiaoshan, (d) Fuyang, (e) LinAn, (f) Tonglu, (g) Jiande and (h) ChunAn. See Figure 3 for an explanation of the symbols.
3.5 Direct Aerosol radiative forcing at the Earth's surface and TOA

In this study, only clear sky direct aerosol radiative forcings could investigated because the aerosol microphysical and optical parameters were derived from ground-based retrievals under free cloud conditions. For the direct aerosol radiative forcing calculations, the solar fluxes are only evaluated for solar zenith angles (SZA) between 50º and 80º, which is where the solar geometry conditions are the most appropriate for retrieving the aerosol properties

457 (Dubovik et al., 2000, 2002).

458 The annual direct DARF-BOA values under clear conditions for Hangzhou, Xiaoshan,

459 Fuyang, LinAn, Tonglu, Jiande and ChunAn were -93 ± 44, -84 ± 40, -80 ± 40, -81 ± 39, -79

460 ± 39, -82 ± 40 and -74 ± 34 W/m^2, respectively (Figure 6a). The DARF-BOA at Hangzhou was

461 ~ -20 W/m^2 lower than that at the rural ChunAn site. The DARFs at the Earth's surface and

462 TOA are governed by the aerosol microphysical and optical properties, primarily particle size

463 distributions, AODs and SSAs. The large negative DARF-BOA values at Hangzhou can be

464 attributed to the high aerosol extinction ($AOD_{440\ nm} \sim 0.76$) and small absorption (SSA at 440

465 nm ~0.91). These calculations indicate that effects of those particles on radiative fluxes can

466 cause significant surface cooling at that urban site. In comparison, at the rural ChunAn site,

467 less negative DARF-BOA values result from lower aerosol extinction ($AOD_{440\ nm} \sim 0.68$) and

468 higher scattering ($SSA_{440\ nm} \sim 0.94$).

469 The monthly DARF-BOA at the seven sites was most strongly negative in June, followed

470 by March and September. The strong cooling effect at the surface in June was due to the high

471 aerosol extinction (in section 3.2) and in particular the high volumes of fine-mode particles as

472 shown in Fig.2. Weakly absorbing particles with $SSA_{440\ nm}$ ~0.90-0.95 (Fig.6) also would

473 reduce the flux of solar radiation to the surface. A large surface cooling effect also was found in

474 March and April. Although the AOD in spring was lower than in winter, there were more

475 strongly absorbing aerosols with relatively smaller SSAs at shorter wavelengths then, and this

476 can be attributed to the presence of mineral aerosol particles. These coarse mode particles

477 with high volumes and large radii are common in spring (see section 3.1), and they can absorb

478 and scatter solar radiation and in so doing cool the surface. Surface cooling in September can

479 be explained by high aerosol extinction that resulted from the high volumes of weakly

480 absorbing fine-mode particles ($SSA_{440\ nm}$ ~0.90-0.95). These results indicate that the

481 attenuation of the solar radiation by the aerosols leads to significant surface cooling over the
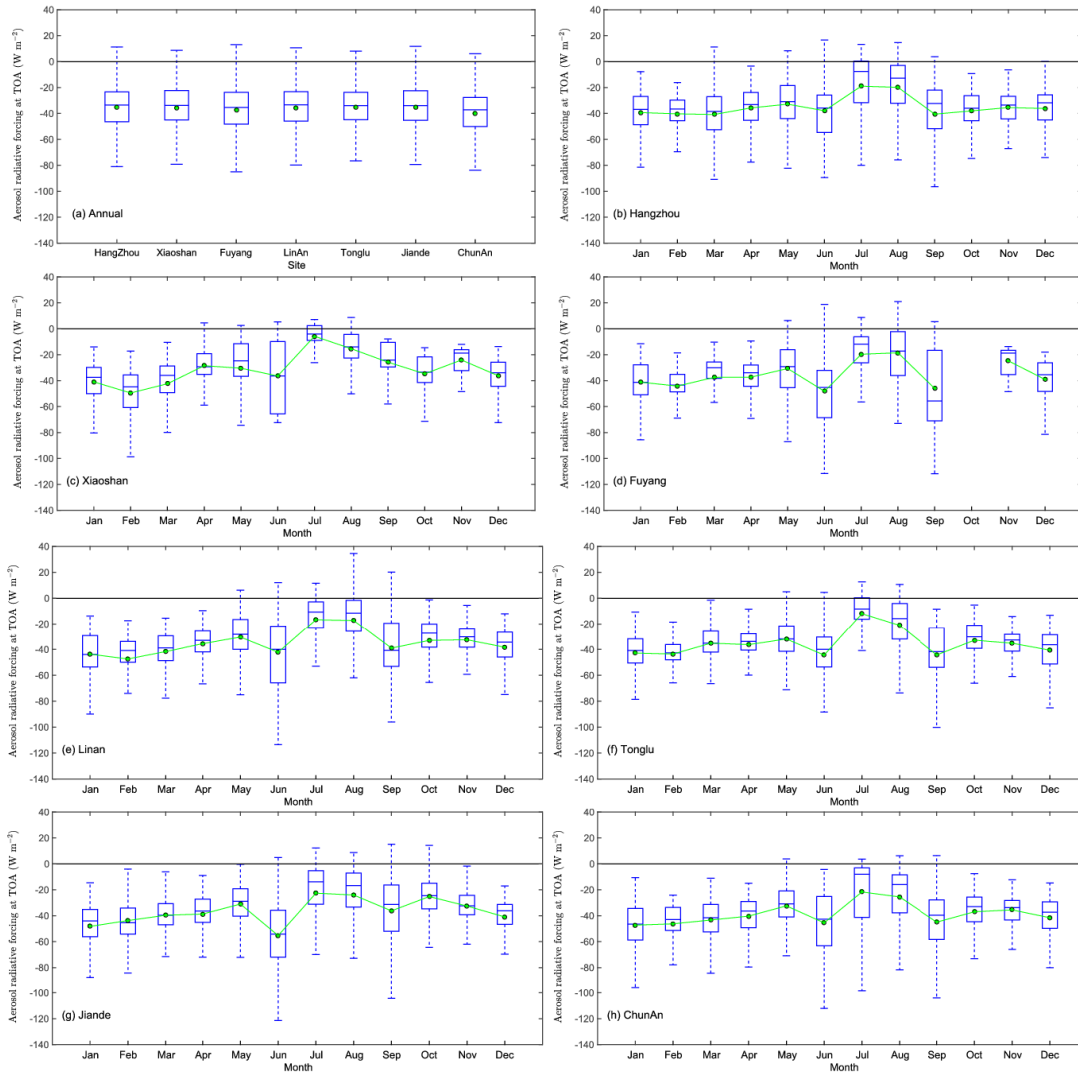

482 YRD.

Figure 6. (a) Annual variations of monthly mean direct aerosol radiative forcing (50-80 degrees SZA) at the bottom of the atmosphere over (b) Hangzhou, (c) Xiaoshan, (d) Fuyang, (e) LinAn, (f) Tonglu, (g) Jiande and (h) ChunAn. See Figure 3 for an explanation of the symbols.

The DARF-TOA mean values under clear conditions were < −40 W/m^2 at all sites (Figure 7a), and these negative DARF-TOA values indicate that the aerosols caused cooling whole earth-atmosphere system in the YRD. This is different from the case in north/northeastern China where the instantaneous DARF-TOA value can be positive in winter due to the high surface reflectance of short wavelength radiation combined with atmospheric heating caused by absorbing aerosols (Zhao et al., 2015, Che et al., 2014).

The monthly DARF-TOA means under clear conditions varied smoothly during two

25

periods: (1) from January to May, (2) from October to December (Fig. 7). The DARF-TOA values were found approximate -40 W/m^2 at all sites in above two periods. However, the monthly DARF-TOA means in June and September exceeded -40 W/m^2 at most sites, which indicated more cooling effects on the whole earth-atmosphere system due to large aerosol extinctions in YRD. The DARF-TOA means were about −20 W/m^2 at the seven sites in July/August, which suggests weak cooling at that time. In contrast, the DARF-TOA values under clear conditions at Shenyang (urban area of Northeastern China), Beijing (urban area of Northern China), and Xianghe (rural area of Northern China) showed the negative peak during June to August due to the large aerosol extinctions in summer season (Zhao et al., 2015; Xia et al., 2016). As noted in section 3.3, the SSA was low in July and August, and that was attributed to absorbing particles from biomass burning. Ding et al. (2016) found that large quantities of black carbon can be emitted from biomass burning in the YRD during the summer, and because these particles strongly absorb at infrared wavelengths, they can cause heating up the atmosphere and resulting in lower negative ARF-TOA. Indeed, the positive DARF-TOA we found under clear conditions from April to October were mainly due to the effects of strongly absorbing particles; that is, the SSAs at 440 nm were < 0.80, and they showed a strong decrease with wavelength (not shown here) when DARF-TOA values were positive. Moreover, strongly absorbing aerosol particles can heat the atmosphere column and the TOA at the same time.

Figure 7. (a) Annual variations in the monthly mean direct aerosol radiative forcing (50-80 degrees SZA) at the top of the atmosphere (TOA) at (b) Hangzhou, (c) Xiaoshan, (d) Fuyang, (e) LinAn, (f) Tonglu, (g) Jiande and (h) ChunAn. See Figure 3 for an explanation of the symbols.

3.6 Aerosol type classification based on the aerosol optical properties

In previous studies, aerosol types have sometimes been simply classified as dust (high AOD, low AE) and anthropogenic aerosols (high AOD, high AE) (Che et al., 2009a, b; Wang et al., 2010). However, aerosol direct radiative forcing is affected by the absorptivity of aerosol and the underlying surface conditions (Haywood and Shine, 1995), and there are advantages to better characterization of the aerosol populations. For example, the classification of

ground-based aerosol types can be used to compare and validate aerosol types in chemical transport models and satellites retrievals (Lee et al., 2010). Thus, it is advantageous to categorize aerosols as absorbing or non-absorbing based on ground-based optical parameters, including SSA, fine-mode fraction, AOD, and EAE etc. In this study, we used the SSA, FMF, and EAE values to classify the fine and coarse mode particles from each site into eight groups of particles following the method of Zheng et al. (2017). The eight types of particles were (I) highly-absorbing fine-mode particles (AE > 1.2, SSA $\leqslant$ 0.85); (II) moderately-absorbing fine-mode particles (AE > 1.2, 0.85 $\leqslant$ SSA < 0.9); (III) slightly-absorbing fine-mode particles (AE > 1.2, 0.9 $\leqslant$ SSA < 0.95); (IV) weakly-absorbing fine-mode particles (AE > 1.2, SSA > 0.95); (V) mixed-absorbing particles (0.6 $\leqslant$ AE < 1.2, SSA $\leqslant$ 0.95); (VI) mixed slightly absorbing particles (0.6 $\leqslant$ AE < 1.2, SSA > 0.95); (VII) strongly absorbing coarse mode particles—mainly dust (AE $\leqslant$ 0.6, SSA $\leqslant$ 0.95); (VIII) weakly-absorbing coarse-mode particles (AE $\leqslant$ 0.6, SSA > 0.95).

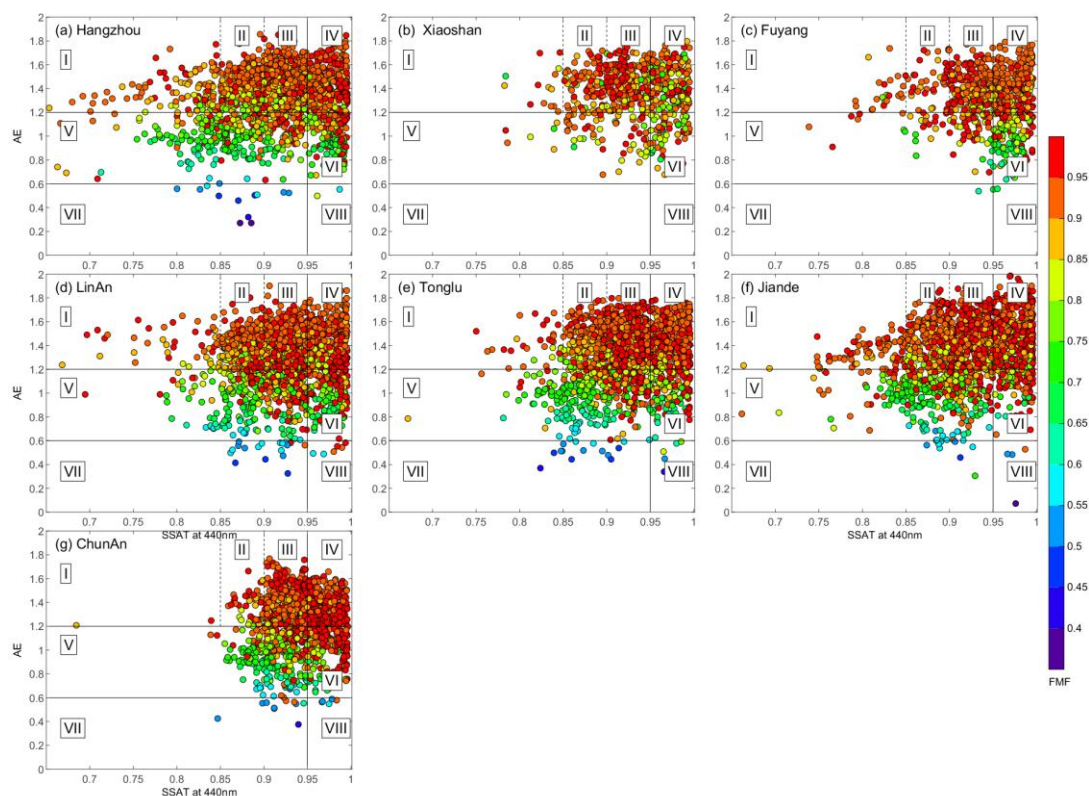

Figure 8. The aerosol type classification using SSA as a function of $AE_{440-870\ nm}$ over (a) Hangzhou, (b) Xiaoshan, (c) Fuyang, (d), LinAn, (e) Tonglu, (f) Jiande and (g) ChunAn. See

28

540   text for description of groups I–VII.

541

542

Figure 9. The distribution of the aerosol type classification over (a) Hangzhou, (b) Xiaoshan, (c) Fuyang, (d), LinAn, (e) Tonglu, (f) Jiande and (g) ChunAn. See text for description of types I–VII.

From Figure 8 and 9, one can see that the absorbing fine-mode particles (Type I, II and III) accounted for ~30 to 50% of the aerosol in the YRD region with the FMF ~0.86-0.94%. The percentages of "highly-absorbing fine-particles" (Type I) was obviously larger at Hangzhou (~8%) (FMF~0.90) than the smaller city sites (~2-3%), and at the ChunAn rural site, the percentages of Type I particles was only ~0.16% (FMF~0.91). This indicates that there were greater emissions of strong absorbing aerosols from sources such as biomass burning and/or

552 urban/industrial activities at the urban site compared with the rural one. The proportion of

553 weakly-absorbing fine-mode particles (Type IV) varied from ~20 to 30% for all sites, and the

554 FMF varies from 0.89~0.95 at same time, which suggests the second largest aerosol type in

555 the area is weakly-absorbing fine-mode particles. The percentage of mixed absorbing particle

556 (Type V) was about ~25-26% both at Hangzhou and the rural ChunAn site, which is slightly

557 higher than that at small city sites (~10-20%) where the FMF of these particles was ~0.81-0.89.

558 The higher FMF at Hangzhou was probably due to the complex aerosol emission sources that

559 impact that megacity while at ChunAn, which is surrounded by mountains, the basin

560 topography promotes particle mixing. The mixed slightly absorbing particles (Type VI) showed

561 the highest percentages of the total aerosol number at Fuyang (18.05%) and ChunAn

562 (15.32%), and the FMF of this group varied from 0.84-0.91 at all sites. The contribution of Type

563 VI mixed slightly absorbing particles at Hangzhou was ~11.49%, and the FMF (0.86) there was

564 not as high as at ChunAn (0.91). The proportion of strongly absorbing coarse mode

565 particles—mainly dust (Group VII) was only ~1.04% of the total particle count at Hangzhou

566 while at the other sites the percent abundances were < 1%, and the FMF for these particles

567 were ~0.50-0.63 at all sites. These patterns show that the YRD region is different from regions

568 in north China, including Beijing, where dust particles contribute significantly to the coarse

569 mode absorption (Zheng et al., 2017). The percentage of weakly-absorbing coarse–mode

570 particles (Group VIII) at all sites was < 0.54%, which shows that this aerosol type was rare. In

571 addition, the FMF of Group VIII particles was 0.5–0.8 with large uncertainties at all sites.

572 Overall, this analysis of aerosol types shows that the aerosol absorption is relatively weak in

573 the YRD region, and the fine-mode makes up an especially large contribution of the absorbing

574 particles at Hangzhou.

575 **3.7 Discussion**

576 Compared with previous studies on the climatology of aerosol microphysical and optical

577 properties in China, large volumes and effective radii of fine-mode aerosol, as well as high

578 AODs at 440 nm were found at most sites in June and September but not in July or August.

579 This is remarkably different from studies conducted in Northeastern/Northern China where

580   these properties showed the maximum values in July or August (Eck et al., 2005; Zhao et al.,

581   2013; Che et al., 2015b). This reflects the distinctive climatology of aerosol microphysical and

582   optical properties in the YRD region of Eastern China. This information on the distributions and

583   variations of aerosol microphysical and optical properties obtained in our study should be

584   taken into account in the validation of satellite retrievals and aerosol modeling studies in the

585   future.

586   The $AOD_{440\ nm}$ values in our study (0.71- 0.76) are similar to other urban areas of China,

587   such as Shenyang (0.75), Beijing (0.76), Tianjin (0.74), Shanghai (0.70), and Hefei (0.69) (Pan

588   et al., 2010; He et al., 2012; Zhao et al., 2013; Che et al., 2015b, Liu et al., 2017). This

589   indicates that high aerosol loadings caused by anthropogenic activities occur over many urban,

590   suburban, and even rural areas of eastern China. The $AOD_{440\ nm}$ at the rural ChunAn site

591   (~0.68) is ~ 2–6 times higher than in other rural sites in China, such as Longfengshan (0.35;

592   northeastern China), Xinglong (0.28, northern China), Akedala (0.20, northwestern China) and

593   Shangri-La (0.11, southwestern China) (Wang et al., 2010; Che et al., 2011; Zhu et al., 2014;

594   Che et al., 2015b). Therefore, strong aerosol effects on light extinction occur not only in urban

595   areas but also in much or possibly all of the YRD. The $SSA_{440\ nm}$ in our study ranged from

596   0.91–0.94, which is similar to other regions of China, such as Wuhan (0.92), Beijing (0.89) and

597   Xinglong (0.92) (Wang et al., 2015; Xin et al., 2014; Zhu et al., 2014); this suggests aerosol

598   particles in the YRD are slight to relatively strong absorbers of violet/indigo wavelengths.

599   Although the AAE has been used as an indicator of the dominant absorbing aerosol type,

600   the SSA, FMF, and EAE also used to classify the absorption characteristics of fine and coarse

601   mode particles. It should also be mentioned that uncertainties in the AAE calculations due to

602   uncertainties in the SSAs may have contributed to the observed differences between sites

603   (Bergstrom et al., 2007; Giles et al. 2011). Ideally, the aerosol physical and chemical

604   characteristic measurements will be combined at some point to more definitively classify the

605   aerosol types. In addition, even though Zhuang et al. (2017) pointed that the DARFs are not

606   very sensitive to vertical profiles under clear sky condition, future research should take into

607   account the vertical distributions of aerosols to more accurately assess the direct aerosol

608   radiative forcing effects.

609   The useful observations at most sites in this study were made on 439~562 days, but
610   smaller numbers of observation were made in Xiaoshan and Fuyang because of instrument
611   failures, 180 and 217 days, respectively. There were fewer than 15 days of useful data for
612   October and November at Fuyang, and for June, July, September, and November at
613   Xiaoshan. While the available data do provide insights into the aerosol characteristics at
614   the sites, more extended observations should be conducted at the two sites in future.

615   **4. Conclusions**

616   A detailed study of aerosol microphysical and optical properties retrieved from
617   synchronous ground-based sun photometer observations was conducted at seven sites in the
618   Yangtze River Delta region of Eastern China from 2011 to 2015. The aerosol were classified
619   into eight types, and calculations were made for the direct aerosol radiative forcing (DARF) at
620   the top and bottom of the atmosphere. The conclusions of the study can be summarized as
621   follows:

622   A relatively homogeneous distribution of aerosol microphysical properties was found for a
623   megacity, five small cities, and a rural site in the YRD region. High particle volumes of
624   coarse-mode aerosol occurred in March to May, which reflects the existence of large mineral
625   particles from springtime dust storms. High volumes and large effective radii of fine-mode
626   aerosol in June and September were found at most sites, and this was attributed to aerosol
627   hygroscopicity and cloud processing. The low volumes and large bandwidth of both fine- and
628   coarse-mode aerosol found in July and August at all sites was explained by the wet removal of
629   coarse particles during the heavy precipitation in June and the influences of subtropical
630   anticyclones in summer.

631   The AOD_{440nm} generally decreased from the east coast (0.76–Hangzhou) to the inland
632   areas towards the west (0.68–ChunAn), and this can be explained by anthropogenic impacts
633   of the more urbanized regions in the east YRD region. The $AOD_{440 nm}$ values at urban and rural
634   sites of YRD were 0.68–0.76, and the fine-mode fractions were ~0.90, which indicates that

fine-mode particles were more important than the coarse mode for the light extinction. The difference in AODs between the urban and rural sites was less than 10%, and this can be explained by somewhat stronger effects of anthropogenic activities in the urban area. The monthly averaged AODs at 440 nm showed peaks in June and September that resulted from increases fine-mode aerosol particles. However, AODs at 440 nm in July and August were the lowest over the year, and that was related to conditions favorable for aerosol dispersion. The mean extinction Angström exponent was > 1.20 all year indicating that small particles were predominant in the region. The SSAs at 440 nm varied from 0.91 to 0.94 at the urban and rural sites, indicating that the aerosol particles were moderately absorbing, and this is almost surely a result of impacts from the high industrial emissions and other anthropogenic activities in the region. There was an obvious wavelength dependence for the SSA in July and August, and aerosols absorbed most strongly at infrared wavelengths. The AAODs at 440 nm at the seven sites were ~0.04–0.06, which suggests that absorbing aerosols are distributed more-or-less homogeneously throughout the YRD region. The averaged $AAOD_{440\ nm}$ at Hangzhou is about 0.02 higher than that at ChunAn, which indicates the relative proportion of absorbing particles in the urban area is larger compared with the rural area. The $AAOD_{440\ nm}$ in winter was < 0.05, which suggests that light absorption by the particles was low compared with the other seasons. The geographical variability in the distributions of the AAEs suggests that the absorbing aerosols possibly have different optical characteristics related to the local emission sources in the YRD.

The DARF-BOA at Hangzhou was ~ −20 W/m^2 lower than that at the rural ChunAn site, which shows stronger aerosol cooling at the megacity. The monthly DARF-BOA was strongly negative in June due to the high aerosol extinction and especially the high fine-mode volume. The DARF-TOAs under clear conditions were < −40 W/m^2, but about −20 W/m^2 in July/August which suggests weaker cooling in mid summer. The DARF-TOAs were positive from April to October when the $SSA_{440\ nm}$ < 0.80, and the greater effects at shorter wavelengths was likely due to emissions of carbonaceous particles from the burning of crop residues.

The SSA, FMF, and EAE values were used to classify the particles as absorbing or

non-absorbing. Relatively large emissions of strongly absorbing aerosols in the Hangzhou urban area was the result of biomass burning and/or urban/industrial activities. The aerosol type classification showed overall that the aerosol absorption is weak to moderate in the YRD, and the fine-mode has a large contribution to the higher percentage of absorbing particles at the Hangzhou site.
