

Response to reviewer comments: Reviewer #1

The authors thank the reviewer for their comments that improve the quality of the paper. The reviewer comments are shown in italic fonts, the responses are in regular fonts, and revised text in bold fonts.

[The numbers in some of the reviewer's comments are added by the authors to help address the comments more clearly.]

Review of “Decadal change of summertime 1 reactive nitrogen species and surface ozone over the Southeast United States” by Li et al.

This manuscript investigates the ozone and reactive nitrogen changes over the southeastern US (SE) using a high-resolution global model (AM3), applied, apparently, to July and August of 2004 and 2013. They also look to see what a further 40% reduction in NO_x emissions would do. (The reason I use “apparently” is that they sometimes use “summer” to say their application period, but do not specify exactly what summer entails: they should make this more clear.) As part of this study, they evaluate the model using both aircraft and ground-based, routine monitors. They find that reactive nitrogen and ozone have both decreased in the SE, and further decreases are expected in response to a 40% NO_x reduction.

This study is both of interest to the community and, for the most part, well executed, though there are aspects that need to be corrected before it should be accepted for publication in ACP. The strength is the focus on the oxidized nitrogen species and associated chemistry. The weaknesses include an inadequate evaluation for the analysis conducted, a short application period (2 months), a potentially poor choice of years, lack of consideration of condensed phase species in their assessment and evaluation.

Specific Comments

Comment 1

(1) *Evaluation of the model is particularly important in such applications where one is trying to explain the reasons behind the observed (both in the model as well as in the ambient) changes, and, further, when using the model to extrapolate to further changes. Currently, the article relies on presenting plots with no quantitative statistical analysis. This needs to be corrected for further consideration of the article. Such an evaluation should be summarized in the main article with details in the supplemental.*

(2) *Looking at Figure 7, one sees rather considerable differences. How does this relate to other studies? If one is to assess how well the model may be relied upon to provide details of why the model may be capturing observed changes, and to what degree one can rely on the model to simulate future air quality, a more rigorous evaluation is required. One can look at the recent work done at EPA (e.g., [Simon et al., 2012]), or as part of AQMEII (e.g., [Appel et al., 2012];*

Dennis et al., 2010] [Solazzo and Galmarini, 2015]) or Environ [Emery et al., 2017] to provide the types of metrics that should be considered.

(3) Along those lines, there are ways to adjust deposition results to account for differences in precipitation rates other than the way they have chosen, and those should be considered. They should use total deposition fields from their modeling with total deposition fields estimated by NADP (<http://nadp.sws.uiuc.edu/committees/tdep/tdepmaps/>).

Response 1

(1) We now include statistical analysis of ozone and major reactive oxidized nitrogen following this reviewer's suggestion. Results are listed in the following Table 1 and included in the revised supplemental material (Table S4). Discussion of these statistics are also included in the revised manuscript in lines 331-335 as

“Performance statistics of O₃ in the boundary layer listed in Table S4 also indicate positive biases in the model, with the fractional bias (FB) of 9.4 – 17%, fractional error (FE) of 16 – 19 %, normalized mean bias (NMB) of 9.4 – 16% and normalized mean error (NME) of 16 – 19 %.”

and in lines 368-369 as

“Performance metrics in Table S4 also indicate better agreement of the model with observations if hydrolysis of ISOPNB assumed.”

(2) We performed similar statistical analysis for surface MDA8 ozone in figure 7. Results are listed in the following table and included in the revised supplemental material (Table S4). Discussion of these statistics are also included in the revised manuscript in lines 580-582 as

“In general, AM3 overestimates surface MDA8 ozone in both years by about 16 ppb on average, with the NMB of 33 - 45 % and NME of 35 - 46 % respectively.”

(3) We agree with the reviewer that there are other ways to account for the bias in modeled precipitation rates. However, these are beyond the scope of this manuscript. We think the direct way to minimize the bias of precipitation in the model is to compare the observed monthly average concentration of NO_3^- , with model estimates using modeled wet deposition flux of NO_3^- divided by the observed precipitation. For a better evaluation of model's performances, we performed statistical analysis of the wet deposition of NO_3^- . The text has been revised in lines 404-406 as:

“This reduction in monthly averaged NO_3^- wet deposition flux is well captured by our model (-29 %), despite a low relative bias of 40 % in both years and NMB of - 39 – - 43 % (Table S4).”

Total deposition fields use wet deposition measurements from the NADP NTN (used in our model evaluation) and dry deposition combined of model estimates and ambient air monitoring data. The data might introduce biases from the model. Therefore, we didn't use the total deposition estimates.

Table 1. Statistical analysis of ozone and major RON species from the base case and no_hydro case^a.

Tracers ^b	2004								2013							
	base				no_hydro				base				no_hydro

NO _y ^c	6.4×10^{-2} (6.5×10^{-2})	0.33 (0.40)	6.3×10^{-2} (3.8×10^{-2})	0.32 (0.36)	0.11 (0.12)	0.34 (0.39)	0.11 (0.10)	0.34 (0.38)	-5.7×10^{-3}	0.27	-4.2×10^{-2}	0.27	-2.9×10^{-2}	0.29	-6.0×10^{-2}	0.28
Wet deposition of NO ₃ ⁻	-0.40	0.50	-0.39	0.46	—	—	—	—	-0.51	0.56	-0.43	0.45	—	—	—	—

MDA8 ozone	0.30	0.32	0.33	0.35	—	—	—	—	0.39	0.40	0.45	0.46	—	—	—	—
---------------	------	------	------	------	---	---	---	---	------	------	------	------	---	---	---	---

^a Description of the two cases can be found in Table 2. $FB = \frac{2}{N} \sum_{i=1}^N (P_i - O_i) / (P_i + O_i)$, $FE = \frac{2}{N} \sum_{i=1}^N |P_i - O_i| / (P_i + O_i)$,

$NMB = \sum_{i=1}^N (P_i - O_i) / \sum_{i=1}^N O_i$, $MNE = \frac{1}{N} \sum_{i=1}^N |P_i - O_i| / \sum_{i=1}^N O_i$, where P_i , O_i , and N are modeled and observed data and N is number of valid data.

^b For ozone, NO_x , HNO_3 , PAN, $\sum ANs$ and NO_y , observations are from ICARTT, SENEX and SEAC⁴RS within the boundary layer (< 1.5 km); For wet deposition of NO_3^- , observations are from NADP; For MDA8 ozone, observations are from EPA AQS data during July-August of 2004 and 2013 at monitoring stations in Figure S3.

^c Statistical results of HNO_3 and NO_y in 2004 (ICARTT) outside of and within the brackets used observed HNO_3 measured by mist chamber/IC by University of New Hampshire and Chemical Ionization Mass Spectrometer (CIMS) by California Institute of Technology, respectively.

^d Statistical results of $\sum ANs$ in 2013 used observations during SEAC⁴RS.

Comment 2

I was a bit surprised that they focus on just two months (July and August) for their analysis (and that this was not more clearly stated, if that is, indeed, the case). This, along with focusing on just one historical and one semi-current year, makes the results very sensitive to the choice of time period. Along those lines, the summer of 2013 was cold and wet in the Southeast, and the meteorological adjustment determined by EPA was relatively large (in the Southeast data available at <https://www.epa.gov/airtrends/trends-ozone-adjusted-weather-conditions>). This was also the case for 2004, but the concern here is the timing as the adjustments are for the season, while the modeling conducted is just two months. More analysis is needed to tell how much impact is just from the meteorology of these two years specific to the two months.

Response 2

We choose July-August for analysis is mainly because our model is evaluated in this time window by three aircraft campaigns. We make this clear in the revised manuscript in lines 300-302 as

“We choose July – August as our ‘summer’ since this is the common period of all the measurements used in model evaluation.”

We agree with the reviewer that meteorology plays an important role in ozone formation. Such impact has been discussed in the original manuscript in lines 642 - 657. Specifically, the observed changes of temperature and RH between summer of 2004 and 2013 are marginal, same with model estimates. Moreover, Camalier et al. (2007) showed that summertime surface ozone over SEUS was more impacted by RH than temperature. The relative change of RH from our model (less than 1%) and observations (+ 2.7%) are very small. Therefore, influence of meteorology on decadal changes of ozone is expected to be very small. We have emphasized this in the revised manuscript in lines 608-620 as:

“Our model shows marginal differences in RH (less than 1 %) and temperature (+ 2.4 K) within the PBL over the Southeast U.S. between the summers of 2004 and 2013, consistent with observed changes of RH (+ 2.7 %) and temperature (+ 2.6 K) during ICARTT and SENEX. This small variation in the model is also consistent with climatology data (Hidy et al., 2014). Camalier et al. (2007) showed that RH has a much bigger impact on summertime ozone than temperature over the Southeast U.S., suggesting little influence of meteorology on ozone trend. Using the same model but with the standard AM3 chemical mechanism, Lin et al. (2017) found that meteorology changes would have caused high surface ozone over the eastern U.S. to increase by 0.2 - 0.4 ppb yr⁻¹ in the absence of emission controls from 1988 to 2014. Therefore, we conclude that the impact of climate variability and change on O₃ is relatively small compared to NO_x emission reductions over the Southeast U.S., consistent with previous studies (Lam et al., 2011; Hidy et al., 2014; Lin et al., 2017; Rieder et al., 2015).”

Comment 3

Such an analysis, particularly when considering reactive nitrogen species, should provide additional focus on aerosol nitrate, including in the regional model evaluation. When they use the term “reactive nitrogen” are they including ammonia and ammonium? If not, they should add “oxidized”.

Response 3

We did include aerosol organic nitrate in Σ ANs and stated in several places (i.e. lines 287-288, lines 308-309, and lines 340-341) in the original manuscript. There are high uncertainties in the kinetics of organic nitrate aerosol formation such as the hydrolysis rate of different organic nitrates. Evaluation of this mechanism is beyond the scope of our work. For model evaluation of inorganic nitrate aerosols, unfortunately, this cannot be accomplished since their formation is not included in the current version of AM3. Moreover, Ng et al. (2017) has reviewed the global distribution of particulate nitrates, finding that the major component over the Southeast U.S. is organic nitrates. Therefore, inorganic nitrate aerosols were ignored in this work. We didn't include ammonia or ammonium in our analysis either. For clarification, we have revised the terminology ‘reactive nitrogen species’ to “**reactive oxidized nitrogen**” in all the places mentioned in the manuscript. We also add following sentences in lines 319-322:

“We do not consider inorganic nitrates in particle phase in this analysis, due to lack of thermodynamic model for inorganic aerosols in current version of AM3. This simplification is expected to have minimal effects, as they only account for a small fraction of aerosol nitrates in the Southeast U.S. (Ng et al., 2017).”.

Comment 4

There is a logical mismatch in the current paper. They state that there is a linear relationship between ozone and NO_x emissions (line 627). This indicates a constant OPE. However, they also state that there is a transition from low to high OPE (line 633), though, admittedly, they do not say that after transitioning to a high OPE, it does not become constant. However, the discussion of OPE suffers from their not actually calculating an OPE. I might suggest removing much, if not all, of the OPE discussion unless they can bolster it further. If they do not remove this section, line 639: stating that OPE has increased very little and had little impact on net ozone production needs more definitive evidence.

Response 4

We have removed this discussion as the reviewer suggested.

Comment 5

I might suggest they integrate some of their findings with those in Blanchard et al., “ACP (2016) “Effects of emission reductions on organic aerosol in the southeastern United States”. While this article is focused on organic aerosol, it relates to NO_x controls in the SE.

Response 5

We add discussion in lines 534-536 as:

“As an important source of organic aerosols (OA), Σ ANs may contribute to the decrease of OA over the Southeast U.S. in the past decade (Blanchard et al., 2016).”

Comment 6

Line 66: EPA still targets VOC emissions. (Look at the reductions in mobile VOCs over the period of interest!). Over the 2004 to 2013 period, how much of the ozone reduction is due to NO_x vs. VOC controls? Do mobile emission reductions have a big impact in the rural areas under investigation here?

Response 6

We find that modeled ozone in summer in the Southeast U.S. is insensitive to VOC emissions from mobile sources, because VOCs in the Southeast U.S. is predominantly of biogenic origin.

Comment 7

There should be more discussion about the potential reasons for model bias following the work by Travis et al., (2016), and how this paper fits into that discussion.

Response 7

We now add in lines 386 – 395:

“Given the good agreement between observed and modeled RON in both 2004 and 2013, we find that the ozone bias, shown in Figure 1, cannot be completely explained by an overestimate of anthropogenic NO_x emissions. A recent GEOS-Chem study (Travis et al., 2016) shows that the ozone bias in their model can be largely reduced by scaling down anthropogenic NO_x emissions. We find that a similar reduction of anthropogenic NO_x emissions in 2013, from 0.25 Tg N mon^{-1} to 0.15 Tg N mon^{-1} , would lead to an underestimate of NO_y , HNO_3 and PAN by 30 %, 33 % and 30 %, respectively. Such a reduction would be also inconsistent with the relative changes in EPA estimates of NO_x emissions shown above. Indeed, other processes, such as ozone dry deposition, may also contribute to this bias and warrant further investigation.”

Comment 8

(1) Abstract: The final sentence states that ‘further reductions of NO_x emissions will lead to...less frequent extreme ozone events’, however, the paper does not address extreme ozone events, just averages. This should be removed.

(2) Some reorganization of the paper could help improve its interpretation. A few suggestions: 1. The operational evaluation of the model and discussion of trends over time overlap (e.g., lines 343-363 and 488-499 discuss changes over time). I recommend splitting the evaluation section into ‘operational’ and ‘dynamic’ subsections (see Dennis et al. 2010 for an example). The dynamic

evaluation section can address observed/modeled changes as related to emissions reductions, but the bulk of the discussion on this point should be reserved for its own section (currently section 5).

(3) 2. Define metrics used for comparison. ‘Bias’ is used here in both absolute (e.g., line 352) and relative (e.g., line 401) In the paragraph from lines 488-499, for example, the authors combine discussion of operational and dynamic evaluation, observed changes in response to emissions, and comparisons with previous modeling efforts.

Response 8

(1) We have revised ‘extreme’ ozone events to ‘high’ ozone events in all the places mentioned in the manuscript.

(2) We thank the reviewer for introducing these two evaluation types. Since our work starts with model evaluation in both 2004 and 2013 for aircraft and surface datasets, operational and dynamic evaluation are closely coupled in section 4. We find it difficult to split into operational and dynamic evaluations.

(3) We have revised ‘bias’ all mentioned in the manuscript to ‘absolute bias’ or ‘relative bias’ correspondingly, if needed.

Comment 9

Lines 567-575: why does the response of NO_y concentration change from linear (from 2004-2013) to nonlinear with further emissions reductions?

Response 9

We now clarify this in lines 539-540 of the revised manuscript as:

“The slower decrease of NO_y is likely due to ΣANs , which decrease at a slower rate and becomes a larger fraction of NO_y .”

Comment 10

Change all mentions of ‘future’ 40% reduction in NO_x emissions to ‘hypothetical’ reduction (e.g., line 661). This analysis was performed partly to investigate the hypothesis that NO_x emissions are overestimated, and there’s no proof that the future will bring continued reductions. Also, I believe this model run was performed with 2013 meteorology, but this should be made clear.

Response 10

We have replaced all the ‘future’ 40% reduction in NO_x emissions to ‘hypothetical’ reduction in the revised text. We also include the following sentence in lines 520-522:

“We also investigate the impacts of further decreases in NO_x emissions by applying a hypothetical 40 % reduction of anthropogenic NO_x emissions of 2013 but keeping other emissions and meteorology the same (“hypo” case in Table 2).”

A table with descriptions of all the cases performed is added in the revised manuscript (shown below).

Table 2. Case descriptions

Case name	Heterogeneous Loss of organic nitrates	NO _x emissions	Meteorology
base	ISOPNB with a γ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
no_hydro	—	2004 and 2013	2004 and 2013
hydro_full	ISOPNB and DHDN with a γ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$; TERPN1 with a γ of 0.01 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
hypo	Same with the base case	40 % reduction of NO _x emissions of 2013	2013

Comment 11

In the discussion or Data sections, add some mention of reliability/consistency of measurements as a basis for model evaluation across the decade

Response 11

We have added a few sentences about the reliability of measurements in lines 120-124:

“These data have been widely used to evaluate model estimates of RON and ozone (Singh et al., 2007; Pierce et al., 2007; Perring et al., 2009; Fischer et al., 2014; Hudman et al., 2007; Henderson et al., 2011; Hudman et al., 2009; Edwards et al., 2017; Baker and Woody, 2017; Travis et al., 2016; Mao et al., 2013; Fisher et al., 2016; Yu et al., 2016; Liu et al., 2016).”

Comment 12

Line 715: Change upto to ‘up to’

Response 12

All the typos have been corrected.

Response to reviewer comments: Reviewer #2

The authors thank the reviewer for their comments that improve the quality of the paper. The reviewer comments are shown in italic fonts, the responses are in regular fonts, and revised text in bold fonts.

[The numbers in some of the reviewer's comments are added by the authors to help address the comments more clearly.]

Title: Decadal change of summertime reactive nitrogen species and surface ozone over the Southeast United States Authors: Jingyi Li et al.

Summary: This article examines observations and modeling for two years with extensive field campaigns and examines decadal changes between the years. The article uses a somewhat coarse resolution (when applied to a region) and evaluates NO_y species. The evaluation is mostly qualitative and the explanations for mean biases (the quantitative metric) are somewhat speculative. Overall the manuscript provides interesting insights into the decadal changes despite using short snapshots no inter-annual variation.

Response Overview: The manuscript provides interesting insights in reactive nitrogen speciation and trends. There are several places that need clarification or further discussion. There is at least one methodological issue (time step) that has been show to affect speciation and is not discussed.

Specific Comments

Overall:

Comment 1

** The article uses "as shown below." and the like frequently. I recommend being more specific so that the reader can connect subsequent discussion.*

Response 1

We have clarified the phrase 'as shown below' all mentioned in the manuscript.

Comment 2

** The nomenclature for the 40% hypothetical reduction from 2013 is confusing, particularly because the 40% number is also relevant for the 2004-2013 change.*

Response 2

The reason we reduced NO_x by 40% of 2013 as a hypothetical scenario in future (in a decade) is based on the change rate of NO_x from 2004 to 2013.

Comment 3

** I found the introduction and subsequent discussion of AM3h confusing. Consider separating paragraphs at 248 and more clearly lay out the paragraph.*

Response 3

The text has been revised in lines 257-261 as:

“Besides the base case that only includes ISOPNB for heterogeneous loss (Jacobs et al., 2014), we include two additional sensitivity tests to evaluate the potential impact of organic nitrate hydrolysis. One is “hydro_full” case including heterogeneous loss of a C₅ dihydroxy dinitrate (DHDN) and monoterpene nitrates from OH oxidation (TERPN1), and the other one is “no_hydro” case assuming no heterogeneous loss for any organic nitrates.”

Comment 4

* DAM3 introduced in Figure 4 is an unclear nomenclature. If I understand it correctly, DAM3 is replaying the Y-axis with a subset of ANs. It is not a separate model. Why prepend the D to DAM3 and DObs?

Response 4

Figure 4 has been revised as following:

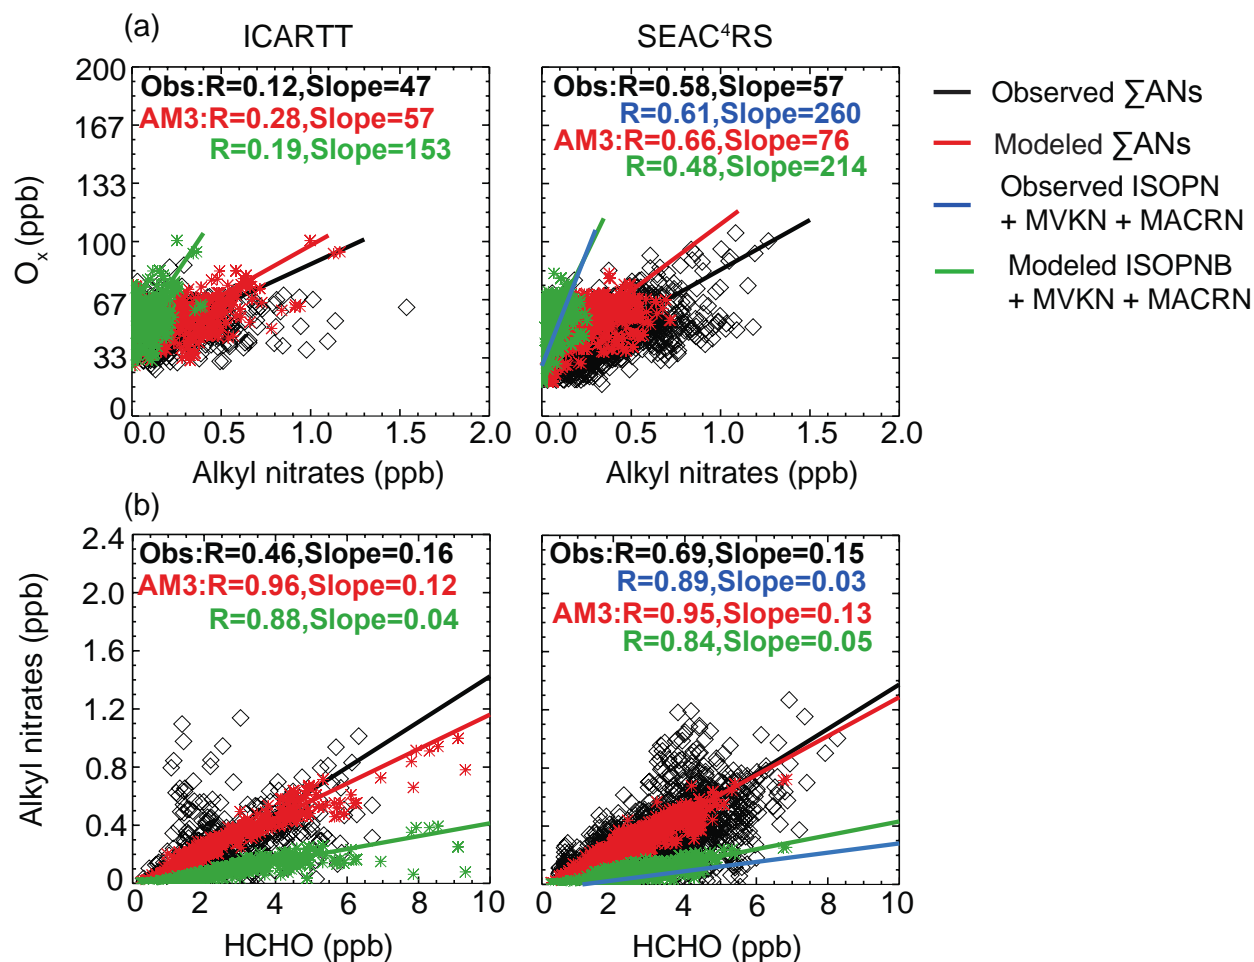

Figure 1. Figure 4 in the manuscript.

Comment 5

* Emissions are reported for the CONUS and average annual rates (1/mo), but spatial allocation and temporal allocation may be important to understand how they affect the region/time being reported.

Response 5

We show in the following Figure 2 (Figure S1 in the original supplement) that NO_x emissions in our model exhibit a similar spatial pattern to the one in NEI11v1 inventory. We apply a diurnal variation to anthropogenic NO_x emissions in the model. This has been clarified in the revised text in lines 180-181:

“We also apply a diurnal variation to anthropogenic NO_x emissions following Mao et al. (2013b).”

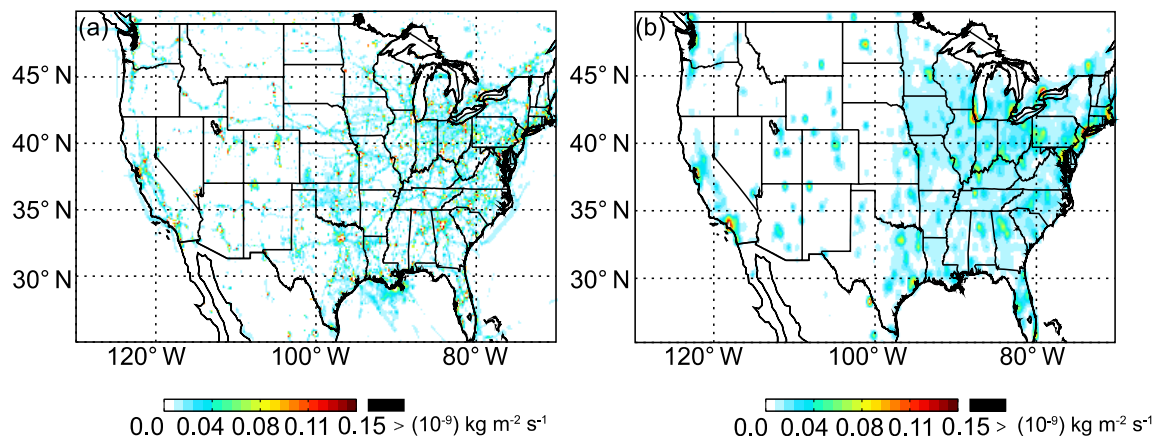

Figure 2. Anthropogenic NO_x emission rate during July-August 2013 of (a) NEI11v1 inventory and (b) RCP8.5.

Comment 6

* The "discrepancy" introduced on lines 413-415 and explained in Figure S5 seems like a major point. Consider moving Figure S5 into the main text. Even if the figure stays in the supplement, describe the "discrepancy" and make a citation to clarify.

Response 6

Our focus is the comparison of major RON species and the total (NO_y). As Σ ANs only accounts for a small fraction of NO_y and there are high uncertainties in RONO₂ chemistry, we intend to show the figure in supplement and explain the ‘discrepancy’ in the caption of the figure as:

“The discrepancy between Σ ANs and sum of ISOPN, MVKN and MACRN is attributed to monoterpene nitrates and a C5 dihydroxy dinitrate (DHDN) and nighttime NO₃ oxidation products from isoprene.”

Comment 7

* The OPE discussion covers a long time-range (1993 to near present day), and ultimately is suggested to be "small and to have little impact". Consider moving this discussion to the conclusions and tightening the language.

Response 7

We have removed the OPE discussion in the text following Reviewer #1's suggestion (Comment 4) to avoid confusion.

Comment 8

** The balance between NO_x and products has been shown to be sensitive to computational time step at the surface[1]. How has this been treated in AM3?*

Response 8

We agree with the reviewer on the impact of computational time on NO_y speciation. The current computational time step is 20 minutes. With this setting, our model can well reproduce the vertical profiles of all the major reactive oxidized nitrogen. We have emphasized this in lines 155-158 of the revised manuscript as

“The current time step for chemistry and transport in our model is 20 mins. We show below in section 4.1 that, with the current setting, our model can well reproduce the vertical profiles of RON. Sensitivity of RON to operator duration should refer to Philip et al. (2016).”

Line by line:

Comment 9

140 - I did not see transport/chemistry time steps. Time steps have been shown to affect chemical partitioning[1], and likely export form. Please report this information and consider the implications on the export speciation outcome.

Response 9

Please refer to Response 8.

Comment 10

359 - I do not think you show how reactive nitrogen oxides would change with a 53% reduction. see below... where?

Response 10

This has been explained as “We find that if we reduce anthropogenic NO_x emission in our model by another 40 %, from 0.25 Tg N mon^{-1} to 0.15 Tg N mon^{-1} as suggested by Travis et al. (2016), simulated NO_y , HNO_3 and PAN decrease by 30 %, 33 % and 30 % respectively, leading to a noticeable underestimate for these nitrogen reservoirs.” in lines 393-397 of the original manuscript. This sentence has been moved and revised in lines 390-392 of the current version of manuscript as:

“We find that a similar reduction of anthropogenic NO_x emissions in 2013, from 0.25 Tg N mon^{-1} to 0.15 Tg N mon^{-1} , would lead to an underestimate of NO_y , HNO_3 and PAN by 30 %, 33 % and 30 %, respectively.”

Comment 11

387 - *If lightning N had "likely ... insufficient production", why is it also too uncertain to change? Is there a similar reference for 2013?*

Response 11

High uncertainties associated with the production rate of NO_x by lightning is partially due to lightning NO_x production per flash, altitude of lightning NO_x in models and impacts of temperature. Therefore, it is difficult to adjust lightning NO_x in our model. We have revised the text in lines 362-365 as:

“This underestimate can be improved by scaling up lightning emission by a factor of 5-10 (Fang et al., 2010). We do not adjust the lightning NO_x emissions in this work due to its high uncertainty (Ott et al., 2010; Pickering et al., 1998).”

Comment 12

402 - *The low bias may be good for SEAC⁴S, but it would also be bad for ICARTT. This sentence reads as though there is a tidy explanation.*

Response 12

We have modified the text in lines 371-373 as:

“This low bias can be partially due to neglecting small alkyl nitrates, which could contribute 20 - 30 ppt to ΣANs (less than 10% near the surface) during SEAC⁴RS (Fisher et al., 2016). Including small alkyl nitrates will increase modeled ΣANs a bit in ICARTT as well.”

Comment 13

446 - *The discussion of implemented chemistry seems to belong in section 2.*

Response 13

We have shortened the discussion in Section 2 as the reviewer suggested, particularly on heterogeneous chemistry.

Comment 14

459 - *R5 is not the exclusive fate of NO₂. This should be more clear and consistent in the narrative. Perhaps using O_x would simplify and correct the narrative.*

Response 14

We have explained O_x to connect R5 to the narrative in lines 432-433 as

“We show that the model can roughly reproduce the correlation of O_x (= O₃ + NO₂) vs. ΣANs during both ICARTT and SEAC⁴RS (Figure 4), ...”

Comment 15

508,510 - *Not clear here if you are referencing simulated or observed abundances.*

Response 15

This is simulated abundances. We have stated in line 508-509 of the original manuscript as “Figure 5 shows the mean vertical profiles of modeled monoterpene nitrates (MNs) and isoprene nitrates (INs) during ICARTT and SEAC⁴RS.”

Comment 16

542 - *"prompt production" is often used as a technical term in chemical mechanisms to mean implemented without the intermediate, perhaps rate limiting, reaction. If this is implemented as "prompt production", then it seems inappropriate to say that you "In our model, we see prompt production." please clarify.*

Response 16

The text in lines 505-506 has been revised as:

“In our model, we see a rapid increase of PROPNN after sunrise in the boundary layer (Figure S7), ...”

Comment 17

562 - *This sentence and what precisely it references is unclear. I'm assuming 561,562 is observations. The differences from the model are calculable from Figure 6, but not immediately available. Clarify and or add numbers to the text.*

Response 17

This sentence has been explained as **“Based on model estimates in Figure 6, most RON are reduced proportionally ...”** in lines 530-531 of the revised manuscript.

Comment 18

702,705 and elsewhere - *The Pollack study is compared to this study several times. The differences. I am not sure why this is important to the conclusions.*

Response 18

The trend of RON, specifically PAN, is not only dependent on changes of NO_x but also on that of VOC precursors. Pollack study exhibited a different conclusion from our study on PAN trend, likely due to different VOC precursors in the two studied regions.

Response to reviewer comments: Reviewer #3

The authors thank the reviewer for their comments that improve the quality of the paper. The reviewer comments are shown in italic fonts, the responses are in regular fonts, and revised text in bold fonts.

[The numbers in some of the reviewer's comments are added by the authors to help address the comments more clearly.]

General comments:

This manuscript examines “decadal changes in summertime reactive nitrogen species and ozone over the Southeast U.S.”, and finds they “decline proportionally with decreasing NO_x emissions in this region” and concludes that “this linear response is in part due to the nearly constant summertime supply of biogenic VOC emissions in this region”. There are several concerns with the overall quality of the current manuscript.

Comment 1

In the manuscript, some critical definition/terminology used are not accurate or ambiguous. For example, (1) NO_y refers to reactive oxidized nitrogen not reactive nitrogen, the latter includes NH₃.

(2) It seems summertime is defined in the manuscript as July-August, but the three aircraft measuring campaigns, whose observations were extensively used to evaluate the modeling results and derive the changes in observed concentrations, were conducted at, respectively, July-August, 2004, June-July, 2013, and August-September, 2013. For regulatory purpose, surface ozone is studied for a period in a year defined as ozone season, which is usually defined as April-October in the Southeast of United States.

Response 1

The authors thank the reviewer for this important comment. We have read the manuscript thoroughly and improved any ambiguous definition/terminology that might cause confusion. Specifically, for the two examples the reviewer mentioned:

(1) We didn't include ammonium or ammonia in the analysis. We have revised the terminology 'reactive nitrogen species' to '**reactive oxidized nitrogen**' in all the places mentioned in the manuscript.

(2) We defined summertime as July-August since this is the common period covered in the three aircraft campaigns used for model evaluation. The analysis of decadal change of ozone and reactive oxidized nitrogen were based on the evaluated model results. We make this clear in the revised manuscript as “**We choose July – August as our ‘summer’ since this is the common period of all the measurements used in model evaluation.**” in lines 300-302.

Comment 2

The decadal changes in both observation and simulations are not elucidated by using a well-designed comparison method. Reduction in NO_x emissions are one of the major reasons that can cause the resulting reduced surface ozone and NO_y concentrations, but it is not the only one. The method used in the manuscript is not convincing by removing other impacting factors such as meteorology and emissions reduction on other pollutants, which confounds the conclusions this manuscript makes. For example, (1) the aircraft measurements were collected at different locations and different days/months, how exactly such measurements can reveal the real changes of NO_y between the two years a decade apart. (2) The model simulations were conducted for the same months for 2004 and 2013, a decade apart, but in what quantity are the impacts on species concentrations resulting from the differences in meteorology between the two years?

Response 2

(1) The authors thank the reviewer for this excellent comment. Our strategy is that if our model can well reproduce vertical profiles of RON and related species from aircraft measurements, we assume model is representative of this chemical environment and then use the model to derive the real changes between the two years a decade apart. We now add in the text (lines 517-520):

“As RON and related species from aircraft and surface measurements are well reproduced in our model for both 2004 and 2013, we assume that the model is representative of this chemical environment, and then use the model to derive monthly mean changes between 2004 and 2013.”

(2) We discussed about meteorology impacts on ozone changes during 2004-2013 in lines 642-657 of the original manuscript. In short, the changes of temperature and relative humidity in summers of the two years over SEUS are small according to our model, consistent with climatology data reported by Hidy et al. (2014). Decreases of ozone is mostly attributed to NO_x emission reduction other than meteorology changes. The text has been revised in lines 608-620 as:

“Our model shows marginal differences in RH (less than 1 %) and temperature (+ 2.4 K) within the PBL over the Southeast U.S. between the summers of 2004 and 2013, consistent with observed changes of RH (+ 2.7 %) and temperature (+ 2.6 K) during ICARTT and SENEX. This small variation in the model is also consistent with climatology data (Hidy et al., 2014). Camalier et al. (2007) showed that RH has a much bigger impact on summertime ozone than temperature over the Southeast U.S., suggesting little influence of meteorology on ozone trend. Using the same model but with the standard AM3 chemical mechanism, Lin et al. (2017) found that meteorology changes would have caused high surface ozone over the eastern U.S. to increase by 0.2 - 0.4 ppb yr⁻¹ in the absence of emission controls from 1988 to 2014. Therefore, we conclude that the impact of climate variability and change on O₃ is relatively small compared to NO_x emission reductions over the Southeast U.S., consistent with previous studies (Lam et al., 2011; Hidy et al., 2014; Lin et al., 2017; Rieder et al., 2015).”

Comment 3

There is no quantitative evaluation results presented for the model simulation on surface ozone. But according to the description from the manuscript: “AM3 overestimates surface MDA8 ozone in both years by about 16ppb on average”, and “MDA8 ozone averaged ... is observed to decrease by 11 ppb (23% of observed mean MDA8 ozone in July-August of 2004)”, one can deduce that the overestimation of surface MDA8 ozone in July-August of 2004 and 2013 are roughly 33% and 43%, respectively. Note that the USEPA recommends a better than 30% of mean normalized error for surface ozone performance for regulatory modeling. With worse than the EPA recommended performance, the modeling results from this study are not that meaningful for surface ozone regulation purposes.

Response 3

We have added statistical analysis of RON and surface ozone in Table 1 shown below (Table S4 in the revised supplement). We now add (lines 681-683):

“Care should be exercised in applying the modeling results for surface ozone regulation purposes, given the high ozone bias shown in our model”.

Table 1. Statistical analysis of ozone and major RON species from the base case and no_hydro case^a.

Tracers ^b	2004								2013							
	base				no_hydro				base				no_hydro

MDA8 ozone	0.30	0.32	0.33	0.35	—	—	—	—	0.39	0.40	0.45	0.46	—	—	—	—
---------------	------	------	------	------	---	---	---	---	------	------	------	------	---	---	---	---

^a Description of the two cases can be found in Table 2. $FB = \frac{2}{N} \sum_{i=1}^N (P_i - O_i) / (P_i + O_i)$, $FE = \frac{2}{N} \sum_{i=1}^N |P_i - O_i| / (P_i + O_i)$,

$NMB = \sum_{i=1}^N (P_i - O_i) / \sum_{i=1}^N O_i$, $MNE = \frac{1}{N} \sum_{i=1}^N |P_i - O_i| / \sum_{i=1}^N O_i$, where P_i , O_i , and N are modeled and observed data and N is number of valid data.

^b For ozone, NO_x , HNO_3 , PAN, $\sum ANs$ and NO_y , observations are from ICARTT, SENEX and SEAC⁴RS within the boundary layer (< 1.5 km); For wet deposition of NO_3^- , observations are from NADP; For MDA8 ozone, observations are from EPA AQS data during July-August of 2004 and 2013 at monitoring stations in Figure S3.

^c Statistical results of HNO_3 and NO_y in 2004 (ICARTT) outside of and within the brackets used observed HNO_3 measured by mist chamber/IC by University of New Hampshire and Chemical Ionization Mass Spectrometer (CIMS) by California Institute of Technology, respectively.

^d Statistical results of $\sum ANs$ in 2013 used observations during SEAC⁴RS.

Comment 4

The organization and presentation of the manuscript cause a lot of confusions. (1) The authors constantly blends trends found in observations and trends found in simulations next to each other without distinguishing them clearly. (2) The purpose of the aircraft measurements and the surface observation, and the purpose of the simulations are not clearly presented. (3) A lot of qualitative statements, only supported with citations of ambiguous supporting meanings.

Response 4

For (1) and (3), we have revised the text carefully to improve understanding of the manuscript. For (2), we now add (lines 124-128):

“Together with measurements from networks, including the National Atmospheric Deposition Program (NADP) and EPA Air Quality System (AQS), these datasets enable a close examination of responses of RON and surface ozone to NO_x emissions reduction in this region.”

We have added descriptions of each simulation in Table 2 shown below (Table 2 in the revised manuscript), and in the text in lines 257-261 as:

“Besides the base case that only includes ISOPNB for heterogeneous loss (Jacobs et al., 2014), we include two additional sensitivity tests to evaluate the potential impact of organic nitrate hydrolysis including heterogeneous loss of a C₅ dihydroxy dinitrate (DHDN) and monoterpene nitrates from OH oxidation (TERPN1), and the other one is “no_hydro” case assuming no heterogeneous loss for any organic nitrates.”

and in lines 520-522 as:

“We also investigate the impacts of further decreases in NO_x emissions by applying a hypothetical 40 % reduction of anthropogenic NO_x emissions of 2013 but keeping other emissions and meteorology the same (“hypo” case in Table 2)

Table 2. Case descriptions

Case name	Heterogeneous Loss of organic nitrates	NO _x emissions	Meteorology
base	ISOPNB with a γ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
no_hydro	—	2004 and 2013	2004 and 2013
hydro_full	ISOPNB and DHDN with a γ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$; TERPN1 with a γ of 0.01 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
hypo	Same with the base case	40 % reduction of NO _x emissions of 2013	2013

Specific comments:

Comment 5

(1) Page 4, “high-resolution (50x50 km²)”. When conducting chemical transport modeling at regional scale, this is no way a high-resolution.

Response 5

We use a global chemistry-climate model in this work. We now revise the text in lines 144-148 as:

“We apply a high-resolution (50 x 50 km²) version of the GFDL AM3 global chemistry-climate model to study decadal changes of RON and O₃ over the Southeast U.S. Chemistry-climate models provide a unique capability to both evaluate model representation of these observed changes and use that to improve future projections of air quality in the same region.”

Comment 6

(2) Page 5 “. . . both inventories have a similar spatial distribution (Figure S1). Compare the two panels in Figure S1, apparently, the local maximum levels in the Southeast of RCP8.5 are somewhat 30% lower than the NEI2011 (no red spots are seen in the Southeast in the RCP8.5 panel). Also, why compared to NEI2011 version 1, why not the NEI2011 final version? More importantly, why don't just use NEI2011?

Response 6

We have compared NEI2011 version 1 with the final version NEI2011 version 2. NO_x emissions from this two versions are very similar. We now reflect this in the text in lines 176-179:

“The resulting anthropogenic NO_x emissions (0.25 Tg N mon⁻¹) are 14 % lower than NEI11v1 emission inventory estimate of 0.29 Tg N mon⁻¹ (0.28 Tg N mon⁻¹ from the updated NEI11v2 emission inventory),...”

As this work focuses on the relative change of RON and related species from 2004 to 2013 in a global climate-chemistry model, we find it difficult to interpret model results in 2004 using NEI2011. We now state in the text in lines 167-170:

“Anthropogenic emissions follow the Representative Concentration Pathway 8.5 (RCP 8.5) projection (Lamarque et al., 2011) for both 2004 and 2013, to compare the model to observations in a consistent fashion and also enable future projection of air quality in this region.”

Comment 7

(3) Figure S3, why Florida surface ozone data were not included? This study is for the Southeast, which should include Florida.

Response 7

We didn't include ozone data in Florida to avoid influences of ocean impacts (such as emissions, circulation, etc.).

Comment 8

(4) Page 9, lines 329-331, why aircraft measurements for biomass burning and urban plumes are excluded for the model evaluation?

Response 8

This is because these cannot be well represented on the scale of model. We have explained this in the revised text in lines 306-309 as

“Data from biomass burning (CH₃CN ≥ 225 ppt or HCN ≥ 500 ppt), urban plumes (NO₂ ≥ 4 ppb or NO_x/NO_y ≥ 0.4 (if NO_y is available)), and stratospheric air (O₃/CO >1.25 mol mol⁻¹) are excluded (Hudman et al., 2007) in all the analyses, as these subgrid processes may not be well represented in our model.”

Comment 9

- (5) 1. Page 9, lines 334-335, “. . . use model output sampled along the flight track with 1-min resolution”. How exactly this has been done?
2. What are the time-steps of the model?
3. What are the time intervals of the model outputs?
4. Is this necessary since all the presented comparisons are for monthly averaged values anyway?
5. Is there any statistical metrics calculated for the comparisons at the 1-min resolution?

Response 9

1. We mapped model outputs with observations at different locations (i.e. latitude, longitude and pressure) and local sampling time (for example, 8:12 CST sampling time corresponds to model estimate during 8:00-9:00 CST).
2. The chemistry and transport time step of the model is 20 mins. We now add “**The current time step for chemistry and transport in our model is 20 mins.**” in lines 155-156.
3. The output time interval of the model in this study is 1 hour for chemical tracers and 1 month for depositions of these tracers.
4. We used 1-min time resolution average of measurements to sample model output to better capture the locations of aircraft as well as atmospheric composition. This is the best way to compare the model with aircraft measurements.
5. We have calculated NMB, NME, FB, and FE using aircraft measurements and model estimates and included the results in Table S4 in the revised supplement.

Comment 10

- (6) 1. Table 1 and table 2, “Monthly averaged”, or two month (July-August) averaged?
2. Table 1, Why not present the NO_x emissions for the Southeastern US too, instead of for only North America totals?
3. Are they still 40% reduction for the Southeast only?
4. Also, how about those numbers of emissions amounts for the Southeast only used in the model compared to the NEI 2011 final version inventory?
5. Also, what about anthropogenic emissions pollutants other than NO_x, such as VOC, CO etc.?

Response 10

1. ‘Monthly averaged’ in the original Table 1 and Table 2 are two-month averaged for July and August.
2. We calculated national total NO_x emissions for better comparison with NEI11 inventory. We also have included NO_x emissions over the Southeast U.S. in Table 1 in the revised manuscript as well.
3. 40% reduction was applied to eastern U.S. that contributes 74% of the national total NO_x emissions.
4. The comparison between NEI 2011 and RCP 8.5 shows similar relative differences in both national and Southeast region. We now add this in the text in lines 188-190

“Compared to the NEI11v1 inventory, RCP 8.5 used in our model shows similar relative differences in both national and Southeast region.”

5. The dominate VOC precursor of summertime ozone in the Southeast U.S. is biogenic isoprene. Contributions of anthropogenic VOCs and CO are quite small compare to isoprene on summertime ozone in this region. Therefore, we didn't compare anthropogenic VOCs and CO from NEI2011 inventory and that from our model.

Comment 11

(7) Figure 7, there are bumps at around 30ppb in the 2013 simulations, but not seen from the 2004 simulation and any observations. Why those bumps?

Response 11

We are unclear about the cause of those bumps. We find that those values appear to be related to urban and suburban areas where NO_x sources are concentrated.

Comment 12

(8) Page 10, lines 370-372, what is this “regionally-averaged NO_y”? It seems jumped from the observations to simulations here?

Response 12

This sentence has been removed to avoid confusion.

Comment 13

(9) Page 10, line 369, “This is likely due to the different sampling regions (Figure S4) from the two campaigns”. If this is the case, then why you can trust the other derived reduction numbers from comparing the observations form the two campaigns? And why you can trust the changes derived from these observations to represent the real changes in the Southeastern US as a region?

Response 13

All the analysis exhibited in section 4.1 is mainly for evaluation of our model by comparison with measurements during the three aircraft campaigns. As the flight tracks, although were not exactly identical, were all within the Southeast U.S. region, reduction numbers derived from these sampling data represent the general trend in this region to some extent.

Our strategy is that if our model can well reproduce vertical profiles of RON and related species from aircraft measurements, we assume model is representative of this chemical environment and then use model to derive the real changes between the two years a decade apart. This is showed in section 5. We have clarified this in the revised manuscript in lines 517-520 as:

“As RON and related species from aircraft and surface measurements are well reproduced in our model for both 2004 and 2013, we assume that the model is representative of this

chemical environment, and then use the model to derive monthly mean changes between 2004 and 2013.”

Comment 14

(10) 1. Page 18, lines 649-651. What are the quantitative differences in both simulated and observed RH and temperature between 2004 and 2013 in July-August?

2. What about the differences in cloud cover, precipitation etc. that also impact on ozone formation? 3. Lines 654-657, this statement, for changes between 2004 and 2013, is not supported by convincing evidence. How exactly the citation in lines 651-654 supports this statement? Since this is also the base for deriving the major finding: “reactive nitrogen species and ozone over the Southeast U.S.”, “decline proportionally with decreasing NO_x emissions in this region”, solid demonstration of this statement is needed.

Response 14

1. Based on observations (ICARTT and SENEX), changes of temperature and RH are + 2.6 K (291.5 - 294.1 K) and + 2.7 % (68.9 - 71.6 %), respectively. Our model predicts + 2.4 K (290.0 - 292.4 K) and - 0.88 % (77.3 - 76.4 %) of changes for temperature and RH. Therefore, our model can well capture this trend of meteorology. It also proves that decreases of ozone over the Southeast U.S. from 2004 to 2013 is not attributed to meteorology. We reflect this in the revised text in lines 608-611 as:

“Our model shows marginal differences in RH (less than 1 %) and temperature (+ 2.4 K) within the PBL over the Southeast U.S. between the summers of 2004 and 2013, consistent with observed changes of RH (+ 2.7 %) and temperature (+ 2.6 K) during ICARTT and SENEX.”

2. There are no observations of cloud cover and precipitation from aircraft measurements. Based on measurements from NADP, there are no significant changes of observed precipitation between 2004 and 2013 in July-August (total precipitation of 14.6 m in two months). Our model showed good agreement with observations, with 13.1 m for 2004 and 15.3 m 2013.

3. Lin et al. (2017) found 0.2 – 0.4 ppb/yr increase of ozone due to meteorology changes. this is not significant compared to observed 1.1 ppb/yr decrease of ozone. Camalier et al. (2007) also showed that summertime ozone over the Southeast U.S. is more affected by RH that mostly varied little during 2004-2013, according to both observations and model estimates. We have revised the text in lines 612-620 as:

“Camalier et al. (2007) showed that RH has a much bigger impact on summertime ozone than temperature over the Southeast U.S., suggesting little influence of meteorology on ozone trend. Using the same model but with the standard AM3 chemical mechanism, Lin et al. (2017) found that meteorology changes would have caused high surface ozone over the eastern U.S. to increase by 0.2 - 0.4 ppb yr⁻¹ in the absence of emission controls from 1988 to 2014. Therefore, we conclude that the impact of climate variability and change on O₃ is relatively small compared to NO_x emission reductions over the Southeast U.S., consistent with previous studies (Lam et al., 2011; Hidy et al., 2014; Lin et al., 2017; Rieder et al., 2015)”

47 Abstract

48 Widespread efforts to abate ozone (O₃) smog have significantly reduced nitrogen oxides
49 (NO_x) emissions over the past two decades in the Southeast U.S. (SEUS), a place heavily
50 influenced by both anthropogenic and biogenic emissions. How reactive nitrogen
51 speciation responds to the reduction in NO_x emissions in this region remains to be
52 elucidated. Here we exploit aircraft measurements from ICARTT (July-August, 2004),
53 SENEX (June-July, 2013), and SEAC⁴RS (August-September, 2013) and long-term
54 ground measurement networks alongside a global chemistry-climate model to examine
55 decadal changes in summertime reactive oxidized nitrogen (RON)~~species~~ and ozone over
56 the Southeast U.S. We show that our model can well reproduce the mean vertical profiles of
57 major RON species and the total (NO_y) in both 2004 and 2013. Among the major RON species,
58 nitric acid (HNO₃) is dominated (~ 42 – 45 %), followed by NO_x (31 %), total peroxy nitrates
59 (ΣPNs; 14 %), and total alkyl nitrates (ΣANs; 9 – 12 %) on a regional scale. We find that
60 most RON, reactive nitrogen species, including NO_x, ΣPNs~~peroxyacetyl nitrate (PAN)~~
61 and ~~nitric acid (HNO₃)~~ decline proportionally with decreasing NO_x emissions in this
62 region, leading to a similar decline in ~~exported~~-NO_y. This linear response might be in
63 part due to the nearly constant summertime supply of biogenic VOC emissions in this
64 region. Our model captures the observed relative change of RON~~reactive nitrogen species~~
65 and surface ozone from 2004 to 2013. Model sensitivity tests indicate that further
66 reductions of NO_x emissions will lead to a continued decline in surface ozone and less
67 frequent high~~extreme~~ ozone events.

68 1 Introduction

69 Since the 1990s, the U.S.A. Environmental Protection Agency (U.S. EPA) has targeted
70 emissions of nitrogen oxides (NO_x) to improve air quality by lowering regional
71 photochemical smog (The 1990 Clean Air Amendment). Satellite- and ground-based
72 observations imply significant declines in U.S. NO_x emissions, with a decreasing rate of
73 roughly - 4 % yr⁻¹ after 2005 (Krotkov et al., 2016; Russell et al., 2012; Tong et al., 2015;
74 Miyazaki et al., 2017; Lu et al., 2015; Lamsal et al., 2015). This has proven effective at
75 lowering near-surface ozone (O₃) in the past few decades (Cooper et al., 2012; Simon et
76 al., 2015; Hidy and Blanchard, 2015; Stoeckenius et al., 2015; Xing et al., 2015; Yahya et
77 al., 2016). ~~The . According to U.S. EPA data, the~~ average of the annual 4th highest
78 ~~maximum~~-daily ~~averaged~~-maximum 8-~~h~~ ~~average~~~~hr~~ (MDA8) ozone over ~~206212~~ sites has
79 decreased by ~~3133~~ % from 101 ppb in 1980 to ~~7068~~ ppb in ~~20162014~~ across the
80 continental U.S., with more significant reductions in rural areas of the eastern U.S. in
81 summer (Simon et al., 2015; Cooper et al., 2012). Here we use both~~combine~~ aircraft and
82 ground-based datasets, combined with a high resolution~~for both ozone and reactive~~
83 ~~nitrogen to evaluate a~~ chemistry-climate model, used ~~to evaluate project future~~ responses
84 of reactive oxidized nitrogen (RON) and surface ozone to the ~~to changes in~~-NO_x emission
85 reductions in the Southeast U.S.~~emissions.~~

86 In the troposphere, ozone is produced through photochemical reactions involving NO_x
87 and volatile organic compounds (VOCs) in the presence of sunlight. During
88 photooxidation, a large fraction of NO_x is transformed into its reservoirs, including nitric
89 acid (HNO₃), peroxy nitrates (RO₂NO₂; dominated by peroxyacetyl nitrate (PAN)), and
90 alkyl nitrates (RONO₂). These species, together with NO_x, are known as total reactive
91 oxidized nitrogen (NO_y = NO_x + HNO₃ + HONO + 2 × N₂O₅ + total peroxy nitrates
92 (ΣPNs) + total alkyl nitrates (ΣANs)). Some of these reservoir species, particularly those
93 with an organic component, tend to be less soluble and longer lived. They may carry
94 reactive nitrogen far from the NO_x source region (Stohl et al., 2002; Parrish et al., 2004;
95 Li et al., 2004) and thereby affect NO_x concentrations and O₃ formation on a regional to
96 global scale (Liang et al., 1998; Horowitz et al., 1998; Perring et al., 2013; Paulot et al.,
97 2016; Hudman et al., 2004).

98 RONO₂ originating from biogenic VOCs (BVOCs) represents a major uncertainty in the
99 NO_y budget, as BVOC emissions account for more than 80 % of global VOC emissions
100 (Millet et al., 2008). To a large extent, this is due to the uncertainties in current
101 understanding of BVOC oxidation chemistry. Biogenic RONO₂ species are mainly
102 produced from the oxidation of BVOCs by OH in the presence of NO_x during daytime
103 and by nitrate radical (NO₃) during nighttime. Laboratory and field studies show a wide
104 range of RONO₂ yields from their BVOC precursors (Browne et al., 2014; Fry et al.,
105 2014; Lockwood et al., 2010; Paulot et al., 2009; Rindelaub et al., 2015; Rollins et al.,
106 2009; Lee et al., 2014; Xiong et al., 2015; Xiong et al., 2016; Teng et al., 2015). Another
107 uncertainty lies in the fate of RONO₂, i.e. recycling RONO₂ into NO_x or versus converting
108 it to HNO₃ ~~as a NO_x sink~~ have important implications for the NO_y budget and thus O₃
109 production (Fiore et al., 2005; Horowitz et al., 2007; Ito et al., 2009; Perring et al., 2013;
110 Paulot et al., 2012). This is further complicated by particle-phase ~~In addition, recent field~~
111 ~~studies have shown that~~ RONO₂, an important component is a potential source
112 of secondary organic aerosol (SOA) over the Southeast U.S. (Xu et al., 2015; Lee et al.,
113 2016). The fate of particle-phase RONO₂ is unclear, with the possibility for removal by
114 hydrolysis to form HNO₃ (Jacobs et al., 2014; Hu et al., 2011; Darer et al., 2011;
115 Rindelaub et al., 2015; Szmigielski et al., 2010; Sato, 2008; Romer et al., 2016; Wolfe et
116 al., 2015), photochemical aging (Nah et al., 2016; Boyd et al., 2015), ~~and~~ deposition
117 (Nguyen et al., 2015). To what extent RONO₂ affect the partitioning of RON and surface
118 ozone remains to be elucidated.

119 Extensive datasets in ~~Over~~ the Southeast U.S. offer a great opportunity to study the
120 decadal change of RON; ~~photochemistry in summer is strongly influenced by both~~
121 biogenic and surface ozone, resulting from NO_x emission decline. ~~anthropogenic~~
122 emissions, implying strong sensitivity of O₃ production to changes in anthropogenic NO_x
123 emissions (Simon et al., 2015). Aircraft campaigns during the summers of 2004 and 2013,
124 including (i.e. the International Consortium for Atmospheric Research on Transport and

125 Transformation (ICARTT) (Fehsenfeld et al., 2006; Singh et al., 2006), the Southeast
126 Nexus (SETEX) (Warneke et al., 2016), and ~~the~~ Studies of Emissions ~~and~~, Atmospheric
127 Composition, Clouds and Climate Coupling by Regional Surveys (SEAC⁴RS) (Toon et
128 al., 2016),) provide detailed characterization of tropospheric composition in this region
129 separated by nearly a decade. ~~These data have been widely used to evaluate model~~
130 ~~estimates of RON and ozone (Singh et al., 2007; Pierce et al., 2007; Perring et al., 2009;~~
131 ~~Fischer et al., 2014; Hudman et al., 2007; Henderson et al., 2011; Hudman et al., 2009;~~
132 ~~Edwards et al., 2017; Baker and Woody, 2017; Travis et al., 2016; Mao et al., 2013b;~~
133 ~~Fisher et al., 2016; Yu et al., 2016; Liu et al., 2016).~~ Together with ~~measurements from~~
134 ~~networks, including the wet deposition flux of nitrate (NO_3^-) from the~~ National
135 Atmospheric Deposition Program (NADP) and ~~NO_y and O_3 measurements from EPA Air~~
136 ~~Quality System (AQS),) surface network,~~ these ~~datasets enable aircraft datasets provide~~
137 ~~insights into changes in O_3 pollution and NO_y speciation over a~~ close examination of
138 ~~responses of RON and surface ozone to decadal period when~~ NO_x emissions ~~reduction in~~
139 ~~this region were declining rapidly as pollution control programs were implemented.~~

140 Here we use a high-resolution global 3D climate-chemistry model, the Geophysical Fluid
141 Dynamics Laboratory (GFDL) AM3 model, with updated isoprene and organic nitrate
142 chemistry to investigate decadal changes of ~~RONNO_y (and its specific constituents)~~ and
143 surface O_3 during summer between 2004 and 2013 over the Southeast U.S. We first
144 evaluate the model with comprehensive measurements from three aircraft campaigns in
145 the summer of 2004 (ICARTT) and 2013 (SETEX and SEAC⁴RS). ~~Model~~The model
146 estimates of nitrate wet deposition flux are also evaluated against measurements from ~~the~~
147 NADP; model estimates ~~offer~~ NO_y are compared ~~with~~against measurements from EPA
148 AQS to provide an additional constraint on the fate of ~~RONNO_y species~~ in the model. We
149 then investigate the repartitioning of ~~RONNO_y species~~ in response to NO_x emission
150 reductions from 2004 to 2013 ~~on a regional scale.~~ From there, we examine the model
151 estimate of decadal changes of summertime surface O_3 at 157 EPA AQS monitoring sites
152 over the Southeast U.S. ~~We also by comparing to the measurements from EPA AQS. Last,~~
153 ~~we~~ demonstrate the sensitivity of ~~RON and MDA8 O_3 to a hypothetical and NO_y~~
154 ~~speciation to projected~~ NO_x emission ~~reduction decreases~~ over the next decade. ~~(to 2022).~~

155 2 Methodology

156 2.1 AM3 Model

157 We apply a high-resolution (50 x 50 km²) version of the GFDL AM3 ~~global chemistry-~~
158 ~~climate~~ model to study decadal changes of ~~RONO_3 and O_3 organic nitrates~~ over the
159 Southeast U.S. ~~Chemistry-climate models provide a unique capability to both evaluate~~
160 ~~model representation of these observed changes and use that to improve future~~
161 ~~projections of air quality in the same region.~~ The model configuration is to a large extent

162 | similar to that used in ~~another companion~~ paper (Li et al., 2016); and a short summary is
163 | provided below. The dynamical core, physical parameterizations, cloud and precipitation
164 | processes, and cloud-aerosol interactions mainly follow Donner et al. (2011), except that
165 | convective plumes are computed on a vertical grid with finer resolution (Paulot et al.,
166 | 2016). Dry deposition in the model has been updated to use dry deposition velocities
167 | calculated in the GEOS-Chem model (Paulot et al., 2016), to reflect rapid deposition of
168 | organic nitrates and oxidized volatile organic compounds (OVOCs) (Nguyen et al., 2015).
169 | The current time step for chemistry and transport in our model is 20 mins. We show
170 | below in section 4.1 that, with the current setting, our model can well reproduce the
171 | vertical profiles of RON. Sensitivity of RON to operator duration should refer to Philip et
172 | al. (2016).;

173 | Isoprene emissions are computed in the model using the Model of Emissions of Gases
174 | and Aerosols from Nature (MEGAN). In 2004, isoprene emissions over the continental
175 | U.S. (25-50° N, 130-70° W) are computed to be 8.0 Tg C in July and August together,
176 | with a previous model estimate of 7.5 Tg C by Mao et al. (2013b). In 2013, model
177 | estimates of isoprene emissions were scaled down by 20% following Li et al. Isoprene
178 | emissions are computed in the model using the Model of Emissions of Gases and
179 | Aerosols from Nature (MEGAN). In July August of 2004, the computed isoprene
180 | emissions over the continental U.S. (25-50° N, 130-70° W) are 8.0 Tg C and appear to be
181 | consistent with a previous model estimate of 7.5 Tg C by Mao et al. (2013) in the same
182 | region during this period. For 2013, we applied a 20 % reduction of MEGAN for
183 | isoprene emissions as described in Li et al. (2016). The resulting isoprene emissions
184 | are emission is 7.7 Tg C in July-August in over this region, with little difference compared
185 | to 2004. Monoterpene emissions follow Naik et al. (2013) and do not vary interannually,
186 | with a total of 4.0 Tg C in July and August.

187 | Anthropogenic emissions follow the Representative Concentration Pathway 8.5 (RCP 8.5)
188 | projection (Lamarque et al., 2011) for both 2004 and 2013, to compare the model to
189 | observations in a consistent fashion and also enable future projection of air quality in this
190 | region. As shown in Table 1, anthropogenic NO_x emissions over the continental U.S.
191 | during July-August of 2004 amount to 0.42 Tg N mon⁻¹, consistent with Hudman et al.
192 | (2007) but 11 % lower than EPA estimates of 0.47 Tg N mon⁻¹ (Granier et al., 2011). For
193 | the year of 2013, we apply a 25 % reduction to the anthropogenic NO_x emissions from
194 | the RCP 8.5 projection (from base year of 2010), to best reproduce the vertical profiles of
195 | RONNO_y species during SENEX as shown below in section 4.1. This adjustment is also
196 | consistent with recent estimates of NO_x emissions over the Southeast U.S. (Anderson et
197 | al., 2014). The resulting anthropogenic NO_x emissions (0.25 Tg N mon⁻¹) are 14 % lower
198 | than NEI11v1 emission inventory estimate of 0.29 Tg N mon⁻¹ (0.28 Tg N mon⁻¹ from the
199 | updated NEI11v2 emission inventory), although both inventories have a similar spatial
200 | distribution (Figure S1). We also apply a diurnal variation to anthropogenic NO_x

emissions following Mao et al. (2013b). Soil NO_x emissions in our model, 3.6 Tg N yr⁻¹ globally (Naik et al., 2013), are considerably lower than other model estimates, including 5.5 Tg N yr⁻¹ in Yienger and Levy (1995) and 9.0 Tg N yr⁻¹ in Hudman et al. (2012). As a result, the anthropogenic NO_x emissions over the continental U.S. are 0.84 Tg N for July-August of 2004, and 0.50 Tg N in July-August of 2013, with 40 % reduction from 2004 to 2013 (Table 1). This relative change in anthropogenic NO_x emissions is consistent with EPA estimates (<https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data>) and satellite observations. The resulting anthropogenic NO_x emissions (0.25 Tg N mon⁻¹) are 14 % lower than NEI11v1 emission inventory estimate (0.29 Tg N mon⁻¹), although both inventories have a similar spatial distribution (Figure S1). Soil NO_x emissions in our model, 3.6 Tg N yr⁻¹ globally (Naik et al., 2013), are considerably lower than other model estimates, including 5.5 Tg N yr⁻¹ in Yienger and Levy (1995) and 9.0 Tg N yr⁻¹ in Hudman et al. (2012). Lightning NO_x, calculated as a function of parameterized convection in the model following Price et al. (1997), is also lower than that of Hudman et al. (2007). Compared to the NEI11v1 inventory, RCP 8.5 used in our model shows similar relative differences in both national and Southeast region. –by a factor of 8 over the U.S. As a result, the total NO_x emissions over the continental U.S. are 0.98 Tg N for July-August of 2004, and 0.64 Tg N in July-August of 2013 (Table 1). The 40 % reduction of anthropogenic NO_x emissions from 2004 to 2013 over the eastern U.S. is consistent with EPA Air Pollutant Emissions Trends Data (<https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data>) and satellite observations (Krotkov et al., 2016; Lu et al., 2015).

2.2 Gas-phase chemistry

We apply the same isoprene mechanism as described by Li et al. (2016). A full list of the reactions can be found in Table S1. This mechanism is based on Mao et al. (2013b), but has been significantly revised to incorporate recent laboratory updates on isoprene oxidation by OH and O₃. –A full list of the reactions can be found in Table S1. This mechanism is based on Mao et al. (2013), but has been significantly revised to incorporate recent laboratory updates on isoprene oxidation by OH and O₃ (Schwantes et al., 2015; Bates et al., 2016; Peeters et al., 2014; St. Clair et al., 2016; Bates et al., 2014; Praske et al., 2015; Müller et al., 2014; Lee et al., 2014; Crouse et al., 2011). One major feature is the suppression of δ-isoprene hydroxyl peroxy radical (δ-ISOPO₂) and subsequent reaction pathways in the model, as these channels are considered to be of minor importance under ambient conditions (Peeters et al., 2014; Bates et al., 2014). The fraction of ISOPO₂ undergoing isomerization is calculated using bulk isomerization estimates (Crouse et al., 2011). As a result, the first-generation isoprene alkyl nitrate is assumed to be β-hydroxy nitrate (ISOPNB) in the model with a yield of 10 % from the ISOPO₂ + NO pathway. This differs from a recent GEOS-Chem study of organic nitrates over the Southeast U.S. that assumed 9 % yield of the first-generation isoprene alkyl

240 nitrate comprised of 90 % ISOPNB and 10 % δ -hydroxy nitrate (ISOPND) (Fisher et al.,
241 2016). The treatment of β - and δ -ISOPO₂ will not only affect the speciation of organic
242 nitrates but also the production of O₃ due to different NO_x recycling efficiency in their
243 secondary products. We also include updated chemistry for methylvinyl ketone (MVK)
244 (Praske et al., 2015), an updated yield of hydroxy hydroperoxides (ISOPOOH) (Bates et
245 al., 2016; St. Clair et al., 2016), fast photolysis of carbonyl organic nitrates (Müller et al.,
246 2014), and an updated ozonolysis rate of ISOPNB (Lee et al., 2014). In addition, we
247 reduce the yield of organic nitrates (MACRN) from methacrolein (MACR) oxidation
248 from 15 % to 3 %, which is estimated from the measured yield of nitrate from MVK
249 oxidation (Praske et al., 2015).

250 Another major model revision involves the treatment of ~~the~~ nighttime oxidation of
251 isoprene. Instead of following Mao et al. [\(2013b\)](#), ~~we revised(2013)~~, ~~we revised the~~
252 nighttime oxidation of isoprene largely based on the Leeds Master Chemical Mechanism
253 v3.2 (MCM v3.2), allowing a more complete description of isoprene oxidation by NO₃.
254 In particular, MCM v3.2 suggests significant production of propanone nitrate (PROPNN)
255 from the photooxidation of the C₅ carbonyl nitrate, consistent with recent laboratory
256 experiments (Schwantes et al., 2015). We also updated the products of the reaction of
257 nitrooxy alkylperoxy radical (INO₂), the peroxy radical from isoprene oxidation by NO₃,
258 with HO₂ to reflect a lower molar yield (0.77) of C₅ nitrooxy hydroperoxide (INPN)
259 (Schwantes et al., 2015). The differences between MCM v3.2 and the most updated
260 version, MCM v3.3.1, in isoprene nighttime chemistry appears to be small (Jenkin et al.,
261 2015). We therefore use MCM v3.2 as the reference in this work.

262 We include a highly simplified chemistry for the oxidation of monoterpenes in this work,
263 mainly to quantify their contribution to organic nitrates. Monoterpenes are lumped into
264 one chemical species (C₁₀H₁₆) in our model. The organic nitrate yield is set to 26 % from
265 OH-initiated oxidation (Rindelaub et al., 2015) and to 10 % from NO₃-initiated oxidation
266 (Browne et al., 2014). Details of the monoterpene chemistry can be found in Table S2.

267 **2.3 Heterogeneous loss of organic nitrates**

268 Field and laboratory studies have indicated a potential contribution to aerosol formation
269 of organic nitrates from BVOC oxidation (Ayres et al., 2015; [Fry et al., 2014](#); [Nah et al.,](#)
270 [2016](#); [Rollins et al., 2009](#); [Rindelaub et al., 2015](#); [Boyd et al., 2015](#); [Lee et al., 2016](#); [Ng](#)
271 [et al., 2008](#); [Fry et al., 2009](#); [Xu et al., 2015](#); [Lee et al., 2014](#); [Bean and Hildebrandt Ruiz,](#)
272 [2016](#); [Spittler et al., 2006](#)); ~~Error! Hyperlink reference not valid.~~~~Fry et al., 2014~~; ~~Error!~~
273 ~~Hyperlink reference not valid.~~~~Nah et al., 2016~~; ~~Error! Hyperlink reference not valid.~~~~Rollins et~~
274 ~~al., 2009~~; ~~Error! Hyperlink reference not valid.~~~~Rindelaub et al., 2015~~; ~~Error! Hyperlink~~
275 ~~reference not valid.~~~~Boyd et al., 2015~~; ~~Error! Hyperlink reference not valid.~~~~Lee et al., 2016~~;
276 ~~Error! Hyperlink reference not valid.~~~~Ng et al., 2008~~; ~~Error! Hyperlink reference not valid.~~~~Fry~~
277 ~~et al., 2009~~; ~~Error! Hyperlink reference not valid.~~~~Xu et al., 2015~~; ~~Error! Hyperlink reference~~

278 | ~~not valid.~~Lee et al., 2014; ~~Error! Hyperlink reference not valid.~~Bean and Hildebrandt Ruiz,
279 | ~~2016; Error! Hyperlink reference not valid.~~Spittler et al., 2006). Aerosol yield depends on
280 | both the VOC precursor and the oxidant. For example, Δ -3-carene oxidation by NO_3 can
281 | produce a 38-65 % yield of organic aerosols in a smog chamber (Fry et al., 2014), which
282 | is much higher than the 1-24 % yield from NO_3 -initiated isoprene oxidation (Ng et al.,
283 | ~~2008; Rollins et al., 2009; (Error! Hyperlink reference not valid.~~Ng et al., 2008; ~~Error!~~
284 | ~~Hyperlink reference not valid.~~Rollins et al., 2009; Ayres et al., 2015). Recent chamber
285 | studies indicate a very low aerosol yield from α -pinene oxidation by NO_3 (Nah et al.,
286 | 2016; Fry et al., 2014), the aerosol yield increases to ~ 18 % when α -pinene is oxidized
287 | by OH (Rollins et al., 2010; Rindelaub et al., 2015). It should be noted that these results
288 | from laboratory experiments might not be representative ~~of~~ atmospheric conditions in
289 | terms of the RO_2 reaction partner or RO_2 lifetime.

290 | In the condensed phase, organic nitrates can undergo hydrolysis reactions ~~producing~~
291 | ~~produce~~ HNO_3 (Darer et al., 2011; Hu et al., 2011; Rindelaub et al., 2015; Boyd et al.,
292 | 2015; Szmigielski et al., 2010; Sato, 2008; Jacobs et al., 2014; Bean and Hildebrandt
293 | Ruiz, 2016). However, the hydrolysis rate varies greatly with the structure of nitrate, ~~and~~
294 | ~~for most species remains highly uncertain, though certain trends have been elucidated, e.g.~~
295 | ~~tertiary nitrates favor hydrolysis while primary and secondary nitrates are more stable~~
296 | (Bean and Hildebrandt Ruiz, 2016; Darer et al., 2011; Hu et al., 2011; Boyd et al., 2015).
297 | Here we assume a first-order irreversible reactive uptake for the heterogeneous loss of
298 | organic nitrates onto aerosols (R1), followed by its hydrolysis reaction returning HNO_3
299 | and alcohols (R2) (Fisher et al., 2016):

300 | ~~where RONO_2 , AONJ and ROH represent gas- and particle-phase organic nitrates and~~
301 | ~~alcohols respectively. We allow heterogeneous loss of organic nitrates to sulfate, black~~
302 | ~~carbon, primary organic carbon, sea salt, mineral dust and SOA following Mao et al.~~
303 | ~~(2013a). Besides the base case that only includes ISOPNB for heterogeneous loss (Jacobs~~
304 | ~~et al., 2014), we include two additional sensitivity tests to evaluate the potential impact of~~
305 | ~~organic nitrate hydrolysis. One is “hydro full” case including heterogeneous loss of a C_5~~
306 | ~~dihydroxy dinitrate (DHDN) and monoterpene nitrates from OH oxidation (TERPN1),~~
307 | ~~and the other one is “no hydro” case assuming no heterogeneous loss for any organic~~
308 | ~~nitrates. We adopt an effective uptake coefficient 0.005 for ISOPNB and DHDN, and~~
309 | ~~0.01 for TERPN1, following Fisher et al. (2016), with a 3-h bulk lifetime in particle~~
310 | ~~phase where RONO_2 , AONJ and ROH represent gas- and particle-phase organic nitrates~~
311 | ~~and alcohols respectively. For the daytime isoprene organic nitrates (mainly from the~~
312 | ~~$\text{ISOPO}_2 + \text{NO}$ pathway), we only consider heterogeneous loss of ISOPNB to aerosols,~~
313 | ~~since this has been detected in field and laboratory studies (Jacobs et al., 2014). Lee et al.~~

~~(2014) hypothesized a significant amount of C₅ dinitrate (DHDN, with a molar yield of 21 % via the ISOPNB peroxy radical + NO pathway) produced from OH oxidation of ISOPNB. Since DHDN is highly functionalized and might partition to the condensed phase forming SOA, we test the impact of this process on the estimate of NO_y speciation and O₃ concentration in a sensitivity study (AM3h, Figure S2). Aerosol formation from nighttime isoprene organic nitrates (from isoprene oxidation by NO₃) are neglected due to the low mass yields. Information about hydrolysis of daytime monoterpene nitrates (from OH oxidation of monoterpenes) is quite sparse. Two chamber studies to date have examined the hydrolysis of nitrates from α -pinene oxidation by OH (Rindelaub et al., 2015; Bean and Hildebrandt Ruiz, 2016). They found that the hydrolysis rate is dependent on relative humidity (RH) and aerosol acidity. We also examine the hydrolysis of daytime monoterpene nitrates (TERPN1) in the above sensitivity study (AM3h, Figure S2). We do not consider heterogeneous loss of nighttime monoterpene nitrates in this work due to inadequate information.~~

~~We allow heterogeneous loss of organic nitrates to sulfate, black carbon, primary organic carbon, sea salt, mineral dust and SOA following Li et al. (2016) (Table S3). Details of each case are listed in Table 2.~~

~~The first order rate constant k_1 is determined using an effective uptake coefficient 0.005 for isoprene nitrates (ISOPNB in all hydrolysis cases and DHDN in AM3h, equivalent to 1.8 h lifetime in the atmosphere) and 0.01 for daytime monoterpene nitrates (TERPN1, in AM3h) following Fisher et al. (2016), which are consistent with other estimates (Wolfe et al., 2015; Marais et al., 2016). Due to the large uncertainties of lifetimes against hydrolysis, we assume a 3-h bulk lifetime for the three particle phase nitrates following Pye et al. (2015), consistent with recent estimate of organic nitrate aerosol lifetime at a ground monitoring site in Centreville, Alabama (CTL) (Lee et al., 2016). We also conduct another sensitivity test (AM3 w/o hydro in Figure 1 and Figure 2) without accounting for the heterogeneous loss of organic nitrates.~~

3 Observational datasets

We use measurements from a series of field campaigns (2004 ICARTT, 2013 SENEX, and 2013 SEAC⁴RS) to evaluate ~~model~~the performance ~~on~~of the model in estimating O₃, NO_x, HNO₃, PAN, Σ ANs and NO_y over the Southeast U.S. ~~in~~during summer.

The ICARTT aircraft campaign provided a detailed characterization of tropospheric chemistry over the eastern U.S. in the summer of 2004 (July 1 - August 15, 2004). Two ~~aircrafts~~aircraft, the NASA DC-8 and the NOAA WP-3D, were deployed to collect measurements of ozone, ~~RONNO_y species~~, isoprene and its oxidation products. Here we focus on data including O₃, NO_x, HCHO (Tunable Diode Laser (TDL) absorption spectrometry), HNO₃ (mist chamber/IC by University of New Hampshire and Chemical

351 Ionization Mass Spectrometer (CIMS) by California Institute of Technology), PAN and
352 Σ ANs (including gas and aerosol RONO₂) ~~collected from 11 science flights~~ on the NASA
353 DC-8 aircraft over the Southeast U.S. Details of the instrument operation and accuracy
354 are summarized in Singh et al. (2006) and references therein.

355 ~~Two SENEX was a NOAA aircraft campaigns were conducted in the summer of 2013~~
356 ~~over the Southeast U.S. The first one is NOAA SENEX campaign, using NOAA WP-3D~~
357 ~~aircraft – aimed to investigate the interaction between biogenic and anthropogenic~~
358 ~~emissions and the formation of secondary pollutants over the Southeast U.S. in summer~~
359 ~~2013 (May 27 - July 10, 2013). We focus on daytime The NOAA WP-3D aircraft was~~
360 ~~launched to collect measurements of a variety of chemical compounds during 18~~
361 ~~scientific flights. Here we focus on data, including O₃, NO_x, HNO₃, PAN, speciated~~
362 ~~RONO₂ and NO_y in this work. from 15 daytime flights only. We also used measurements~~
363 ~~of ISOPN, methylvinylketone nitrates (MVKN) and methacrolein nitrates (MACRN)~~
364 ~~taken by University of Washington from 10 daytime flights during June 3–July 3 of the~~
365 ~~campaign. Details of the instrument operation and accuracy are summarized in Warneke~~
366 ~~et al. (2016) and references therein. The second one is NASA SEAC⁴RS campaign,~~
367 ~~which took place in August - September of 2013, with a focus on~~

368 ~~Because Σ ANs and several speciated RONO₂ were not measured on the NOAA WP-3D~~
369 ~~aircrafts during SENEX, we include another aircraft campaign for model evaluation~~
370 ~~despite that this campaign has a major coverage in September of 2013. SEAC⁴RS was a~~
371 ~~NASA aircraft campaign with the field mission based in Houston, Texas during August-~~
372 ~~September 2013, designed to examine vertical transport of atmospheric pollutants from~~
373 ~~the surface to the stratosphere. Here we focus on It provides comprehensive~~
374 ~~measurements of atmospheric composition in the lower troposphere over North America.~~
375 ~~Here we use observations of O₃, NO₂, HCHO (laser-induced fluorescence, LIF), Σ ANs~~
376 ~~(including gas and aerosol RONO₂) and speciated RONO₂ collected on from 20 NASA~~
377 ~~DC-8 aircraft science flights to evaluate model representation the correlations of Σ ANs~~
378 ~~and several major RONO₂ originating from isoprene oxidation, during daytime with O_x (=~~
379 ~~O₃ + NO₂) and with HCHO, respectively, as additional constraints to the model. Details~~
380 ~~of the instrument operation and accuracy are summarized in Toon et al. (2016) and~~
381 ~~references therein. We mainly focus on RONO₂ and related species from SEAC⁴RS in~~
382 ~~this work.~~

383 Besides these aircraft campaigns, we also use surface observations for model evaluation,
384 including nitrate (NO₃⁻) wet deposition flux and concentration from the National
385 TrendsTrend Network (NTN) of NADP (accessible at <http://nadp.sws.uiuc.edu/data/>) and
386 surface O₃ and NO_y from EPA AQS (accessible at
387 https://aq5.epa.gov/aqsweb/documents/data_mart_welcome.html). NTN provides the
388 [monthly NO₃⁻ concentration and precipitation so that the monthly mean concentration of](#)

389 NO₃ and wet deposition flux could be derived for model evaluation. The AQS database
390 provides measurements of important ambient air pollutants (O₃, NO_x, SO₂, PM_{2.5} species,
391 etc.) collected at monitoring sites across the continental U.S. We focus on NO₃ wet
392 deposition fluxes at 53 NADP sites (Figure 3) and MDA8 O₃ at 157 EPA AQS sites
393 (Figure S3) ~~located~~ in the Southeast U.S. during July - August of 2004 and 2013. NO_y
394 measurements at 10 out of the 157 AQS sites in the same episodes are compared with
395 model estimates as an additional constraint on the decadal change of NO_y. We choose
396 July – August as our ‘summer’ since this is the common period of all the measurements
397 used in model evaluation.

398 **4 Model evaluation of ozone and reactive nitrogen species**

399 We evaluate our model against observations from aircraft campaigns in 2004 and 2013.
400 For each of the three field campaigns, all measurements are averaged to a 1-min time
401 resolution. Data from biomass burning (CH₃CN ≥ 225 ppt or HCN ≥ 500 ppt), urban
402 plumes (NO₂ ≥ 4 ppb or NO_x/NO_y ≥ 0.4 (if NO_y is available)), and stratospheric air
403 (O₃/CO > 1.25 mol mol⁻¹) are excluded (Hudman et al., 2007) in all the analyses, as these
404 subgrid processes may not be well represented in our model. We focus on the Southeast
405 U.S. region, using ~~only~~ data within the domain of 25 - 40° N latitude and 100 - 75° W
406 longitude for our analyses. A map of all the flight tracks of each campaign is shown in
407 Figure S4. All model results ~~are for comparison with observations use model output~~
408 sampled along the flight track with 1-min time resolution.

409 **4.1 Mean vertical profiles of O₃ and RON reactive nitrogen species**

410 Figure 1 shows the observed and modeled mean vertical profiles of O₃, NO_x, HNO₃, PAN,
411 ΣANs and NO_y during ICARTT and SENEX. We use ΣANs measurements from
412 SEAC⁴RS to evaluate model performance during summer 2013, due to the lack of ΣANs
413 measurements from SENEX. Our model results include both gas and aerosol RONO₂ in
414 ΣANs, although aerosol RONO₂ accounts for 7~11% of ΣANs in the planetary boundary
415 layer (PBLBL, < 1.5 km). We do not consider inorganic nitrates in particle phase in this
416 analysis, due to lack of thermodynamic model for inorganic aerosols in current version of
417 AM3. This simplification is expected to have minimal effects, as they only account for a
418 small fraction of aerosol nitrates in the Southeast U.S. (Ng et al., 2017). To investigate
419 the impact of RONO₂ hydrolysis, we include two model simulations, the base case with
420 heterogeneous loss of ISOPNB, and a sensitivity run ‘no hydro’ without heterogeneous
421 loss of organic nitrates.

422 Mean observed O₃ in the surface layer decreased from 50 ppb during ICARTT to 35 ppb
423 during SENEX, consistent with the declining trend in surface MDA8 ozone at AQS
424 monitoring sites (section 5.2). As we show in section 5.2, this decline in ozone is mainly

425 ~~driven by NO_x emission reduction, with little influence by meteorology in the two years.~~
426 ~~Our model can reproduce the vertical gradient and the relative change of O₃ from 2004 to~~
427 ~~2013, except for a positive absolute bias of 6 - 12 ppb in the boundary layer. Performance~~
428 ~~statistics of O₃ in the boundary layer listed in Table S4 also indicate positive biases in the~~
429 ~~model, with the fractional bias (FB) of 9.4 - 17%, fractional error (FE) of 16 - 19 %,~~
430 ~~normalized mean bias (NMB) of 9.4 - 16% and normalized mean error (NME) of 16 -~~
431 ~~19 %. This overestimate of O₃ is higher than that reported (3 - 5 ppb) by Mao et al.~~
432 ~~(2013b) for their simulation of the ICARTT dataset, likely due to faster photolysis of~~
433 ~~carbonyl nitrates that increases the NO_x recycling efficiency from isoprene oxidation.~~

434 ~~We further examine mean vertical profiles of NO_x and its reservoirs in 2004 and 2013~~
435 ~~(Figure 1). Mean observed O₃ in the surface layer decreased from 50 ppb during ICARTT~~
436 ~~to 35 ppb during SENEX, consistent with the decline in surface MDA8 ozone at AQS~~
437 ~~monitoring sites during July-August from 2004 to 2013 over the Southeast U.S. as shown~~
438 ~~below. Differences in meteorology may account for some of this decline as this region~~
439 ~~was cool and wet in Summer 2013 (Hidy et al., 2014), conditions that suppress ozone~~
440 ~~formation. We show below that this impact is relatively small compared to that from NO_x~~
441 ~~emission reductions in this region. Our model can reproduce the vertical gradient of O₃ as~~
442 ~~well as the relative change from 2004 to 2013, but the model has a positive bias of upto 6~~
443 ~~ppb and 12 ppb in the boundary layer during ICARTT and SENEX respectively. This~~
444 ~~overestimate of O₃ appears to be higher than that reported (3-5 ppb) by Mao et al. (2013)~~
445 ~~for their simulation of the ICARTT dataset, likely due to faster photolysis of carbonyl~~
446 ~~nitrates that increases the NO_x recycling efficiency from isoprene oxidation. A recent~~
447 ~~study using the GEOS-Chem model (Travis et al., 2016) shows that this regional bias can~~
448 ~~be reduced (though not eliminated) with a 53 % reduction of anthropogenic NO_x~~
449 ~~emissions from the 2011 EPA national emission inventory (NEI11v1). Despite some~~
450 ~~evidence of overestimated NO_x emissions in NEI11v1 (Souri et al., 2016; Ahmadov et al.,~~
451 ~~2015), we find that such a reduction of NO_x emissions would lead to a significant~~
452 ~~underestimate of the simulated vertical profiles of reactive nitrogen oxides in our model,~~
453 ~~as we show below. Therefore, we conclude that the bias in the vertical profile of O₃ in~~
454 ~~our model, even though the cause is not entirely understood so far, may not be solely due~~
455 ~~to biases in NO_x emissions.~~

456 ~~We further examine mean vertical profiles of NO_x and its reservoirs in 2004 and 2013. In~~
457 ~~the boundary layer along the flight tracks, (Figure 1), HNO₃ is the most abundant~~
458 ~~RONreactive nitrogen compound, accounting for 40 - 46 % of NO_y, followed by NO_x~~
459 ~~(18 - 23 %), PAN (20-24 %), and ΣANs (11 - 21 %). Between 2004 and 2013, mean~~
460 ~~observed NO_y in the boundary layer decreased by 20 %, from 2.0 ppb to 1.6 ppb, a~~
461 ~~weaker change than the 35 % reduction of total NO_x emissions (Table 1). This is likely~~
462 ~~due to the different sampling regions (Figure S4) from the two campaigns. We show later~~
463 ~~that regionally averaged NO_y indicates a 34 % reduction over the Southeast U.S. from~~

464 ~~2004 to 2013, more consistent with the emission reductions (-35 %).~~ The responses of
465 major ~~RON~~ reactive nitrogen compounds are mostly proportional to the change in NO_x
466 emissions, with the notable exception of ΣANs. We find significant decreases in NO_x (-
467 35 %) and HNO₃ (-29 %) as well as a slight decrease in PAN (-13 %) from observations.
468 The relative trends of HNO₃ and PAN are opposite to those found in the Los Angeles
469 (LA) basin, where PAN decreased much faster than HNO₃ (Pollack et al., 2013). This
470 difference results mainly from the rapid decrease of anthropogenic VOC emissions in the
471 LA basin that also serves as major precursors of PAN. In contrast, isoprene is the major
472 precursor of PAN over the Southeast U.S. Its BVOC emissions show a constant supply
473 (within 5 % differences over the two summers) in this region over the Southeast U.S.
474 ΣANs shows a different trend from the above compounds, increasing from 0.23 ppb to
475 0.27 ppb (+17 %) near the surface. ~~(Figure 1).~~ As we show below in section 5.1, these
476 changes (except for ΣANs) are mostly consistent with model estimates on a regional
477 average. Discrepancy in their trends of vertical profiles and regional average might be
478 due to representative, despite possible representativeness errors from different sampling
479 areas during the three aircraft campaigns on spatial (Figure S4) and temporal (different
480 episodes, referring to observation data description in section 3) scales. ~~(Figure S4).~~

481 The model can well reproduce ~~RON~~ all the NO_y species in the boundary layer but
482 tend to underestimate them in the free troposphere. This is likely due to insufficient
483 production of NO_x from lightning in the free troposphere in our model, which is 0.048 Tg
484 N in total over North America during July - August of 2004, lower by almost a factor of
485 5 compared to the value (0.27 Tg N from July 1-August 15, 2004) reported by Hudman et
486 al. (2007). This underestimate can be improved by scaling up lightning emission by a
487 factor of 5-10 (Fang et al., 2010). We do not adjust the lightning NO_x emissions in this
488 work due to its high uncertainty (Ott et al., 2010; Pickering et al., 1998).

489 Hydrolysis of organic nitrates affects RONO₂ significantly in the boundary layer. -
490 Underestimate of NO_x in the free troposphere might also be due to rapid conversion of
491 NO_x to HNO₃ (Henderson et al., 2011) in the model. However, we did not adjust the
492 model due to the high uncertainty in the estimate of lightning NO_x. We find that if we
493 reduce anthropogenic NO_x emission in our model by another 40 %, from 0.25 Tg N mon⁻¹
494 to 0.15 Tg N mon⁻¹ as suggested by Travis et al. (2016), simulated NO_y, HNO₃ and
495 PAN decrease by 30 %, 33 % and 30 % respectively, leading to a noticeable
496 underestimate for these nitrogen reservoirs.

497 ~~Hydrolysis of organic nitrates affects RONO₂ significantly in the boundary layer.~~ By
498 introducing hydrolysis of ISOPNB, we find that model relative bias of ΣANs in the
499 boundary layer is reduced from +20 % to +2 % during ICARTT (Figure 1). Performance
500 metrics in Table S4 also indicate better agreement of the model with observations if
501 hydrolysis of ISOPNB assumed. However, the relative ~~However, the~~ bias is increased in

is calculated by multiplying the measured NO_3^- concentration and precipitation at each monitoring site as $F_{o,i} = C_{o,i} P_{o,i}$ where $F_{o,i}$ is the monthly-mean wet deposition flux, $C_{o,i}$ and $P_{o,i}$ are the monthly-mean observed NO_3^- concentration precipitation at monitoring site i . The modeled wet deposition flux includes HNO_3 and all the alkyl nitrates. Observations indicate a 24 % reduction of wet deposition flux in summer from 2004 to 2013 over the Southeast U.S., likely due to NO_x emission reductions. This reduction in monthly averaged wet deposition flux is well captured by our model (-29 %), despite a low relative bias of 40 % in both years and NMB of -39 -- -43 % (Table S4).

Since errors in modeled precipitation could strongly affect the modeled NO_3^- wet deposition flux (Appel et al., 2011; Grimm and Lynch, 2005; Metcalfe et al., 2005; Paulot et al., 2014; Tost et al., 2007), we also evaluate the modeled NO_3^- concentration ($C_{p,i}$), which is calculated by using the modeled NO_3^- wet deposition flux ($F_{p,i}$) and observed precipitation ($P_{o,i}$; $C_{p,i} = F_{p,i} / P_{o,i}$), as a separate constraint. The model shows a similar declining trend from the observations with a relative bias of -2348 % and -4140 % on NO_3^- concentration for 2004 and 2013 respectively. Our results are consistent with the base case of Paulot et al. (2016), which showed that convective removal is likely insufficient in AM3, leading to underestimates of both NO_3^- wet deposition flux and concentrations. Our results are somewhat different from a recent GEOS-Chem study (Travis et al., 2016). They found that reducing anthropogenic NO_x emissions from NEI11v1 by 5360 % can significantly improve the overestimate of 71 % on wet deposition flux in their model during August-September of 2013. A further reduction of anthropogenic NO_x emission in our model (to 0.15 Tg N mon^{-1}), as suggested by Travis et al. (2016), in the previous study, would lead to an even greater negative bias compared to observations.

4.3 RONO_2 and related species Chemistry

~~We further RONO_2 can serve as either a temporary NO_x reservoir by releasing NO_2 via photooxidation or a permanent NO_x sink via hydrolysis to produce HNO_3 . The modeled fate of RONO_2 affects simulated O_3 . Therefore, it is necessary to evaluate the RONO_2~~

573 ~~chemistry and related species in this section, with a large focus on measurements from~~
574 ~~ICARTT and SEAC⁴RS. to understand its speciation.~~

575 The major pathway for the production of daytime RONO₂ is the reaction of NO with RO₂
576 originating from VOC oxidation by OH:

577 where α is the branching ratio for alkyl nitrate formation. NO₂ subsequently ~~further~~
578 undergoes photolysis to produce O₃:

579 For isoprene, α is 9 ± 4 % (for ISOPN) according to a recent study (Xiong et al., 2015).
580 For monoterpenes, specifically α -pinene, α ranges from 1 % to 26 % (Rindelaub et al.,
581 2015; Nozière et al., 1999; Aschmann et al., 2002). Here, we use 10 % for isoprene and
582 26 % for monoterpenes. ~~(Table S2), and take α as an average of RONO₂ from all the~~
583 ~~precursors.~~ As RONO₂ and O₃ are both produced from (R4), a correlation between them
584 is expected. We show that the model can roughly reproduce the correlation of O_x (~~= O₃ +~~
585 ~~NO₂) vs. Σ ANs during both ICARTT and SEAC⁴RS (Figure 4), although the slope has a~~
586 positive relative bias of about 21 % and 33 % respectively, largely due to an overestimate
587 of O₃ in the model. ~~In particular, we find that the model shows better agreement with the~~
588 ~~observed correlation of O_x vs. daytime isoprene nitrates (the sum of ISOPN, MVKN and~~
589 ~~MACRN) than O_x vs. Σ ANs during SEAC⁴RS. This is expected since these three RONO₂~~
590 ~~species are directly coproduced with O₃ from (R4), but only account for a small fraction~~
591 ~~of Σ ANs (Figure S5).~~ The good agreement between observed and modeled O_x vs.
592 daytime RONO₂ provides additional support for our treatment of the yields and fate of
593 these daytime isoprene nitrates.

594 Another metric to evaluate RONO₂ chemistry is the correlation between Σ ANs and
595 HCHO, as the latter is a coproduct from (R4). ~~Since HCHO can be produced from other~~
596 ~~pathways of isoprene hydroxyl peroxy radicals (ISOPO₂) besides (R4) (such as~~
597 ~~isomerization of ISOPO₂ and ISOPO₂ + HO₂), changes in the slope of Σ ANs vs. HCHO~~
598 ~~may help to quantify decadal changes in isoprene oxidation pathways.~~ We show in Figure
599 4 that the model can roughly capture the observed Σ ANs-HCHO slope, with an
600 underestimate by 25 % and 13 % during ICARTT and SEAC⁴RS, respectively. The
601 underestimate is in part due to small alkyl nitrates that are neglected in the model, as
602 mentioned in section 4.1. above. During ICARTT, the slope estimated by AM3 is 0.12,
603 similar to the value (0.15) from a previous GEOS-Chem study using a different isoprene
604 oxidation mechanism that assumed a higher α (of ~~41.7% from ISOPNB and 7.0%~~ from

605 | ~~both ISOPNB and~~ ISOPND vs. 10 % of ISOPNB and zero ISOPND in AM3) and a lower
606 | yield of HCHO (66 % vs. 90 % in AM3) ([Mao et al., 2013b](#)), (~~Mao et al., 2013~~). The
607 | reason for such similarity between the two models might be two-fold: (a) the additional
608 | contribution of monoterpene nitrates to Σ ANs in AM3 compensates for the decrease in α
609 | from isoprene nitrates compared to GEOS-Chem and (b) the coarse grid resolution of ~~that~~
610 | GEOS-Chem simulation ($2^\circ \times 2.5^\circ$) may lead to a higher estimate of HCHO compared to
611 | the result from a finer grid resolution (Yu et al., 2016).

612 | Since HCHO can be produced from other pathways of isoprene hydroxyl peroxy radicals
613 | (ISOPO₂) besides (R4) (such as isomerization of ISOPO₂ and ISOPO₂ + HO₂), changes
614 | in the slope of Σ ANs vs. HCHO may help to quantify decadal changes in isoprene
615 | oxidation pathways. We find in Figure 4 that the observed slope of Σ ANs-HCHO shows
616 | very little change from 2004 to 2013. This is in part due to substantial HCHO production
617 | from isoprene oxidation under low NO_x conditions (Li et al., 2016), and in part due to the
618 | buffering of Σ ANs in response to decreasing NO_x, as shown below [in section 5.1](#). Our
619 | model is able to reproduce such behavior. We also find ~~in our model~~ that the branching
620 | ratios for the reactions of ISOPO₂ change marginally from 2004 to 2013 over the
621 | Southeast U.S. (Figure S6). The fraction of ISOPO₂ + NO has decreased from 81 % in
622 | 2004 to 66 % in 2013. The fraction of ISOPO₂ + HO₂ has increased from 15 % to 28 %,
623 | and the fraction of ISOPO₂ isomerization has increased from 4 % to 6 %. Our result is
624 | slightly different from the results of GEOS-Chem, which found a lower contribution from
625 | the NO pathway (54 %) and higher from isomerization (15 %) during August - -
626 | September of 2013 (Travis et al., 2016).

627 | We also compare the correlation between major daytime isoprene nitrates and HCHO
628 | during 2013, which provides a constraint on the yield of these nitrates. Our model shows
629 | a slight overestimate on the slope (Figure 4 (b)), consistent with comparison of mean
630 | vertical profiles shown in Figure 2. The ~~computed~~ ~~estimated~~ slope (5 %) in this study is
631 | different from that (2.5 %) of a recent GEOS-Chem simulation by Fisher et al. (2016).
632 | This is partially due to the different treatment of β - and δ -ISOPO₂ between GEOS-Chem
633 | and AM3. Another factor is that MVKN and MACRN are not allowed to hydrolyze in
634 | AM3, leading to a higher ~~abundance~~ ~~burden~~ of these two nitrates.

635 | Figure 5 shows the mean vertical profiles of modeled monoterpene nitrates (MNs) and
636 | isoprene nitrates (INs) during ICARTT and SEAC⁴RS. INs are the most abundant
637 | RONO₂, accounting for 76-80 % below 3 km over the Southeast U.S., [consistent with](#)
638 | [the large isoprene emissions in this region in summer \(Palmer et al., 2003\)](#). In the
639 | measurements, ISOPN + MVKN + MACRN only contribute one third of the total INs
640 | (Figure S5). We show below that the discrepancy of Σ ANs and speciated RONO₂ can be
641 | explained by other daytime and nighttime INs [as well as MNs](#) in the model. More than
642 | 60 % of modeled INs originate from isoprene oxidation during daytime. The first-

643 generation nitrate ISOPN contributes slightly more (31 %) than the second-generation
644 nitrates MVKN + MACRN (28 %) to the total daytime INs during ICARTT. This is
645 different from Mao et al. (2013b)(2013) who showed a higher contribution of MVKN +
646 MACRN than the first-generation INs, due to the different treatment of β - and δ -ISOPO₂.
647 We see more ISOPN (32 %) than MVKN + MACRN (26 %) from the daytime INs
648 during SEAC⁴RS, consistent with Fisher et al. (2016). A large uncertainty in our model is
649 attributed to DHDN, which contributes 32 % to the daytime INs. Fisher et al. (2016)
650 showed less DHDN during SEAC⁴RS since it was removed rapidly by hydrolysis (1-h
651 lifetime) in their model. Our sensitivity test (hydro_fullAM3h, Figure S2) indicates that
652 AM3 would significantly underestimate Σ ANs if we assume a similar heterogeneous loss
653 of DHDN as ISOPN. In fact, DHDN was hypothesized originally in Lee et al. (2014) for
654 the imbalance of nitrogen in their lab experiments, and may serve as a proxy for a large
655 number of unidentified daytime INs. It remains unclear what the dominant loss of DHDN
656 is. Daytime nitrates from monoterpene oxidation are another important source of Σ ANs
657 in this region, accounting for 17 - 20 % (24 - 26 ppt) of the total. Fisher et al. (2016)
658 estimate a smaller burden of MNs, of about 10 - 20 ppt due to a lower molar yield (18 %
659 vs. 26 % in AM3) and faster hydrolysis of MNs in their model.

660 Nighttime chemistry contributes about 30 - 36 % of Σ ANs, which is dominated by
661 isoprene oxidation as well (Figure 5). 33 - 41 % of the INs are produced during night,
662 similar to the value (44 %) reported by Mao et al. (2013b)(2013) but with different
663 speciation, due to the different treatment of chemistry. PROPNN contributes about 29-38 %
664 of the total INs. PROPNN in this work is mainly produced from the oxidation of C5
665 carbonyl nitrate (ISN1) and C5-nitrooxy hydroperoxide (INPN) and C5 carbonyl nitrate
666 (ISN1; (dominantly by photolysis) that are generated from isoprene oxidation by NO₃
667 during the nighttime. This is different from Fisher et al. (2016), who showed that
668 PROPNN is partially from the δ -ISOPO₂ + NO pathway and partially from the oxidation
669 of ISN1 by NO₃ and INPN. In our model, we see a rapid increase prompt production
670 of PROPNN after sunrise in the boundary layer (Figure S7), consistent with observations at
671 the Southern Oxidants and Aerosols Study (SOAS) ground site CTL (Schwantes et al.,
672 2015). Our model overestimates the mean vertical profile of PROPNN by a factor of 3
673 (not shown). As our model may largely underrepresent the chemical complexity of
674 nighttime isoprene oxidation as shown by Schwantes et al. (2015), we consider PROPNN
675 as a proxy for other unspecified isoprene nighttime nitrates. Over all As a result,
676 PROPNN contributes a significant fraction of Σ ANs in the model, 23 - 29 % in the
677 boundary layer as shown in section 4.1. With monoterpene nitrates and isoprene derived
678 DHDN and nighttime NO₃ oxidation products taken into account, we find that model can
679 well reproduce both observed Σ ANs and speciated alkyl nitrates (Figure S5).

680 **5- Decadal Change of PBL RONNO_y species and surface ozone over SEUS**

681 As RON and related species from aircraft and surface measurements are well reproduced
682 in our model for both 2004 and 2013, we assume that the model is representative of this
683 chemical environment, and then use the model to derive monthly mean changes between
684 2004 and 2013. We also investigate the impacts of further decreases in NO_x emissions by
685 applying a hypothetical 40 % reduction of anthropogenic NO_x emissions of 2013 but
686 keeping other emissions and meteorology the same (“hypo” case in Table 2).

687 5.1 RON ~~5.1~~ NO_y-species

688 We first examine the simulated decadal change of RON ~~NO_y-species~~ in the boundary
689 layer over the Southeast U.S. as shown in Figure 6. In summer of 2004, ~~shows the model~~
690 suggests that mean modeled boundary layer concentrations of NO_x, HNO₃, ΣPNs, ΣANs
691 and NO_y in the summer of 2004 and 2013 as well as a scenario with a further 40 %
692 reduction from 2013 anthropogenic NO_x emissions to simulate possible future emission
693 reductions. In summer 2004, modeled NO_y is mainly comprised of HNO₃ (45 %), NO_x
694 (31 %), ΣPNs (14 %) and ΣANs (9 %). In response to imposing a 40 % reduction in
695 anthropogenic NO_x emissions (35 % reduction in total NO_x emissions, Table 1) from
696 2004 to 2013, NO_y declined by 34 %. This modeled response is comparable to consistent
697 with long-term NO_y measurements from the AQS surface network dataset, which shows
698 on average a 4542 % decrease from 2004 to 2013 over the Southeast U.S. Based on
699 model estimates in Figure 6, most RON ~~Most~~ NO_y-species are reduced proportionally,
700 with decreases of 38 % for HNO₃, 32 % for NO_x and 34% for ΣPNs. The different
701 change in ΣPNs and PAN (the majority of ΣPNs) in Figure 1 might be due to the
702 difference in sampling regions. The only exception is ΣANs, with a smaller decline of
703 19 %. As an important source of organic aerosols (OA), ΣANs may contribute to it
704 should be noted that the decrease ~~change~~ of OA over ~~ΣANs discussed here is different~~
705 from the Southeast U.S. in the past decade (Blanchard et al., 2016). ~~surface concentrations~~
706 ~~discussed in Section 4.1.~~

707 We conducted a sensitivity test with an additional 40 % reduction of anthropogenic NO_x
708 emissions from 2013. ~~(Table 2).~~ We find that NO_y decreases by 29 %, with a proportional
709 decrease in HNO₃, NO_x, and ΣPNs (Figure 6). The slower decrease of NO_y is likely due
710 to. Again, we find that ΣANs, which decrease at a slower rate and becomes, becoming a
711 larger fraction of ~~total~~ NO_y. The buffering of ΣANs is consistent with previous studies
712 (Browne and Cohen, 2012; Fisher et al., 2016), mainly due to decreasing NO_x leading to
713 lower OH resulting from decreased NO_x (Figure S8) and thus a prolonged
714 lifetimes ~~lifetime~~ of NO_x and ΣANs (Browne and Cohen, 2012). As shown in Figure S8,
715 averaged noontime OH decreases by 11 % from 2004 to 2013 and by 29 % after we
716 impose an additional 40 % NO_x emission reduction from 2013 levels.

717 The historical NO_x emission reduction also affects reactive nitrogen export out of the
718 boundary layer. Here we define exported nitrogen as the difference of the sources
719 (chemical production and emissions) and sinks (chemical loss, wet and dry deposition).
720 As shown in Table 32, total summertime NO_y export from the Southeast U.S. boundary
721 layer decreases proportionally, from 24.1 Gg N in 2004 to 16.6 Gg N in 2013. The
722 NO_y export efficiency, calculated as net exported nitrogen divided by total
723 NO_x emissions, remains roughly the same (12 %) for 2004 and 2013, comparable
724 ~~to consistent with~~ previous studies (Fang et al., 2010; Li et al., 2004; Parrish et al., 2004;
725 Mao et al., 2013; Sanderson et al., 2008; Hudman et al., 2007). Among all exported
726 species, NO_x contributes most of net export from the PBL (6 % of total NO_x emissions),
727 followed by PAN (4 %) and ΣANs (2 %). We emphasize in Table 32 that a major
728 fraction of NO_x is exported through the top of the boundary layer (convection). From a
729 budget calculation throughout the tropospheric column over the same region, we find that
730 despite being the same NO_y export efficiency (12 %), HNO₃ becomes the major exporter,
731 accounting for half of NO_y export efficiency from the total column (6 %). The
732 contributions from PAN and ΣANs are roughly the same as their export from the
733 boundary layer (4 % and 2 %). This suggests that surface NO_x ventilated through the
734 boundary layer, converted to HNO₃ in the free troposphere and exported as HNO₃ is
735 likely the major NO_y export mechanism over the Southeast U.S. in our model, which is in
736 agreement with previous observations (Parrish et al., 2004; Neuman et al., 2006). PAN
737 and ΣANs together account for another half of NO_y export efficiency. As PAN
738 and ΣANs are of biogenic origin and longer lived than HNO₃, they may play a key role in
739 influencing ~~RON~~reactive nitrogen and ozone in downwind regions (Moxim et al., 1996;
740 Fischer et al., 2014).

741 5.2 Surface ozone

742 ~~Understanding oxidation chemistry of NO_x and VOCs is essential to improve surface~~
743 ~~ozone air quality by implementing effective control strategies.~~ Since the mid-1990s, NO_x
744 emission controls have led to significant improvement on ozone air quality over the
745 eastern U.S. (Simon et al., 2015; Cooper et al., 2012). As NO_x emissions continue to
746 decrease, ozone production efficiency (OPE) may increase due to the lower NO_x removal
747 rate by OH and to some extent may compensate the ozone reduction (Sillman, 2000).
748 Meanwhile, surface ozone production may be further complicated by the increasing
749 importance of ~~RO₂ISOP~~RO₂ISOP~~O₂ isomerization and RO₂ + HO₂.~~~~(Peeters et al., 2014).~~ Here we
750 first evaluate our model against surface ozone observations in 2004 and 2013, and then
751 project the future response of surface ozone to even lower NO_x emissions to examine the
752 efficacy of near-term NO_x emission controls at lowering near-surface ozone levels.

753 We first examine the modeled surface ozone against observations at 157 EPA AQS
754 monitoring sites over the Southeast U.S. in July-August of 2004 and 2013 (Figure S9). In

755 general, AM3 overestimates surface MDA8 ozone in both years by about 16 ppb on
756 average, ~~with the NMB of 33 - 45 % and NME of 35 - 46 % respectively.~~ This positive
757 bias of summertime surface O₃ has been a common issue to a number of modeling studies
758 of this region (Fiore et al., 2009; Canty et al., 2015; Brown-Steiner et al., 2015; Strode et
759 al., 2015; Travis et al., 2016). This might be partially attributed to overestimated
760 anthropogenic NO_x emissions from non-power plant sectors, excessive vertical mixing in
761 the boundary layer (Travis et al., 2016) or underestimates of O₃ dry deposition ([Hardacre
762 et al., 2015](#); ~~(Error! Hyperlink reference not valid.~~[Hardacre et al., 2015](#); ~~Error! Hyperlink
763 reference not valid.~~[Val Martin et al., 2014](#)). Further studies are warranted to investigate
764 the cause of this bias in AM3.

765 Surface O₃ concentrations over the Southeast U.S. decline substantially from 2004 to
766 2013 in response to the large NO_x emission reduction (Simon et al., 2015). MDA8 ozone
767 averaged across all the monitoring sites is observed to decrease by 11 ppb (23 % of
768 observed mean MDA8 ozone in July-August of 2004) resulting from approximately 40 %
769 reductions of anthropogenic NO_x emissions (35 % reduction in total NO_x emissions).
770 ~~across the continental U.S.~~ This strong sensitivity of surface ozone to NO_x emission
771 reflects the linear relationship between ozone production rate and NO_x concentrations
772 when NO_x is low (Trainer et al., 2000). ~~In contrast, the sensitivity of surface ozone to
773 NO_x emissions appears to be weaker in the 1980s. Jacob et al. (1993) found that
774 summertime afternoon ozone over the eastern U.S. is only reduced by 15 % with a 50 %
775 reduction of anthropogenic NO_x emissions from 1985 levels, suggesting a lower OPE
776 when NO_x concentrations were high. We attribute this transition from a low OPE in the
777 1980s to high OPE in 2000s to the extended lifetime of NO_x resulting from NO_x emission
778 reductions.~~ Our model is able to capture this strong NO_x-O₃ sensitivity, with the mean
779 MDA8 ozone reduced by 10 ppb from 2004 to 2013. We find that a further 40 %
780 reduction of anthropogenic NO_x emissions with identical meteorological conditions ~~and
781 non-anthropogenic emissions in 2013~~ could lead to an additional 9 ppb decrease, a
782 similar magnitude to the change from 2004 to 2013. ~~Meanwhile, any increase in OPE
783 over the past decade appears to be small and to have little impact on net ozone production,
784 leading to a continued high sensitivity of surface ozone to NO_x emission reductions in the
785 near future.~~

786 We further investigate the impact of temperature and moisture on surface O₃ from 2004
787 to 2013. While several studies suggest that surface O₃ increases with ambient temperature
788 (Jacob and Winner, 2009; Bloomer et al., 2010; Wu et al., 2008; Steiner et al., 2010),
789 Cooper et al. (2012) showed that this temperature related impact is weak during the
790 period of 1990-2010 across the [U.S.AUSA](#). Recent studies suggest that relative humidity
791 (RH) or vapor pressure deficit (VPD) may play an important role in ozone variability
792 through soil-atmosphere or biosphere-atmosphere coupling (Kavassalis and Murphy,
793 2017; Camalier et al., 2007; Tawfik and Steiner, 2013). Our model shows marginal

794 differences in RH (less than 1 %) and temperature (+ 2.4 K) within the PBL over the
795 Southeast U.S. between the summers of 2004 and 2013, consistent with observed changes
796 of RH (+ 2.7 %) and temperature (+ 2.6 K) during ICARTT and SENEX. This small
797 variation in the model is also consistent with climatology data (Hidy et al., 2014).
798 Camalier et al. (2007) showed that RH has a much bigger impact on summertime ozone
799 than temperature over the Southeast U.S., suggesting little influence of meteorology on
800 ozone trend.(~~Hidy et al., 2014~~). Using the same model but with the standard AM3
801 chemical mechanism, Lin et al. (2017) found that meteorology changes would have
802 caused high surface ozone over the eastern U.S. to increase by 0.2 - 0.4 ppb yr⁻¹ in the
803 absence of emission controls from ~~1988+1999~~ to 2014. Therefore, we conclude that the
804 impact of climate variability and change on O₃ is relatively small compared to NO_x
805 emission reductions over the Southeast U.S., consistent with previous studies (Lam et al.,
806 2011; Hidy et al., 2014; Lin et al., 2017; Rieder et al., 2015).

807 Decreasing NO_x ~~emission~~emission also reduces the frequency of highextreme O₃
808 pollution events. Figure 7 shows the probability density function of observed and
809 modeled MDA8 ozone at each monitoring site during July-August of 2004 and 2013, and
810 the probability density function of modeled MDA8 ozone under a hypotheticalfuture
811 scenario with another 40 % reduction in anthropogenic NO_x emissions compared to 2013.
812 We show that the lowest O₃, about 20 ppb in current model simulations, remains
813 invariant with NO_x emission changes over the Southeast U.S., consistent with
814 observations (Figure 7 (a)). Meanwhile, the high tail of MDA8 ozone events has shifted
815 from more than 100 ppb in 2004 to about 85 ppb after the 40_% reduction of
816 anthropogenic NO_x emissions from 2013. A similar shift is found in observations. The
817 narrowing of the range of O₃ with decreasing NO_x is consistent with the observed trends
818 reported by Simon et al. (2015). We also find that further reductions of NO_x emissions
819 will reduce both median O₃ values and the high tail, suggesting that fewer highextreme
820 ozone events will occur under continued NO_x emission controls in the future.

821 **6 Conclusions and Discussions**

822 Near-surface ozone production over the Southeast U.S. is heavily influenced by both
823 anthropogenic and biogenic emissions. We investigate the response of NO_y speciation to
824 ~~such NO_x reduction to~~ the significant NO_x emission controls (about 40 %
825 ~~reduction~~reductions) in this region over the past decade, in light of the fast-evolving
826 understanding of isoprene photooxidation. This knowledge is needed to predict nitrogen
827 and ozone budgets in this region and elsewhere in the world with similar photochemical
828 environments. Here we use extensive aircraft and ground observations, combined with a
829 global chemistry-climate model (GFDL AM3), to examine decadal changes in NO_y
830 abundance and speciation as well as in surface O₃ mixing ratios over the Southeast U.S.
831 between the summers of 2004 and 2013. We then use the model to infer future NO_y

832 speciation and surface ozone abundances in response to further NO_x emission controls in
833 this region.

834 We first evaluate the model with aircraft and surface observations. When we apply the
835 estimated 40 % reductions in anthropogenic NO_x emissions from 2004 to 2013, our
836 model reproduces the major features of vertical profiles of NO_x, HNO₃, PAN, ΣANs and
837 NO_y observed during aircraft campaigns over the Southeast U.S. in the summers of 2004
838 and 2013. By including recent updates ~~to~~ isoprene oxidation, our model can largely
839 reproduce the vertical profiles of ΣANs and several speciated alkyl nitrates, as well as
840 their correlations with O_x and HCHO₂ ~~(Figure 4)~~, lending support to the model
841 representation of isoprene oxidation. On the other hand, we show that ~~the~~ discrepancy
842 between measured ΣANs and speciated RONO₂ can be explained by a combination of
843 ~~monoterpeneterpene~~ nitrates, dinitrates and nighttime NO₃ oxidation products from
844 isoprene. We also show that modeled ozone appears to be insensitive to hydrolysis of
845 ISOPNB, because its photooxidation, mainly by OH, also returns little NO_x.

846 Major ~~RONNO_y species~~ decline proportionally as a result of NO_x emission reductions in
847 the Southeast U.S., except ~~for that ΣANs decline at~~ a slower rate in ΣANs. The slower
848 decline of ΣANs reflects the prolonged lifetime of NO_x when it is decreasing. Our model
849 suggests that summertime monthly averaged NO_x, HNO₃, PAN, and NO_y decline by 30 -
850 -40 %, in response to 40 % ~~reduction~~ reductions in anthropogenic NO_x emissions from
851 2004 to 2013. ~~The slower decline of ΣANs reflects the prolonged lifetime of NO_x with~~
852 ~~decreasing NO_x.~~ This proportional decrease is likely to a large extent driven by high
853 concentrations of biogenic VOCs, the major precursor of PAN VOC in this region that
854 change little in magnitude from 2004 to 2013. In contrast, Pollack et al. (2013) find a
855 faster PAN decrease than HNO₃ in the LA basin over the past several decades, partly due
856 to the decrease in anthropogenic VOC emissions that are major PAN precursors.

857 Deposited and exported NO_y decline with NO_x emission reductions. The model also
858 shows a decrease of NO₃ wet deposition flux by 29 % from 2004 to 2013, consistent with
859 observations from the NADP network (- 24 %). We find from model calculations that the
860 NO_y export efficiency remains at 12 % in both 2004 and 2013, leading to a proportional
861 decrease of exported NO_y. The dominant NO_y export terms include NO_x or HNO₃, each
862 accounting for 6% of the total exported NO_y, followed by ΣPNs (4 %) and ΣANs (2 %).

863 The response ~~Response~~ of surface ozone to NO_x emission reductions reveals a strong O₃-
864 NO_x - O₃ sensitivity in summertime over the Southeast U.S. Observations from EPA
865 AQS surface network suggest that mean MDA8 ozone during July-August has decreased
866 by 23%, from 48 ppb in 2004 to 37 ppb in 2013, ~~a 23 % decrease~~. Despite a positive
867 absolute bias of up to ~~upto~~ 12 ppb in boundary layer ozone and ~~a bias of~~ 16 ppb in surface
868 MDA8 ozone, our model shows a 10 ppb decrease of surface MDA8 ozone from 2004 to

869 2013, very close to the observed 11 ppb decrease from the EPA data. The bias of ozone
870 in our model is not entirely attributed to uncertainties in NO_x emissions, as the
871 overestimate suggested by earlier work would lead to an underestimate of NO_y (Travis et
872 al., 2016). Care should be exercised in applying the modeling results for surface ozone
873 regulation purposes, given the high ozone bias shown in our model. We. ~~More~~
874 ~~importantly, we~~ find from model calculations that modeled MDA8 O₃ will continue to
875 decrease by another 9 ppb assuming anthropogenic NO_x emissions are ~~reduced~~ decreased
876 by 40 % from ~~the~~ 2013 ~~levels~~ level with meteorology and other emissions kept the
877 ~~same~~ constant. In addition, further NO_x emission reduction leads to less frequent
878 ~~high~~ extreme ozone events. ~~(Figure 7).~~ This continued strong sensitivity of surface O₃ to
879 NO_x emissions can guide the development of effective emission control strategies for
880 improving future air quality.

1352

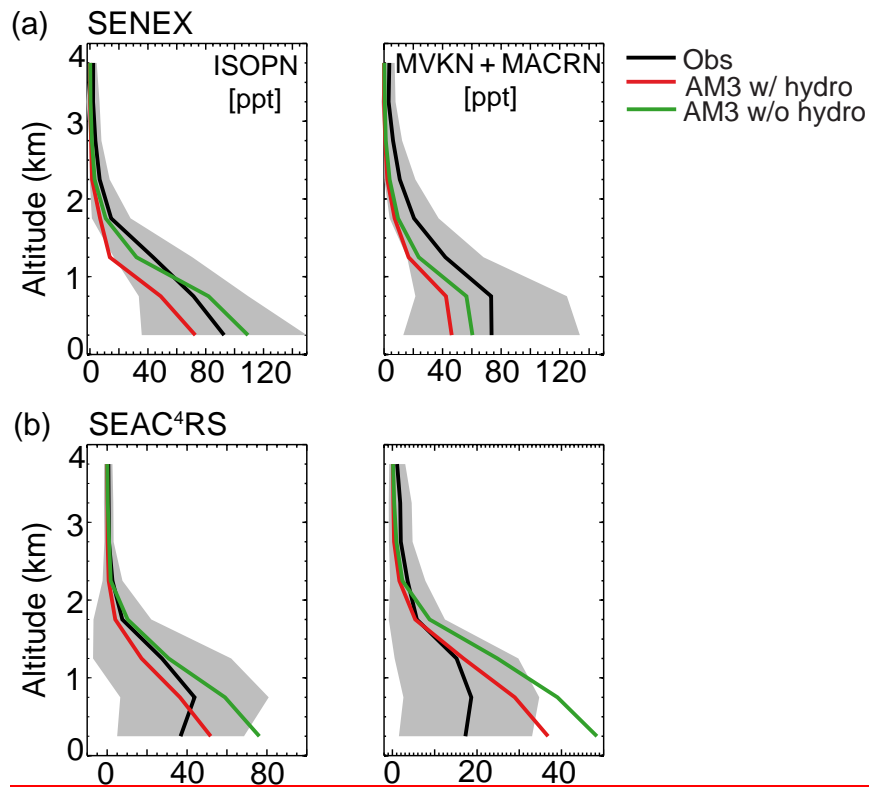

1353

1354 **Figure 1.** Mean vertical profiles of ozone and reactive oxidized nitrogen species from
 1355 observations during ICARTT (top row) and SENEX (bottom row) over SEUS (25° - 40°
 1356 N, 100° - 75° W) during daytime, and model estimates from AM3 with hydrolysis of
 1357 isopropyl nitrates (red) and AM3 without hydrolysis of alkyl nitrates (green). The
 1358 solid and dashed black lines in the HNO₃ of ICARTT represent
 1359 measurements collected using mist chamber/IC by University of New Hampshire (UNH)
 1360 and Chemical Ionization Mass Spectrometer by California Institute of Technology (CIT),
 1361 respectively. NO_y from ICARTT is calculated as the sum of NO_x, HNO₃ (w/ UNH in the
 1362 solid line and w/ CIT in the dashed line), PAN and total alkyl nitrates (ΣANs). ΣANs in
 1363 the bottom row are from SEAC⁴RS.

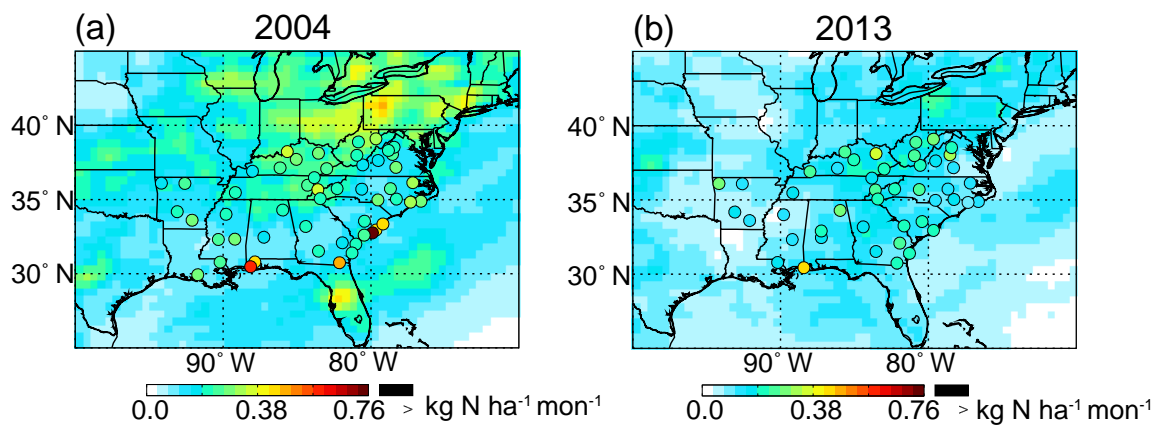

1364

1365

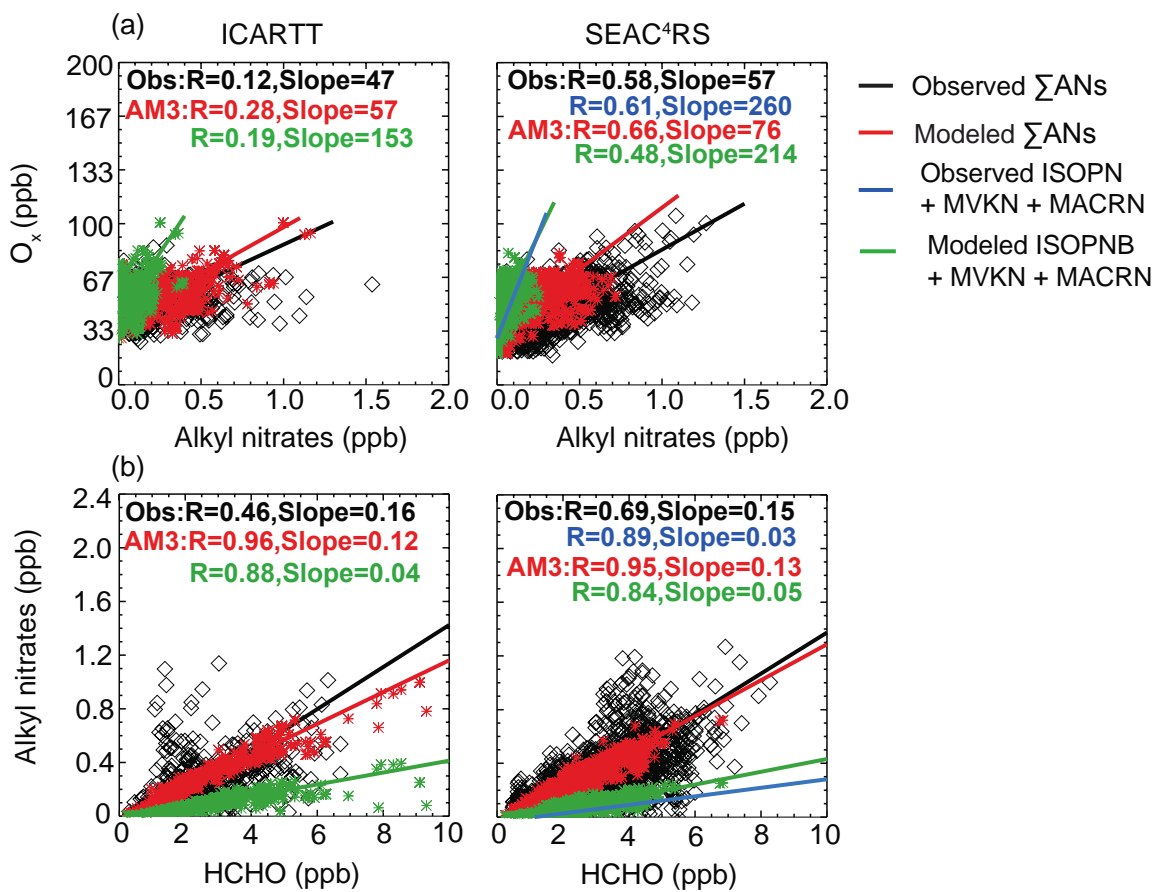

1366 **Figure 2.** Mean vertical profiles of ISOPN and MVNK+MACRN during (a) SENEX and
1367 | (b) SEAC⁴RS over SEUS (25 - -40° N, 100 - -75° W). Black lines are the mean of
1368 observations. Red and green lines are the mean of modeled results with hydrolysis of
1369 ISOPNB and without hydrolysis of alkyl nitrates respectively. Grey shades are the one
1370 standard deviation ($\pm\sigma$) of averaged profiles of the measured tracers.

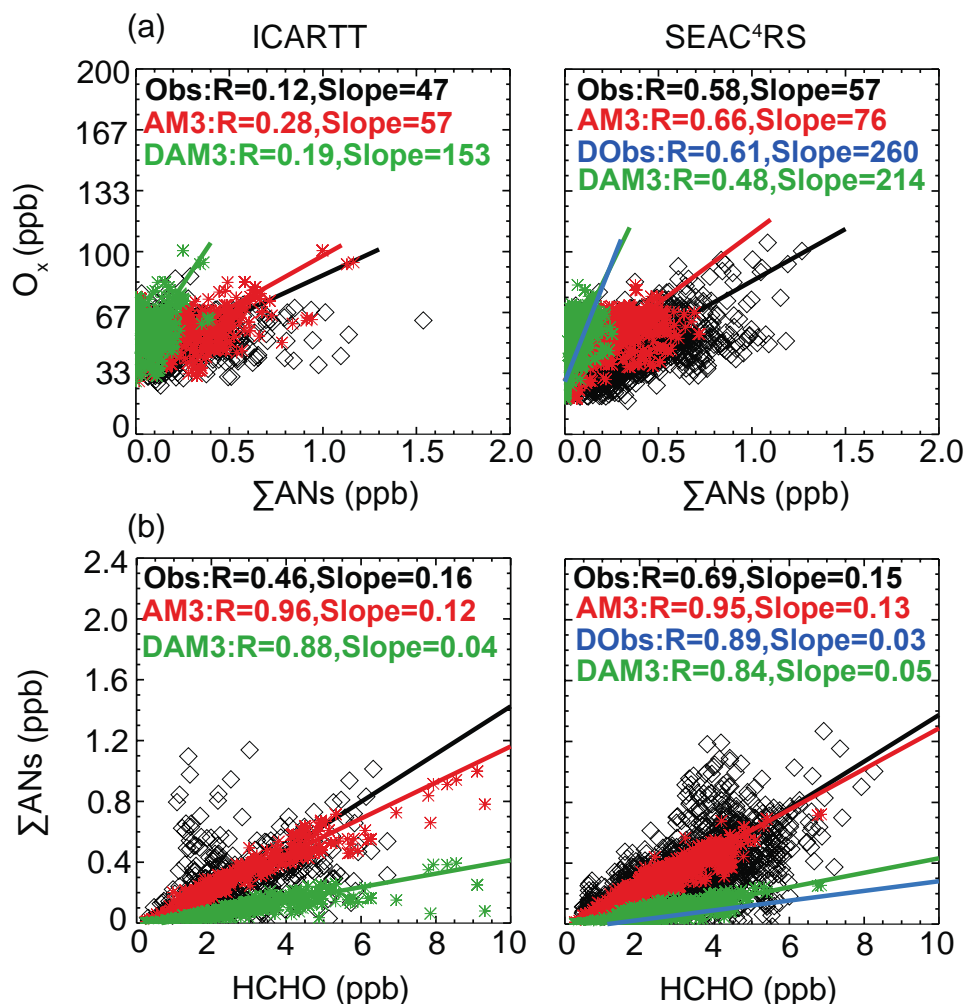

1371

1372 **Figure 3.** Nitrate wet deposition flux ($\text{kg N ha}^{-1} \text{mon}^{-1}$) from NADP (circles) and AM3
 1373 (background) during July - August of 2004 and 2013.

1374

1375

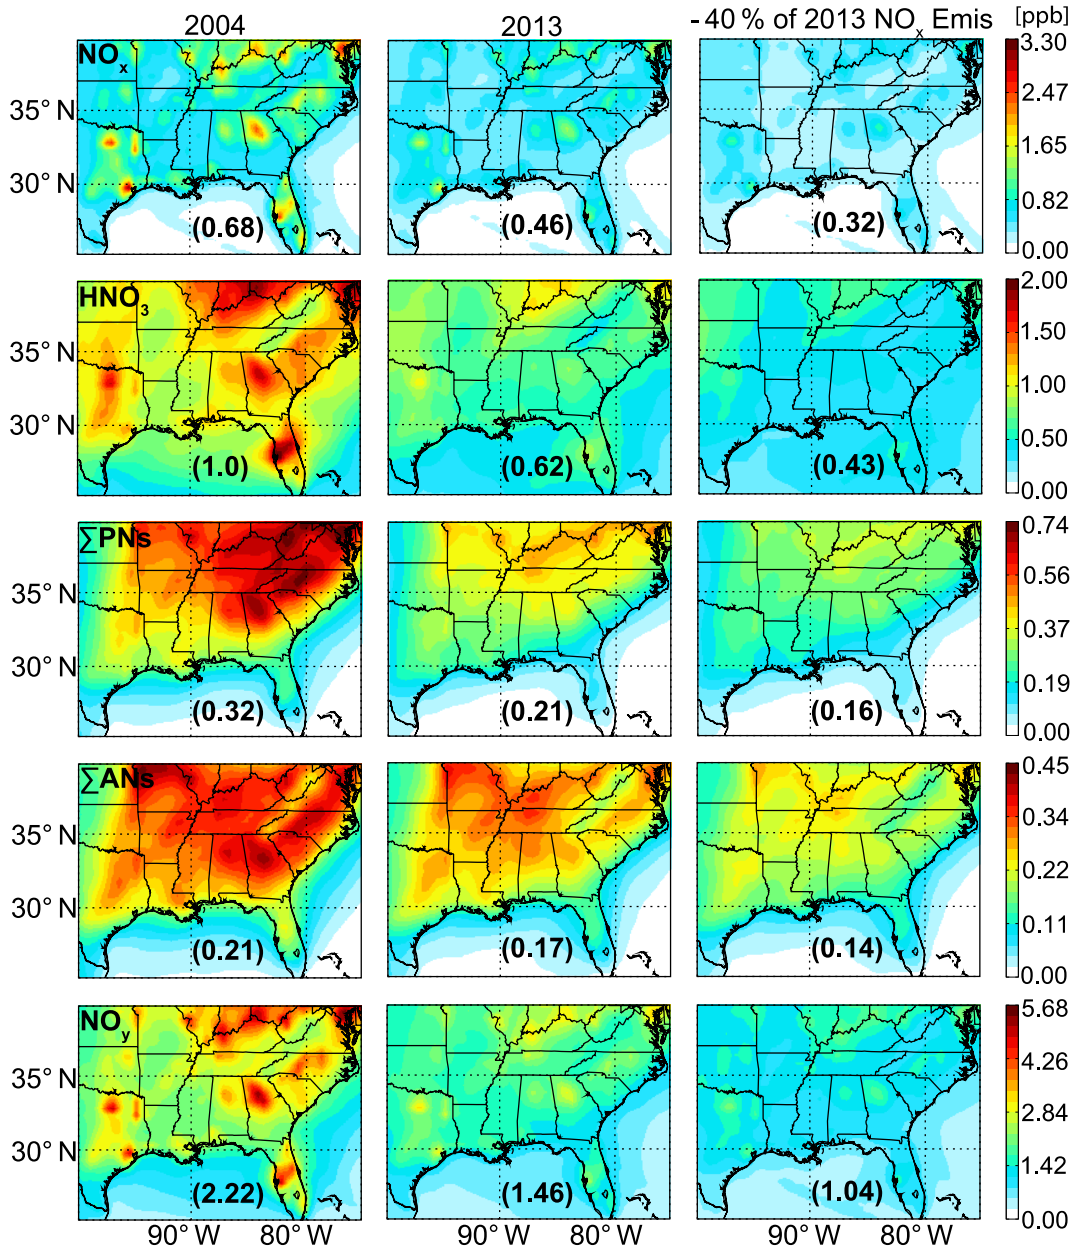

1376 **Figure 4.** O_x versus ΣANs correlation (top; (a)) and ΣANs versus formaldehyde
 1377 correlation (bottom; (b)) within the boundary layer (< 1.5 km) during ICARTT (left) and
 1378 SEAC⁴RS (right). Observations are in black diamonds; model estimates from AM3 with
 1379 ISOPNB hydrolysis are in red symbols. Green symbols (~~DAM3~~) represent the correlation
 1380 using modeled ISOPN + MVKN + MACRN. Blue symbols (~~DObs~~) represent the
 1381 correlation using observed ISOPN + MVKN + MACRN from SEAC⁴RS. Solid lines are
 1382 the reduced major axis regression lines.

1383

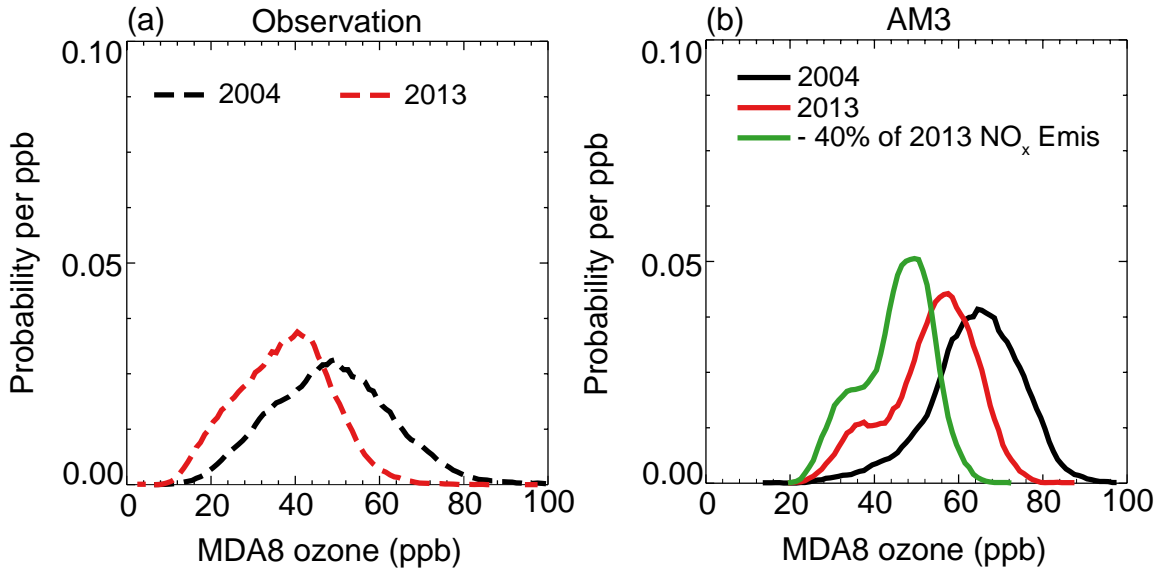

1384

1385 **Figure 5.** Mean vertical profiles of modeled alkyl nitrates from isoprene and
 1386 monoterpene oxidation (left) and major isoprene nitrate species (right) during ICARTT
 1387 (top row) and SEAC⁴RS (bottom row) from AM3 with hydrolysis of ISOPNB.

1388

1389 **Figure 6.** Modeled mean NO_x, HNO₃, total peroxy nitrates (ΣPNs), total alkyl nitrates
 1390 (ΣANs) and NO_y averaged over the boundary layer (< 1.5 km) of the Southeast U.S.
 1391 during July–August of 2004 (left), 2013 (middle), and a scenario assuming 40 %
 1392 reduction of 2013 anthropogenic NO_x emissions (right). Numbers in parentheses indicate
 1393 mean concentrations over the plotted region. Note different color scales represent the
 1394 concentration of each species.

1395
 1396
 1397
 1398
 1399

Figure 7. Observed (a) and simulated (b) probability density function of MDA8 ozone at AQS monitoring sites in Figure S3 during summer of 2004, 2013, and a scenario with 40 % reduction in the anthropogenic NO_x emissions of 2013.

1400 | **Table 1.1.** Monthly averaged NO_x emissions in July-August of 2004 and 2013 over
 1401 | North America (25-50° N, 130-70° W) and over the Southeast US (25-40° N, 100-75° W)
 1402 | in brackets in AM3.in-AM3.

Source Type	2004 (Tg N)	2013 (Tg N)
Anthropogenic	0.42 <u>(0.19)</u>	0.25 <u>(0.11)</u>
Biomass Burning	8.4×10 ⁻³ <u>(2.8×10⁻³)</u>	8.4×10 ⁻³ <u>(2.8×10⁻³)</u>
Soils	2.9×10 ⁻² <u>(9.5×10⁻³)</u>	2.9×10 ⁻² <u>(9.5×10⁻³)</u>
Aircraft	8.8×10 ⁻³ <u>(2.9×10⁻³)</u>	8.0×10 ⁻³ <u>(2.8×10⁻³)</u>
Lightning	0.02 <u>(0.01)</u>	0.02 <u>(0.01)</u>
Total	0.49 <u>(0.22)</u>	0.32 <u>(0.14)</u>

1406 | **Table 3.2.** Monthly NO_y budget in the boundary layer (< 1.5 km) of the Southeast United States for July-August of 2004, 2013 and a
 1407 | scenario with 40 % reduction of anthropogenic NO_x emissions of 2013^a.

Species	2004					2013					- 40 % of 2013 Anthropogenic NO _x Emis				
	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export
NO _x	208.7	-172.4	21.8	-	14.5	132.6	-105	14.2	-	13.4	88.3	-69.6	9.2	-	9.5
ΣPNs ^b		15.2	5.7	-	9.5		10.3	3.9	-	6.4		7.7	3.0	-	4.7
ΣANs		24.3	14.3	6.2	3.8		19.4	11.4	4.7	3.3		15.4	9.1	3.9	2.4
day ^c		13.8	8.7	3.6	1.5		12.0	7.5	3.0	1.6		10.2	6.3	2.6	1.3
night ^d		10.5	5.6	2.6	2.4		7.4	4.0	1.7	1.7		5.3	2.8	1.3	1.1
HNO ₃		131.7	77.8	57.6	-3.7		74.2	45.6	35.1	-6.5		45.8	29.2	25.6	-9.0
NO _y					24.1					16.6					7.6

1408 | ^aWe define the boundary of Southeast US is 25-40° N, 100-75° W. All budget terms are in Gg N.

1409 | ^bΣPNs ~~includes~~ PAN, peroxyacryloyl nitrate (MPAN), and a C5 hydroxy peroxyacyl nitrate (C5PAN1) produced by
 1410 | oxidation of ISN1.

1411 | ^cAlkyl nitrates produced from oxidation of isoprene and monoterpenes by OH.

1412 | ^dAlkyl nitrates produced from oxidation of isoprene and monoterpenes by NO₃.
