

## Response to reviewer comments:

The authors thank the reviewer for the comments that improve the quality of the paper. The reviewer comments are shown in italic fonts, the responses are in regular fonts, and revised text in bold fonts.

*Thank you for the detailed response to reviewers' comments. I think you have addressed their comments sufficiently. I just have a few very minor technical notes. The manuscript will be accepted for publication in ACP once these are addressed.*

*(the line numbers correspond to those in the revised manuscript)*

**Comment 1:** *Line 114. It would also be appropriate to cite Bean and Hildebrandt Ruiz (ACP, 2016), Boyd et al. (ACP, 2015), and Boyd et al. (ES&T, 2017).*

**Response 1:** We have added those citations in lines 107-111 of the revised paper as:  
“**The fate of particle-phase RONO<sub>2</sub> is unclear, with the possibility for removal by hydrolysis to form HNO<sub>3</sub> (Jacobs et al., 2014; Hu et al., 2011; Darer et al., 2011; Rindelaub et al., 2015; Szmigielski et al., 2010; Sato, 2008; Romer et al., 2016; Wolfe et al., 2015; Boyd et al., 2017; Boyd et al., 2015; Bean and Hildebrandt Ruiz, 2016), ...**”

**Comment 2.** *Line 116. Delete citation of Boyd et al. in this sentence, as this work does not discuss photochemical aging.*

**Response 2:** That citation has been removed and the text is revised as:  
“**...photochemical aging (Nah et al., 2016), ...**”

**Comment 3.** *Line 227. Also isoprene oxidation by NO<sub>3</sub>? This was discussed in the next paragraph.*

**Response 3:** We agree with the reviewer. Now the text reads as (in lines 194-196):  
“**This mechanism is based on Mao et al. (2013b), but has been significantly revised to incorporate recent laboratory updates on isoprene oxidation by OH, O<sub>3</sub> and NO<sub>3</sub> ....**”

**Comment 4:** *Line 287. A few recent laboratory studies have investigated the effects of RO<sub>2</sub> fates on aerosol formation from nitrate radical oxidation, representative of different atmospheric environments (Ng et al., ACP, 2008; Boyd et al., ACP, 2015; Schwantes et al., J. Phys. Chem. A, 2015). More studies are needed definitely, especially regarding the role of RO<sub>2</sub> autoxidation in nitrate radical oxidation chemistry.*

**Response 4:** Now the text reads as (in lines 244-248):

**“However, these results might not be representative of atmospheric conditions in terms of the RO<sub>2</sub> reaction partner or RO<sub>2</sub> lifetime, warranting further studies on the effects of RO<sub>2</sub> fates on aerosol formation (Boyd et al., 2017; Boyd et al., 2015; Ng et al., 2008; Schwantes et al., 2015).”**

**Comment 5:** *Line 306. I think the "hydro full" case does not include the hydrolysis of TERPN2 (monoterpene nitrates from NO<sub>3</sub> oxidation)? It would be useful to state this here explicitly for clarity.*

**Response 5:** Hydrolysis of TERPN2 is not included in the “hydro\_full” case. We have emphasized this in lines 262-264 as:

**“One is “hydro\_full” case including heterogeneous loss of a C<sub>5</sub> dihydroxy dinitrate (DHDN) and monoterpene nitrates only from OH oxidation during daytime (TERPN1; nighttime monoterpene nitrates are excluded), ...”**

43 **Abstract**

44 Widespread efforts to abate ozone ( $O_3$ ) smog have significantly reduced nitrogen oxides ( $NO_x$ )  
45 emissions over the past two decades in the Southeast U.S. (SEUS), a place heavily influenced by  
46 both anthropogenic and biogenic emissions. How reactive nitrogen speciation responds to the  
47 reduction in  $NO_x$  emissions in this region remains to be elucidated. Here we exploit aircraft  
48 measurements from ICARTT (July-August, 2004), SENEX (June-July, 2013), and SEAC<sup>4</sup>RS  
49 (August-September, 2013) and long-term ground measurement networks alongside a global  
50 chemistry-climate model to examine decadal changes in summertime reactive oxidized nitrogen  
51 (RON) and ozone over the Southeast U.S. We show that our model can well reproduce the mean  
52 vertical profiles of major RON species and the total ( $NO_y$ ) in both 2004 and 2013. Among the major RON  
53 species, nitric acid ( $HNO_3$ ) is dominated ( $\sim 42 - 45\%$ ), followed by  $NO_x$  (31%), total peroxy nitrates  
54 ( $\Sigma PNs$ ; 14%), and total alkyl nitrates ( $\Sigma ANs$ ; 9 – 12%) on a regional scale. We find that most RON,  
55 including  $NO_x$ ,  $\Sigma PNs$  and  $HNO_3$  decline proportionally with decreasing  $NO_x$  emissions in this  
56 region, leading to a similar decline in  $NO_y$ . This linear response might be in part due to the  
57 nearly constant summertime supply of biogenic VOC emissions in this region. Our model  
58 captures the observed relative change of RON and surface ozone from 2004 to 2013. Model  
59 sensitivity tests indicate that further reductions of  $NO_x$  emissions will lead to a continued decline  
60 in surface ozone and less frequent high ozone events.

61 **1 Introduction**

62 Since the 1990s, the U.S.A. Environmental Protection Agency (U.S. EPA) has targeted  
63 emissions of nitrogen oxides ( $NO_x$ ) to improve air quality by lowering regional photochemical  
64 smog (The 1990 Clean Air Amendment). Satellite- and ground-based observations imply  
65 significant declines in U.S.  $NO_x$  emissions, with a decreasing rate of roughly  $-4\% \text{ yr}^{-1}$  after  
66 2005 (Krotkov et al., 2016; Russell et al., 2012; Tong et al., 2015; Miyazaki et al., 2017; Lu et al.,  
67 2015; Lamsal et al., 2015). This has proven effective at lowering near-surface ozone ( $O_3$ ) in the  
68 past few decades (Cooper et al., 2012; Simon et al., 2015; Hidy and Blanchard, 2015;  
69 Stoeckenius et al., 2015; Xing et al., 2015; Yahya et al., 2016; Astitha et al., 2017). The average  
70 of the annual 4<sup>th</sup> highest daily maximum 8-h average (MDA8) ozone over 206 sites has  
71 decreased by 31% from 101 ppb in 1980 to 70 ppb in 2016 across the continental U.S., with  
72 more significant reductions in rural areas of the eastern U.S. in summer (Simon et al., 2015;  
73 Cooper et al., 2012). Here we use both aircraft and ground-based datasets, combined with a high  
74 resolution chemistry-climate model, to evaluate responses of reactive oxidized nitrogen (RON)  
75 and surface ozone to the  $NO_x$  emission reductions in the Southeast U.S.

76 In the troposphere, ozone is produced through photochemical reactions involving  $NO_x$  and  
77 volatile organic compounds (VOCs) in the presence of sunlight. During photooxidation, a large  
78 fraction of  $NO_x$  is transformed into its reservoirs, including nitric acid ( $HNO_3$ ), peroxy nitrates  
79 ( $RO_2NO_2$ ; dominated by peroxyacetyl nitrate (PAN)), and alkyl nitrates ( $RONO_2$ ). These species,  
80 together with  $NO_x$ , are known as total reactive oxidized nitrogen ( $NO_y = NO_x + HNO_3 + HONO$

---

81 + 2 × N<sub>2</sub>O<sub>5</sub> + total peroxy nitrates (ΣPNs) + total alkyl nitrates (ΣANs)). Some of these reservoir  
82 species, particularly those with an organic component, tend to be less soluble and longer lived.  
83 They may carry reactive nitrogen far from the NO<sub>x</sub> source region (Stohl et al., 2002; Parrish et al.,  
84 2004; Li et al., 2004) and thereby affect NO<sub>x</sub> concentrations and O<sub>3</sub> formation on a regional to  
85 global scale (Liang et al., 1998; Horowitz et al., 1998; Perring et al., 2013; Paulot et al., 2016;  
86 Hudman et al., 2004).

87 RONO<sub>2</sub> originating from biogenic VOCs (BVOCs) represents a major uncertainty in the NO<sub>y</sub>  
88 budget, as BVOC emissions account for more than 80 % of global VOC emissions (Millet et al.,  
89 2008). To a large extent, this is due to the uncertainties in current understanding of BVOC  
90 oxidation chemistry. Biogenic RONO<sub>2</sub> species are mainly produced from the oxidation of  
91 BVOCs by OH in the presence of NO<sub>x</sub> during daytime and by nitrate radical (NO<sub>3</sub>) during  
92 nighttime. Laboratory and field studies show a wide range of RONO<sub>2</sub> yields from their BVOC  
93 precursors (Browne et al., 2014; Fry et al., 2014; Lockwood et al., 2010; Paulot et al., 2009;  
94 Rindelaub et al., 2015; Rollins et al., 2009; Lee et al., 2014; Xiong et al., 2015; Xiong et al.,  
95 2016; Teng et al., 2015). Another uncertainty lies in the fate of RONO<sub>2</sub>, i.e. recycling RONO<sub>2</sub>  
96 into NO<sub>x</sub> or converting it to HNO<sub>3</sub> have important implications for the NO<sub>y</sub> budget and thus O<sub>3</sub>  
97 production (Fiore et al., 2005; Horowitz et al., 2007; Ito et al., 2009; Perring et al., 2013; Paulot  
98 et al., 2012). This is further complicated by particle-phase RONO<sub>2</sub>, an important component of  
99 secondary organic aerosol (SOA) over the Southeast U.S. (Xu et al., 2015; Lee et al., 2016). The  
100 fate of particle-phase RONO<sub>2</sub> is unclear, with the possibility for removal by hydrolysis to form  
101 HNO<sub>3</sub> (Jacobs et al., 2014; Hu et al., 2011; Darer et al., 2011; Rindelaub et al., 2015; Szmigielski  
102 et al., 2010; Sato, 2008; Romer et al., 2016; Wolfe et al., 2015; [Boyd et al., 2017](#); [Boyd et al.,  
103 2015](#); [Bean and Hildebrandt Ruiz, 2016](#)), photochemical aging (Nah et al., 2016; ~~[Boyd et al.,  
104 2015](#)~~), and deposition (Nguyen et al., 2015). To what extent RONO<sub>2</sub> affect the partitioning of  
105 RON and surface ozone remains to be elucidated.

106 Extensive datasets in the Southeast U.S. offer a great opportunity to study the decadal change of  
107 RON and surface ozone, resulting from NO<sub>x</sub> emission decline. Aircraft campaigns during the  
108 summers of 2004 and 2013, including the International Consortium for Atmospheric Research on  
109 Transport and Transformation (ICARTT) (Fehsenfeld et al., 2006; Singh et al., 2006), the  
110 Southeast Nexus (SENEX) (Warneke et al., 2016), and the Studies of Emissions and  
111 Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys (SEAC<sup>4</sup>RS)  
112 (Toon et al., 2016), provide detailed characterization of tropospheric composition in this region  
113 separated by nearly a decade. These data have been widely used to evaluate model estimates of  
114 RON and ozone (Singh et al., 2007; Pierce et al., 2007; Perring et al., 2009; Fischer et al., 2014;  
115 Hudman et al., 2007; Henderson et al., 2011; Hudman et al., 2009; Edwards et al., 2017; Baker  
116 and Woody, 2017; Travis et al., 2016; Mao et al., 2013b; Fisher et al., 2016; Yu et al., 2016; Liu  
117 et al., 2016). Together with measurements from networks, including the National Atmospheric  
118 Deposition Program (NADP) and EPA Air Quality System (AQS), these datasets enable a close  
119 examination of responses of RON and surface ozone to NO<sub>x</sub> emissions reduction in this region.

---

120 Here we use a high-resolution global 3D climate-chemistry model, the Geophysical Fluid  
121 Dynamics Laboratory (GFDL) AM3 model, with updated isoprene and organic nitrate chemistry  
122 to investigate decadal changes of RON and surface O<sub>3</sub> during summer between 2004 and 2013  
123 over the Southeast U.S. We first evaluate the model with comprehensive measurements from  
124 three aircraft campaigns in the summer of 2004 (ICARTT) and 2013 (SENEX and SEAC<sup>4</sup>RS).  
125 Model estimates of nitrate wet deposition flux are also evaluated against measurements from  
126 NADP; model estimates of NO<sub>y</sub> are compared with measurements from EPA AQS to provide an  
127 additional constraint on the fate of RON in the model. We then investigate the repartitioning of  
128 RON in response to NO<sub>x</sub> emission reductions from 2004 to 2013 on a regional scale. From there,  
129 we examine the model estimate of decadal changes of summertime surface O<sub>3</sub> at 157 EPA AQS  
130 monitoring sites over the Southeast U.S. We also demonstrate the sensitivity of RON and MDA8  
131 O<sub>3</sub> to a hypothetical NO<sub>x</sub> emission reduction over the next decade.

## 132 **2 Methodology**

### 133 **2.1 AM3 Model**

134 We apply a high-resolution (50 x 50 km<sup>2</sup>) version of the GFDL AM3 global chemistry-climate  
135 model to study decadal changes of RON and O<sub>3</sub> over the Southeast U.S. Chemistry-climate  
136 models provide a unique capability to both evaluate model representation of these observed  
137 changes and use that to improve future projections of air quality in the same region. The model  
138 configuration is to a large extent similar to that used in another paper (Li et al., 2016); and a  
139 short summary is provided below. The dynamical core, physical parameterizations, cloud and  
140 precipitation processes, and cloud-aerosol interactions mainly follow Donner et al. (2011),  
141 except that convective plumes are computed on a vertical grid with finer resolution (Paulot et al.,  
142 2016). Dry deposition in the model has been updated to use dry deposition velocities calculated  
143 in the GEOS-Chem model (Paulot et al., 2016), to reflect rapid deposition of organic nitrates and  
144 oxidized volatile organic compounds (OVOCs) (Nguyen et al., 2015). The current time step for  
145 chemistry and transport in our model is 20 mins. We show below in section 4.1 that, with the  
146 current setting, our model can well reproduce the vertical profiles of RON. Sensitivity of RON to  
147 operator duration should refer to Philip et al. (2016).

148 Isoprene emissions are computed in the model using the Model of Emissions of Gases and  
149 Aerosols from Nature (MEGAN). In 2004, isoprene emissions over the continental U.S. (25-50°  
150 N, 130-70° W) are computed to be 8.0 Tg C in July and August together, with a previous model  
151 estimate of 7.5 Tg C by Mao et al. (2013b). In 2013, model estimates of isoprene emissions were  
152 scaled down by 20% following Li et al. (2016). The resulting isoprene emissions are 7.7 Tg C in  
153 July-August in this region, with little difference compared to 2004. Monoterpene emissions  
154 follow Naik et al. (2013) and do not vary interannually, with a total of 4.0 Tg C in July and  
155 August.

---

156 Anthropogenic emissions follow the Representative Concentration Pathway 8.5 (RCP 8.5)  
157 projection (Lamarque et al., 2011) for both 2004 and 2013, to compare the model to observations  
158 in a consistent fashion and also enable future projection of air quality in this region. As shown in  
159 Table 1, anthropogenic NO<sub>x</sub> emissions over the continental U.S. during July-August of 2004  
160 amount to 0.42 Tg N mon<sup>-1</sup>, consistent with Hudman et al. (2007) but 11 % lower than EPA  
161 estimates of 0.47 Tg N mon<sup>-1</sup> (Granier et al., 2011). For the year of 2013, we apply a 25 %  
162 reduction to the anthropogenic NO<sub>x</sub> emissions from the RCP 8.5 projection (from base year of  
163 2010), to best reproduce the vertical profiles of RON during SENEX as shown below in section  
164 4.1. This adjustment is also consistent with recent estimates of NO<sub>x</sub> emissions over the Southeast  
165 U.S. (Anderson et al., 2014). The resulting anthropogenic NO<sub>x</sub> emissions (0.25 Tg N mon<sup>-1</sup>) are  
166 14 % lower than NEI11v1 emission inventory estimate of 0.29 Tg N mon<sup>-1</sup> (0.28 Tg N mon<sup>-1</sup>  
167 from the updated NEI11v2 emission inventory), although both inventories have a similar spatial  
168 distribution (Figure S1). We also apply a diurnal variation to anthropogenic NO<sub>x</sub> emissions  
169 following Mao et al. (2013b). Soil NO<sub>x</sub> emissions in our model, 3.6 Tg N yr<sup>-1</sup> globally (Naik et  
170 al., 2013), are considerably lower than other model estimates, including 5.5 Tg N yr<sup>-1</sup> in Yienger  
171 and Levy (1995) and 9.0 Tg N yr<sup>-1</sup> in Hudman et al. (2012). As a result, the anthropogenic NO<sub>x</sub>  
172 emissions over the continental U.S. are 0.84 Tg N for July-August of 2004, and 0.50 Tg N in  
173 July-August of 2013, with 40 % reduction from 2004 to 2013 (Table 1). This relative change in  
174 anthropogenic NO<sub>x</sub> emissions is consistent with EPA estimates ([https://www.epa.gov/air-](https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data)  
175 [emissions-inventories/air-pollutant-emissions-trends-data](https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data)) and satellite observations (Krotkov et  
176 al., 2016; Lu et al., 2015). Compared to the NEI11v1 inventory, RCP 8.5 used in our model  
177 shows similar relative differences in both national and Southeast region.

## 178 2.2 Gas-phase chemistry

179 We apply the same isoprene mechanism as described by Li et al. (2016). A full list of the  
180 reactions can be found in Table S1. This mechanism is based on Mao et al. (2013b), but has been  
181 significantly revised to incorporate recent laboratory updates on isoprene oxidation by OH, O<sub>3</sub>  
182 and NO<sub>3</sub>O<sub>3</sub> (Schwantes et al., 2015; Bates et al., 2016; Peeters et al., 2014; St. Clair et al., 2016;  
183 Bates et al., 2014; Praske et al., 2015; Müller et al., 2014; Lee et al., 2014; Crouse et al., 2011).  
184 One major feature is the suppression of δ-isoprene hydroxyl peroxy radical (δ-ISOPO<sub>2</sub>) and  
185 subsequent reaction pathways in the model, as these channels are considered to be of minor  
186 importance under ambient conditions (Peeters et al., 2014; Bates et al., 2014). The fraction of  
187 ISOPO<sub>2</sub> undergoing isomerization is calculated using bulk isomerization estimates (Crouse et  
188 al., 2011). As a result, the first-generation isoprene alkyl nitrate is assumed to be β-hydroxy  
189 nitrate (ISOPNB) in the model with a yield of 10 % from the ISOPO<sub>2</sub> + NO pathway. This  
190 differs from a recent GEOS-Chem study of organic nitrates over the Southeast U.S. that assumed  
191 9 % yield of the first-generation isoprene alkyl nitrate comprised of 90 % ISOPNB and 10 % δ-  
192 hydroxy nitrate (ISOPND) (Fisher et al., 2016). The treatment of β- and δ-ISOPO<sub>2</sub> will not only  
193 affect the speciation of organic nitrates but also the production of O<sub>3</sub> due to different NO<sub>x</sub>  
194 recycling efficiency in their secondary products. We also include updated chemistry for

---

195 methylvinyl ketone (MVK) (Praske et al., 2015), an updated yield of hydroxy hydroperoxides  
196 (ISOPOOH) (Bates et al., 2016; St. Clair et al., 2016), fast photolysis of carbonyl organic nitrates  
197 (Müller et al., 2014), and an updated ozonolysis rate of ISOPNB (Lee et al., 2014). In addition,  
198 we reduce the yield of organic nitrates (MACRN) from methacrolein (MACR) oxidation from  
199 15 % to 3 %, which is estimated from the measured yield of nitrate from MVK oxidation (Praske  
200 et al., 2015).

201 Another major model revision involves the treatment of nighttime oxidation of isoprene. Instead  
202 of following Mao et al. (2013b), we revised nighttime oxidation of isoprene largely based on the  
203 Leeds Master Chemical Mechanism v3.2 (MCM v3.2), allowing a more complete description of  
204 isoprene oxidation by  $\text{NO}_3$ . In particular, MCM v3.2 suggests significant production of  
205 propanone nitrate (PROPNN) from the photooxidation of the  $\text{C}_5$  carbonyl nitrate, consistent with  
206 recent laboratory experiments (Schwantes et al., 2015). We also updated the products of the  
207 reaction of nitrooxy alkylperoxy radical ( $\text{INO}_2$ ), the peroxy radical from isoprene oxidation by  
208  $\text{NO}_3$ , with  $\text{HO}_2$  to reflect a lower molar yield (0.77) of  $\text{C}_5$  nitrooxy hydroperoxide (INPN)  
209 (Schwantes et al., 2015). The differences between MCM v3.2 and the most updated version,  
210 MCM v3.3.1, in isoprene nighttime chemistry appears to be small (Jenkin et al., 2015). We  
211 therefore use MCM v3.2 as the reference in this work.

212 We include a highly simplified chemistry for the oxidation of monoterpenes in this work, mainly  
213 to quantify their contribution to organic nitrates. Monoterpenes are lumped into one chemical  
214 species ( $\text{C}_{10}\text{H}_{16}$ ) in our model. The organic nitrate yield is set to 26 % from OH-initiated  
215 oxidation (Rindelaub et al., 2015) and to 10 % from  $\text{NO}_3$ -initiated oxidation (Browne et al.,  
216 2014). Details of the monoterpene chemistry can be found in Table S2.

### 217 **2.3 Heterogeneous loss of organic nitrates**

218 Field and laboratory studies have indicated a potential contribution to aerosol formation of  
219 organic nitrates from BVOC oxidation (Ayres et al., 2015; Fry et al., 2014; Nah et al., 2016;  
220 Rollins et al., 2009; Rindelaub et al., 2015; Boyd et al., 2015; Lee et al., 2016; Ng et al., 2008;  
221 Fry et al., 2009; Xu et al., 2015; Lee et al., 2014; Bean and Hildebrandt Ruiz, 2016; Spittler et al.,  
222 | 2006; [Boyd et al., 2017](#)).~~)-~~ Aerosol yield depends on both the VOC precursor and the oxidant.  
223 For example,  $\Delta$ -3-carene oxidation by  $\text{NO}_3$  can produce a 38-65 % yield of organic aerosols in a  
224 smog chamber (Fry et al., 2014), which is much higher than the 1-24 % yield from  $\text{NO}_3$ -initiated  
225 isoprene oxidation (Ng et al., 2008; Rollins et al., 2009; Ayres et al., 2015). Recent chamber  
226 studies indicate a very low aerosol yield from  $\alpha$ -pinene oxidation by  $\text{NO}_3$  (Nah et al., 2016; Fry  
227 et al., 2014), the aerosol yield increases to ~ 18 % when  $\alpha$ -pinene is oxidized by OH (Rollins et  
228 | al., 2010; Rindelaub et al., 2015). ~~However, It should be noted that~~ these results ~~from laboratory~~  
229 ~~experiments~~ might not be representative of atmospheric conditions in terms of the  $\text{RO}_2$  reaction  
230 partner or  $\text{RO}_2$  lifetime, warranting further studies on the effects of  $\text{RO}_2$  fates on aerosol  
231 formation (Boyd et al., 2017; Boyd et al., 2015; Ng et al., 2008; Schwantes et al., 2015).-

---

232 In the condensed phase, organic nitrates can undergo hydrolysis reactions producing HNO<sub>3</sub>  
233 (Darer et al., 2011; Hu et al., 2011; Rindelaub et al., 2015; Boyd et al., 2015; Szmigielski et al.,  
234 2010; Sato, 2008; Jacobs et al., 2014; Bean and Hildebrandt Ruiz, 2016). However, the  
235 hydrolysis rate varies greatly with the structure of nitrate (Bean and Hildebrandt Ruiz, 2016;  
236 Darer et al., 2011; Hu et al., 2011; Boyd et al., 2015; Rindelaub et al., 2016). Here we assume a  
237 first-order irreversible reactive uptake for the heterogeneous loss of organic nitrates onto aerosols  
238 (R1), followed by its hydrolysis reaction returning HNO<sub>3</sub> and alcohols (R2) (Fisher et al., 2016):

239 where RONO<sub>2</sub>, AONJ and ROH represent gas- and particle-phase organic nitrates and alcohols  
240 respectively. We allow heterogeneous loss of organic nitrates to sulfate, black carbon, primary  
241 organic carbon, sea salt, mineral dust and SOA following Mao et al. (2013a). Besides the base  
242 case that only includes ISOPNB for heterogeneous loss (Jacobs et al., 2014), we include two  
243 additional sensitivity tests to evaluate the potential impact of organic nitrate hydrolysis. One is  
244 “hydro\_full” case including heterogeneous loss of a C<sub>5</sub> dihydroxy dinitrate (DHDN) and  
245 monoterpene nitrates only from OH oxidation during daytime (TERPN1; nighttime monoterpene  
246 nitrates are excluded), and the other one is “no\_hydro” case assuming no heterogeneous loss for  
247 any organic nitrates. We adopt an effective uptake coefficient 0.005 for ISOPNB and DHDN,  
248 and 0.01 for TERPN1, following Fisher et al. (2016), with a 3-h bulk lifetime in particle phase  
249 (Pye et al., 2015; Lee et al., 2016) (Table S3). Details of each case are listed in Table 2.

### 250 **3 Observational datasets**

251 We use measurements from a series of field campaigns (2004 ICARTT, 2013 SENEX, and 2013  
252 SEAC<sup>4</sup>RS) to evaluate model performance on O<sub>3</sub>, NO<sub>x</sub>, HNO<sub>3</sub>, PAN, ΣANs and NO<sub>y</sub> over the  
253 Southeast U.S. in summer.

254 The ICARTT aircraft campaign provided a detailed characterization of tropospheric chemistry  
255 over the eastern U.S. in the summer of 2004 (July 1 - August 15, 2004). Two aircrafts, the  
256 NASA DC-8 and the NOAA WP-3D, were deployed to collect measurements of ozone, RON,  
257 isoprene and its oxidation products. Here we focus on data including O<sub>3</sub>, NO<sub>x</sub>, HCHO (Tunable  
258 Diode Laser (TDL) absorption spectrometry), HNO<sub>3</sub> (mist chamber/IC by University of New  
259 Hampshire and Chemical Ionization Mass Spectrometer (CIMS) by California Institute of  
260 Technology), PAN and ΣANs (including gas and aerosol RONO<sub>2</sub>) collected on the NASA DC-8  
261 aircraft over the Southeast U.S. Details of the instrument operation and accuracy are summarized  
262 in Singh et al. (2006) and references therein.

263 Two aircraft campaigns were conducted in the summer of 2013 over the Southeast U.S. The first  
264 one is NOAA SENEX campaign, using NOAA WP-3D aircraft to investigate the interaction  
265 between biogenic and anthropogenic emissions and the formation of secondary pollutants (May

---

266 27 - July 10, 2013). We focus on daytime measurements of O<sub>3</sub>, NO<sub>x</sub>, HNO<sub>3</sub>, PAN, speciated  
267 RONO<sub>2</sub> and NO<sub>y</sub> in this work. Details of the instrument operation and accuracy are summarized  
268 in Warneke et al. (2016) and references therein. The second one is NASA SEAC<sup>4</sup>RS campaign,  
269 which took place in August - September of 2013, with a focus on vertical transport of  
270 atmospheric pollutants from the surface to the stratosphere. Here we focus on observations of O<sub>3</sub>,  
271 NO<sub>2</sub>, HCHO (laser-induced fluorescence, LIF), ΣANs (including gas and aerosol RONO<sub>2</sub>) and  
272 speciated RONO<sub>2</sub> collected on NASA DC-8 aircraft to evaluate model representation of ΣANs  
273 and several RONO<sub>2</sub> originating from isoprene oxidation. Details of the instrument operation and  
274 accuracy are summarized in Toon et al. (2016) and references therein.

275 Besides these aircraft campaigns, we also use surface observations for model evaluation,  
276 including nitrate (NO<sub>3</sub><sup>-</sup>) wet deposition flux and concentration from the National Trends Network  
277 (NTN) of NADP (accessible at <http://nadp.sws.uiuc.edu/data/>) and surface O<sub>3</sub> and NO<sub>y</sub> from  
278 EPA AQS (accessible at [https://aq5.epa.gov/aqsweb/documents/data\\_mart\\_welcome.html](https://aq5.epa.gov/aqsweb/documents/data_mart_welcome.html)). We  
279 focus on NO<sub>3</sub><sup>-</sup> wet deposition fluxes at 53 NADP sites (~~Figure 3~~) and MDA8 O<sub>3</sub> at 157 EPA  
280 AQS sites (Figure ~~S2S3~~) in the Southeast U.S. during July - August of 2004 and 2013. NO<sub>y</sub>  
281 measurements at 10 out of the 157 AQS sites in the same episodes are compared with model  
282 estimates as an additional constraint on the decadal change of NO<sub>y</sub>. We choose July - August as  
283 our 'summer' since this is the common period of all the measurements used in model evaluation.

## 284 4 Model evaluation

285 We evaluate our model against observations from aircraft campaigns in 2004 and 2013. For each  
286 of the three field campaigns, all measurements are averaged to a 1-min time resolution. Data  
287 from biomass burning (CH<sub>3</sub>CN ≥ 225 ppt or HCN ≥ 500 ppt), urban plumes (NO<sub>2</sub> ≥ 4 ppb or  
288 NO<sub>x</sub>/NO<sub>y</sub> ≥ 0.4 (if NO<sub>y</sub> is available)), and stratospheric air (O<sub>3</sub>/CO > 1.25 mol mol<sup>-1</sup>) are  
289 excluded (Hudman et al., 2007) in all the analyses, as these subgrid processes may not be well  
290 represented in our model. We focus on the Southeast U.S. region, using data within the domain  
291 of 25 - 40° N latitude and 100 - 75° W longitude for our analyses. A map of all the flight tracks  
292 of each campaign is shown in Figure ~~S3S4~~. All model results are sampled along the flight track  
293 with 1-min time resolution.

### 294 4.1 Mean vertical profiles of O<sub>3</sub> and RON

295 Figure 1 shows the observed and modeled mean vertical profiles of O<sub>3</sub>, NO<sub>x</sub>, HNO<sub>3</sub>, PAN,  
296 ΣANs and NO<sub>y</sub> during ICARTT and SENEX. We use ΣANs measurements from SEAC<sup>4</sup>RS to  
297 evaluate model performance during summer 2013, due to the lack of ΣANs measurements from  
298 SENEX. Our model results include both gas and aerosol RONO<sub>2</sub> in ΣANs, although aerosol  
299 RONO<sub>2</sub> accounts for 7~11% of ΣANs in the planetary boundary layer (PBL, < 1.5 km). We do  
300 not consider inorganic nitrates in particle phase in this analysis, due to lack of thermodynamic  
301 model for inorganic aerosols in current version of AM3. This simplification is expected to have

---

302 minimal effects, as they only account for a small fraction of aerosol nitrates in the Southeast U.S.  
303 (Ng et al., 2017). To investigate the impact of  $\text{RONO}_2$  hydrolysis, we include two model  
304 simulations, the base case with heterogeneous loss of ISOPNB, and a sensitivity run ‘no\_hydro’  
305 without heterogeneous loss of organic nitrates.

306 Mean observed  $\text{O}_3$  in the surface layer decreased from 50 ppb during ICARTT to 35 ppb during  
307 SENEX, consistent with the declining trend in surface MDA8 ozone at AQS monitoring sites  
308 (section 5.2). As we show in section 5.2, this decline in ozone is mainly driven by  $\text{NO}_x$  emission  
309 reduction, with little influence by meteorology in the two years. Our model can reproduce the  
310 vertical gradient and the relative change of  $\text{O}_3$  from 2004 to 2013, except for a positive absolute  
311 bias of 6 - 12 ppb in the boundary layer. Performance statistics of  $\text{O}_3$  in the boundary layer listed  
312 in Table S4 also indicate positive biases in the model, with the fractional bias (FB) of 9.4 – 17%,  
313 fractional error (FE) of 16 – 19 %, normalized mean bias (NMB) of 9.4 – 16% and normalized  
314 mean error (NME) of 16 – 19 %. This overestimate of  $\text{O}_3$  is higher than that reported (3 - 5 ppb)  
315 by Mao et al. (2013b) for their simulation of the ICARTT dataset, likely due to faster photolysis  
316 of carbonyl nitrates that increases the  $\text{NO}_x$  recycling efficiency from isoprene oxidation.

317 We further examine mean vertical profiles of  $\text{NO}_x$  and its reservoirs in 2004 and 2013 (Figure 1).  
318 In the boundary layer along the flight tracks,  $\text{HNO}_3$  is the most abundant RON, accounting for 40  
319 - 46 % of  $\text{NO}_y$ , followed by  $\text{NO}_x$  (18 - 23 %), PAN (20 %), and  $\Sigma\text{ANs}$  (11 - 21 %). Between  
320 2004 and 2013, mean observed  $\text{NO}_y$  in the boundary layer decreased by 20 %, from 2.0 ppb to  
321 1.6 ppb, a weaker change than the 35 % reduction of total  $\text{NO}_x$  emissions (Table 1). The  
322 responses of major RON are mostly proportional to the change in  $\text{NO}_x$  emissions, with the  
323 notable exception of  $\Sigma\text{ANs}$ . We find significant decreases in  $\text{NO}_x$  (- 35 %) and  $\text{HNO}_3$  (- 29 %)  
324 as well as a slight decrease in PAN (- 13 %) from observations. The relative trends of  $\text{HNO}_3$  and  
325 PAN are opposite to those found in the Los Angeles (LA) basin, where PAN decreased much  
326 faster than  $\text{HNO}_3$  (Pollack et al., 2013). This difference results mainly from the rapid decrease of  
327 anthropogenic VOC emissions in the LA basin that also serves as major precursors of PAN. In  
328 contrast, isoprene is the major precursor of PAN over the Southeast U.S. Its emissions show a  
329 constant supply (within 5 % differences over the two summers) in this region.  $\Sigma\text{ANs}$  shows a  
330 different trend from the above compounds, increasing from 0.23 ppb to 0.27 ppb (+ 17 %) near  
331 the surface. As we show below in section 5.1, these changes (except for  $\Sigma\text{ANs}$ ) are mostly  
332 consistent with model estimates on a regional average. Discrepancy in their trends of vertical  
333 profiles and regional average might be due to representative errors from the three aircraft  
334 | campaigns on spatial (Figure [S3S4](#)) and temporal (different episodes, referring to observation  
335 data description in section 3) scales.

336 The model can well reproduce RON in the boundary layer but tend to underestimate them in the  
337 free troposphere. This is likely due to insufficient production of  $\text{NO}_x$  from lightning in the free  
338 troposphere in our model, which is 0.048 Tg N in total over North America during July - August  
339 of 2004, lower by almost a factor of 5 compared to the value (0.27 Tg N from July 1-August 15,

---

2004) reported by Hudman et al. (2007). This underestimate can be improved by scaling up lightning emission by a factor of 5-10 (Fang et al., 2010). We do not adjust the lightning NO<sub>x</sub> emissions in this work due to its high uncertainty (Ott et al., 2010; Pickering et al., 1998).

Hydrolysis of organic nitrates affects RONO<sub>2</sub> significantly in the boundary layer. By introducing hydrolysis of ISOPNB, we find that model relative bias of ΣANs is reduced from + 20 % to + 2 % during ICARTT (Figure 1). Performance metrics in Table S4 also indicate better agreement of the model with observations if hydrolysis of ISOPNB assumed. However, the relative bias is increased in magnitude from - 9 % to - 24 % during SEAC<sup>4</sup>RS. This low bias can be partially due to neglecting small alkyl nitrates, which could contribute 20 - 30 ppt to ΣANs (less than 10% near the surface) during SEAC<sup>4</sup>RS (Fisher et al., 2016). Including small alkyl nitrates will increase modeled ΣANs a bit in ICARTT as well. Hydrolysis of ISOPNB also leads to a slight increase of HNO<sub>3</sub> (Table S4). The impact of hydrolysis of ISOPNB on boundary layer O<sub>3</sub> appears to be small. This is mainly because without hydrolysis, the dominant loss of ISOPNB is oxidation by OH, which then leads to the formation of secondary organic nitrates including MVKN, MACRN and DHDN. The majority of these organic nitrates (MVKN and DHDN) return NO<sub>x</sub> slowly due to their long lifetimes (Table S5), resulting in a similar effect on ozone production as hydrolysis of ISOPNB. In addition to the good agreement of ΣANs, our model shows good agreement with speciated RONO<sub>2</sub> measured during SENEX and SEAC<sup>4</sup>RS, including ISOPN and the sum of MVKN and MACRN (Figure 2). We find that the large discrepancy between ΣANs and speciated alkyl nitrates (Figure ~~S4S5~~) can be explained by a combination of monoterpene nitrates and DHDN and nighttime NO<sub>3</sub> oxidation products from isoprene, accounting for 20 - 24 %, 14 - 17 % and 23 - 29 % of ΣANs respectively in the boundary layer.

Given the good agreement between observed and modeled RON in both 2004 and 2013, we find that the ozone bias, shown in Figure 1, cannot be completely explained by an overestimate of anthropogenic NO<sub>x</sub> emissions. A recent GEOS-Chem study (Travis et al., 2016) shows that the ozone bias in their model can be largely reduced by scaling down anthropogenic NO<sub>x</sub> emissions. We find that a similar reduction of anthropogenic NO<sub>x</sub> emissions in 2013, from 0.25 Tg N mon<sup>-1</sup> to 0.15 Tg N mon<sup>-1</sup>, would lead to an underestimate of NO<sub>y</sub>, HNO<sub>3</sub> and PAN by 30 %, 33 % and 30 %, respectively. Such a reduction would be also inconsistent with the relative changes in EPA estimates of NO<sub>x</sub> emissions shown above. Indeed, other processes, such as ozone dry deposition, may also contribute to this bias and warrant further investigation.

## 4.2 NO<sub>3</sub><sup>-</sup> wet deposition flux and concentration

Figure 3 shows a comparison of NO<sub>3</sub><sup>-</sup> wet deposition flux between observations and model results during the summers of 2004 and 2013. The observed NO<sub>3</sub><sup>-</sup> wet deposition flux is calculated by multiplying the measured NO<sub>3</sub><sup>-</sup> concentration and precipitation at each monitoring

---

376 site as  $F_{o,i}=C_{o,i}P_{o,i}$ , where  $F_{o,i}$  is the monthly-mean  $\text{NO}_3^-$  wet deposition flux,  $C_{o,i}$  and  $P_{o,i}$  are the  
377 monthly-mean observed  $\text{NO}_3^-$  concentration precipitation at monitoring site  $i$ . The modeled  $\text{NO}_3^-$   
378 wet deposition flux includes  $\text{HNO}_3$  and all the alkyl nitrates. Observations indicate a 24 %  
379 reduction of  $\text{NO}_3^-$  wet deposition flux in summer from 2004 to 2013 over the Southeast U.S.,  
380 likely due to  $\text{NO}_x$  emission reductions. This reduction in monthly averaged  $\text{NO}_3^-$  wet deposition  
381 flux is well captured by our model (-29 %), despite a low relative bias of 40 % in both years and  
382 NMB of -39 – -43 % (Table S4).

383 Since errors in modeled precipitation could strongly affect the modeled  $\text{NO}_3^-$  wet deposition flux  
384 (Appel et al., 2011; Grimm and Lynch, 2005; Metcalfe et al., 2005; Paulot et al., 2014; Tost et al.,  
385 2007), we also evaluate the modeled  $\text{NO}_3^-$  concentration ( $C_{p,i}$ ), which is calculated by using the  
386 modeled  $\text{NO}_3^-$  wet deposition flux ( $F_{p,i}$ ) and observed precipitation ( $P_{o,i}$ ;  $C_{p,i}=F_{p,i}/P_{o,i}$ ), as a  
387 separate constraint. The model shows a similar declining trend from the observations with a  
388 relative bias of -23 % and -41 % on  $\text{NO}_3^-$  concentration for 2004 and 2013 respectively. Our  
389 results are consistent with the base case of Paulot et al. (2016), which showed that convective  
390 removal is likely insufficient in AM3, leading to underestimates of both  $\text{NO}_3^-$  wet deposition flux  
391 and concentrations. Our results are somewhat different from a recent GEOS-Chem study (Travis  
392 et al., 2016). They found that reducing anthropogenic  $\text{NO}_x$  emissions from NEI11v1 by 53 % can  
393 significantly improve the overestimate of 71 % on  $\text{NO}_3^-$  wet deposition flux in their model during  
394 August-September of 2013. A further reduction of anthropogenic  $\text{NO}_x$  emissions in our model  
395 (to  $0.15 \text{ Tg N mon}^{-1}$ ), as suggested by Travis et al. (2016), would lead to an even greater negative  
396 bias compared to observations.

### 397 **4.3 RONO<sub>2</sub> and related species**

398 We further evaluate RONO<sub>2</sub> and related species in this section, with a large focus on  
399 measurements from ICARTT and SEAC<sup>4</sup>RS. The major pathway for the production of daytime  
400 RONO<sub>2</sub> is the reaction of NO with RO<sub>2</sub> originating from VOC oxidation by OH:

401 where  $\alpha$  is the branching ratio for alkyl nitrate formation.  $\text{NO}_2$  subsequently undergoes  
402 photolysis to produce  $\text{O}_3$ :

---

403 For isoprene,  $\alpha$  is  $9 \pm 4$  % (for ISOPN) according to a recent study (Xiong et al., 2015). For  
404 monoterpenes, specifically  $\alpha$ -pinene,  $\alpha$  ranges from 1 % to 26 % (Rindelaub et al., 2015;  
405 Nozière et al., 1999; Aschmann et al., 2002). Here, we use 10 % for isoprene and 26 % for  
406 monoterpenes. As  $\text{RONO}_2$  and  $\text{O}_3$  are both produced from (R4), a correlation between them is  
407 expected. We show that the model can roughly reproduce the correlation of  $\text{O}_x$  ( $= \text{O}_3 + \text{NO}_2$ ) vs.  
408  $\Sigma\text{ANs}$  during both ICARTT and SEAC<sup>4</sup>RS (Figure 4), although the slope has a positive relative  
409 bias of about 21 % and 33 % respectively, largely due to an overestimate of  $\text{O}_3$  in the model. The  
410 good agreement between observed and modeled  $\text{O}_x$  vs. daytime  $\text{RONO}_2$  provides additional  
411 support for our treatment of the yields and fate of these daytime isoprene nitrates.

412 Another metric to evaluate  $\text{RONO}_2$  chemistry is the correlation between  $\Sigma\text{ANs}$  and HCHO, as  
413 the latter is a coproduct from (R4). We show in Figure 4 that the model can roughly capture the  
414 observed  $\Sigma\text{ANs}$ -HCHO slope, with an underestimate by 25 % and 13 % during ICARTT and  
415 SEAC<sup>4</sup>RS, respectively. The underestimate is in part due to small alkyl nitrates that are neglected  
416 in the model, as mentioned in section 4.1. During ICARTT, the slope estimated by AM3 is 0.12,  
417 similar to the value (0.15) from a previous GEOS-Chem study using a different isoprene  
418 oxidation mechanism that assumed a higher  $\alpha$  (of 4.7% from ISOPNB and 7.0% from ISOPND  
419 vs. 10 % of ISOPNB and zero ISOPND in AM3) and a lower yield of HCHO (66 % vs. 90 % in  
420 AM3) (Mao et al., 2013b). The reason for such similarity between the two models might be two-  
421 fold: (a) the additional contribution of monoterpene nitrates to  $\Sigma\text{ANs}$  in AM3 compensates for  
422 the decrease in  $\alpha$  from isoprene nitrates compared to GEOS-Chem and (b) the coarse grid  
423 resolution of GEOS-Chem simulation ( $2^\circ \times 2.5^\circ$ ) may lead to a higher estimate of HCHO  
424 compared to the result from a finer grid resolution (Yu et al., 2016).

425 Since HCHO can be produced from other pathways of isoprene hydroxyl peroxy radicals  
426 ( $\text{ISOPO}_2$ ) besides (R4) (such as isomerization of  $\text{ISOPO}_2$  and  $\text{ISOPO}_2 + \text{HO}_2$ ), changes in the  
427 slope of  $\Sigma\text{ANs}$  vs. HCHO may help to quantify decadal changes in isoprene oxidation pathways.  
428 We find in Figure 4 that the observed slope of  $\Sigma\text{ANs}$ -HCHO shows very little change from 2004  
429 to 2013. This is in part due to substantial HCHO production from isoprene oxidation under low  
430  $\text{NO}_x$  conditions (Li et al., 2016), and in part due to the buffering of  $\Sigma\text{ANs}$  in response to  
431 decreasing  $\text{NO}_x$ , as shown below in section 5.1. Our model is able to reproduce such behavior.  
432 We also find that the branching ratios for the reactions of  $\text{ISOPO}_2$  change marginally from 2004  
433 to 2013 over the Southeast U.S. (Figure S5S6). The fraction of  $\text{ISOPO}_2 + \text{NO}$  has decreased from  
434 81 % in 2004 to 66 % in 2013. The fraction of  $\text{ISOPO}_2 + \text{HO}_2$  has increased from 15 % to 28 %,  
435 and the fraction of  $\text{ISOPO}_2$  isomerization has increased from 4 % to 6 %. Our result is slightly  
436 different from the results of GEOS-Chem, which found a lower contribution from the NO  
437 pathway (54 %) and higher from isomerization (15 %) during August - September of 2013  
438 (Travis et al., 2016).

439 We also compare the correlation between major daytime isoprene nitrates and HCHO during  
440 2013, which provides a constraint on the yield of these nitrates. Our model shows a slight

---

441 overestimate on the slope (Figure 4 (b)), consistent with comparison of mean vertical profiles  
442 shown in Figure 2. The computed slope (5 %) in this study is different from that (2.5 %) of a  
443 recent GEOS-Chem simulation by Fisher et al. (2016). This is partially due to the different  
444 treatment of  $\beta$ - and  $\delta$ -ISOP<sub>2</sub> between GEOS-Chem and AM3. Another factor is that MVKN  
445 and MACRN are not allowed to hydrolyze in AM3, leading to higher abundance of these two  
446 nitrates.

447 Figure 5 shows the mean vertical profiles of modeled monoterpene nitrates (MNs) and isoprene  
448 nitrates (INs) during ICARTT and SEAC<sup>4</sup>RS. INs are the most abundant RONO<sub>2</sub>, accounting for  
449 76-80 % below 3 km over the Southeast U.S. In the measurements, ISOPN + MVKN + MACRN  
450 only contribute one third of the total INs (Figure S4S5). We show below that the discrepancy of  
451  $\Sigma$ ANs and speciated RONO<sub>2</sub> can be explained by other daytime and nighttime INs as well as  
452 MNs in the model. More than 60 % of modeled INs originate from isoprene oxidation during  
453 daytime. The first-generation nitrate ISOPN contributes slightly more (31 %) than the second-  
454 generation nitrates MVKN + MACRN (28 %) to the total daytime INs during ICARTT. This is  
455 different from Mao et al. (2013b) who showed a higher contribution of MVKN + MACRN than  
456 the first-generation INs, due to the different treatment of  $\beta$ - and  $\delta$ -ISOP<sub>2</sub>. We see more ISOPN  
457 (32 %) than MVKN + MACRN (26 %) from the daytime INs during SEAC<sup>4</sup>RS, consistent with  
458 Fisher et al. (2016). A large uncertainty in our model is attributed to DHDN, which contributes  
459 32 % to the daytime INs. Fisher et al. (2016) showed less DHDN during SEAC<sup>4</sup>RS since it was  
460 removed rapidly by hydrolysis (1-h lifetime) in their model. Our sensitivity test (hydro\_full,  
461 Figure S6S2) indicates that AM3 would significantly underestimate  $\Sigma$ ANs if we assume a  
462 similar heterogeneous loss of DHDN as ISOPN. In fact, DHDN was hypothesized originally in  
463 Lee et al. (2014) for the imbalance of nitrogen in their lab experiments, and may serve as a proxy  
464 for a large number of unidentified daytime INs. It remains unclear what the dominant loss of  
465 DHDN is. Daytime nitrates from monoterpene oxidation are another important source of  $\Sigma$ ANs  
466 in this region, accounting for 17 - 20 % (24 - 26 ppt) of the total. Fisher et al. (2016) estimate a  
467 smaller burden of MNs, of about 10 - 20 ppt due to a lower molar yield (18 % vs. 26 % in AM3)  
468 and faster hydrolysis of MNs in their model.

469 Nighttime chemistry contributes about 30 - 36 % of  $\Sigma$ ANs, which is dominated by isoprene  
470 oxidation as well (Figure 5). 33 - 41 % of the INs are produced during night, similar to the value  
471 (44 %) reported by Mao et al. (2013b) but with different speciation, due to the different treatment  
472 of chemistry. PROPNN contributes about 29-38 % of the total INs. PROPNN in this work is  
473 mainly produced from the oxidation of C5 nitrooxy hydroperoxide (INPN) and C5 carbonyl  
474 nitrate (ISN1; dominantly by photolysis) that are generated from isoprene oxidation by NO<sub>3</sub>  
475 during the nighttime. This is different from Fisher et al. (2016), who showed that PROPNN is  
476 partially from the  $\delta$ -ISOP<sub>2</sub> + NO pathway and partially from the oxidation of ISN1 by NO<sub>3</sub>. In  
477 our model, we see a rapid increase of PROPNN after sunrise in the boundary layer (Figure S7),  
478 consistent with observations at the Southern Oxidants and Aerosols Study (SOAS) ground site  
479 CTL (Schwantes et al., 2015). Our model overestimates the mean vertical profile of PROPNN by

---

480 a factor of 3 (not shown). As our model may largely underrepresent the chemical complexity of  
481 nighttime isoprene oxidation as shown by Schwantes et al. (2015), we consider PROPNN as a  
482 proxy for other unspecified isoprene nighttime nitrates. Over all, PROPNN contributes a  
483 significant fraction of  $\Sigma$ ANs in the model, 23 - 29 % in the boundary layer as shown in section  
484 4.1. With monoterpene nitrates and isoprene derived DHDN and nighttime  $\text{NO}_3$  oxidation  
485 products taken into account, we find that model can well reproduce both observed  $\Sigma$ ANs and  
486 speciated alkyl nitrates (Figure [S4S5](#)).

## 487 **5 Decadal Change of PBL RON and surface ozone over SEUS**

488 As RON and related species from aircraft and surface measurements are well reproduced in our  
489 model for both 2004 and 2013, we assume that the model is representative of this chemical  
490 environment, and then use the model to derive monthly mean changes between 2004 and 2013.  
491 We also investigate the impacts of further decreases in  $\text{NO}_x$  emissions by applying a hypothetical  
492 40 % reduction of anthropogenic  $\text{NO}_x$  emissions of 2013 but keeping other emissions and  
493 meteorology the same (“hypo” case in Table 2).

### 494 **5.1 RON**

495 We first examine the simulated decadal change of RON in the boundary layer over the Southeast  
496 U.S. as shown in Figure 6. In summer of 2004, the model suggests that  $\text{NO}_y$  is mainly comprised  
497 of  $\text{HNO}_3$  (45 %),  $\text{NO}_x$  (31 %),  $\Sigma$ PNs (14 %) and  $\Sigma$ ANs (9 %). In response to a 40 % reduction in  
498 anthropogenic  $\text{NO}_x$  emissions (35 % reduction in total  $\text{NO}_x$  emissions, Table 1) from 2004 to  
499 2013,  $\text{NO}_y$  declined by 34 %. This modeled response is comparable to long-term  $\text{NO}_y$   
500 measurements from the AQS surface network, which shows on average a 45 % decrease from  
501 2004 to 2013 over the Southeast U.S. Based on model estimates in Figure 6, most RON are  
502 reduced proportionally, with decreases of 38 % for  $\text{HNO}_3$ , 32 % for  $\text{NO}_x$  and 34% for  $\Sigma$ PNs. The  
503 different change in  $\Sigma$ PNs and PAN (the majority of  $\Sigma$ PNs) in Figure 1 might be due to the  
504 difference in sampling regions. The only exception is  $\Sigma$ ANs, with a smaller decline of 19 %. As  
505 an important source of organic aerosols (OA),  $\Sigma$ ANs may contribute to the decrease of OA over  
506 the Southeast U.S. in the past decade (Blanchard et al., 2016).

507 We conducted a sensitivity test with an additional 40 % reduction of anthropogenic  $\text{NO}_x$   
508 emissions from 2013. We find that  $\text{NO}_y$  decreases by 29 %, with a proportional decrease in  
509  $\text{HNO}_3$ ,  $\text{NO}_x$ , and  $\Sigma$ PNs (Figure 6). The slower decrease of  $\text{NO}_y$  is likely due to  $\Sigma$ ANs, which  
510 decrease at a slower rate and becomes a larger fraction of  $\text{NO}_y$ . The buffering of  $\Sigma$ ANs is  
511 consistent with previous studies (Browne and Cohen, 2012; Fisher et al., 2016), mainly due to  
512 lower OH resulting from decreased  $\text{NO}_x$  (Figure S8) and thus a prolonged lifetimes of  $\text{NO}_x$  and  
513  $\Sigma$ ANs (Browne and Cohen, 2012). As shown in Figure S8, averaged noontime OH decreases by  
514 11 % from 2004 to 2013 and by 29 % after we impose an additional 40 %  $\text{NO}_x$  emission  
515 reduction from 2013 levels.

---

516 The historical NO<sub>x</sub> emission reduction also affects reactive nitrogen export out of the boundary  
517 layer. Here we define exported nitrogen as the difference of the sources (chemical production  
518 and emissions) and sinks (chemical loss, wet and dry deposition). As shown in Table 3, total  
519 summertime NO<sub>y</sub> export from the Southeast U.S. boundary layer decreases proportionally, from  
520 24.1 Gg N in 2004 to 16.6 Gg N in 2013. The NO<sub>y</sub> export efficiency, calculated as net exported  
521 nitrogen divided by total NO<sub>x</sub> emissions, remains roughly the same (12 %) for 2004 and 2013,  
522 comparable to previous studies (Fang et al., 2010; Li et al., 2004; Parrish et al., 2004; Mao et al.,  
523 2013b; Sanderson et al., 2008; Hudman et al., 2007). Among all exported species,  
524 NO<sub>x</sub> contributes most of net export from the PBL (6 % of total NO<sub>x</sub> emissions), followed by  
525 PAN (4 %) and  $\Sigma$ ANs (2 %). We emphasize in Table 3 that a major fraction of NO<sub>x</sub> is exported  
526 through the top of the boundary layer (convection). From a budget calculation throughout the  
527 tropospheric column over the same region, we find that despite being the same NO<sub>y</sub> export  
528 efficiency (12 %), HNO<sub>3</sub> becomes the major exporter, accounting for half of NO<sub>y</sub> export  
529 efficiency from the total column (6 %). The contributions from PAN and  $\Sigma$ ANs are roughly the  
530 same as their export from the boundary layer (4 % and 2 %). This suggests that surface  
531 NO<sub>x</sub> ventilated through the boundary layer, converted to HNO<sub>3</sub> in the free troposphere and  
532 exported as HNO<sub>3</sub> is likely the major NO<sub>y</sub> export mechanism over the Southeast U.S. in our  
533 model, which is in agreement with previous observations (Parrish et al., 2004; Neuman et al.,  
534 2006). PAN and  $\Sigma$ ANs together account for another half of NO<sub>y</sub> export efficiency. As PAN  
535 and  $\Sigma$ ANs are of biogenic origin and longer lived than HNO<sub>3</sub>, they may play a key role in  
536 influencing RON and ozone in downwind regions (Moxim et al., 1996; Fischer et al., 2014).

## 537 **5.2 Surface ozone**

538 Since the mid-1990s, NO<sub>x</sub> emission controls have led to significant improvement on ozone air  
539 quality over the eastern U.S. (Simon et al., 2015; Cooper et al., 2012). As NO<sub>x</sub> emissions  
540 continue to decrease, ozone production efficiency (OPE) may increase due to the lower NO<sub>x</sub>  
541 removal rate by OH and to some extent may compensate the ozone reduction (Sillman, 2000).  
542 Meanwhile, surface ozone production may be further complicated by the increasing importance  
543 of RO<sub>2</sub> isomerization and RO<sub>2</sub> + HO<sub>2</sub>. Here we first evaluate our model against surface ozone  
544 observations in 2004 and 2013, and then project the future response of surface ozone to even  
545 lower NO<sub>x</sub> emissions to examine the efficacy of near-term NO<sub>x</sub> emission controls at lowering  
546 near-surface ozone levels.

547 We first examine the modeled surface ozone against observations at 157 EPA AQS monitoring  
548 sites over the Southeast U.S. in July-August of 2004 and 2013 (Figure S9). In general, AM3  
549 overestimates surface MDA8 ozone in both years by about 16 ppb on average, with the NMB of  
550 33 - 45 % and NME of 35 - 46 % respectively. This positive bias of summertime surface O<sub>3</sub> has  
551 been a common issue to a number of modeling studies of this region (Fiore et al., 2009; Canty et  
552 al., 2015; Brown-Steiner et al., 2015; Strode et al., 2015; Travis et al., 2016). This might be  
553 partially attributed to overestimated anthropogenic NO<sub>x</sub> emissions from non-power plant sectors,

---

554 excessive vertical mixing in the boundary layer (Travis et al., 2016) or underestimates of O<sub>3</sub> dry  
555 deposition (Hardacre et al., 2015; Val Martin et al., 2014). Further studies are warranted to  
556 investigate the cause of this bias in AM3.

557 Surface O<sub>3</sub> concentrations over the Southeast U.S. decline substantially from 2004 to 2013 in  
558 response to the large NO<sub>x</sub> emission reduction (Simon et al., 2015). MDA8 ozone averaged across  
559 all the monitoring sites is observed to decrease by 11 ppb (23 % of observed mean MDA8 ozone  
560 in July-August of 2004) resulting from approximately 40 % reductions of anthropogenic NO<sub>x</sub>  
561 emissions (35 % reduction in total NO<sub>x</sub> emissions). This strong sensitivity of surface ozone to  
562 NO<sub>x</sub> emission reflects the linear relationship between ozone production rate and NO<sub>x</sub>  
563 concentrations when NO<sub>x</sub> is low (Trainer et al., 2000). Our model is able to capture this strong  
564 NO<sub>x</sub> - O<sub>3</sub> sensitivity, with the mean MDA8 ozone reduced by 10 ppb from 2004 to 2013. We  
565 find that a further 40 % reduction of anthropogenic NO<sub>x</sub> emissions with identical meteorological  
566 conditions could lead to an additional 9 ppb decrease, a similar magnitude to the change from  
567 2004 to 2013.

568 We further investigate the impact of temperature and moisture on surface O<sub>3</sub> from 2004 to 2013.  
569 While several studies suggest that surface O<sub>3</sub> increases with ambient temperature (Jacob and  
570 Winner, 2009; Bloomer et al., 2010; Wu et al., 2008; Steiner et al., 2010), Cooper et al. (2012)  
571 showed that this temperature related impact is weak during the period of 1990-2010 across the  
572 U.S.A. Recent studies suggest that relative humidity (RH) or vapor pressure deficit (VPD) may  
573 play an important role in ozone variability through soil-atmosphere or biosphere-atmosphere  
574 coupling (Kavassalis and Murphy, 2017; Camalier et al., 2007; Tawfik and Steiner, 2013). Our  
575 model shows marginal differences in RH (less than 1 %) and temperature (+ 2.4 K) within the  
576 PBL over the Southeast U.S. between the summers of 2004 and 2013, consistent with observed  
577 changes of RH (+ 2.7 %) and temperature (+ 2.6 K) during ICARTT and SENEX. This small  
578 variation in the model is also consistent with climatology data (Hidy et al., 2014). Camalier et al.  
579 (2007) showed that RH has a much bigger impact on summertime ozone than temperature over  
580 the Southeast U.S., suggesting little influence of meteorology on ozone trend. Using the same  
581 model but with the standard AM3 chemical mechanism, Lin et al. (2017) found that meteorology  
582 changes would have caused high surface ozone over the eastern U.S. to increase by 0.2 - 0.4 ppb  
583 yr<sup>-1</sup> in the absence of emission controls from 1988 to 2014. Therefore, we conclude that the  
584 impact of climate variability and change on O<sub>3</sub> is relatively small compared to NO<sub>x</sub> emission  
585 reductions over the Southeast U.S., consistent with previous studies (Lam et al., 2011; Hidy et al.,  
586 2014; Lin et al., 2017; Rieder et al., 2015).

587 Decreasing NO<sub>x</sub> emissions also reduces the frequency of high O<sub>3</sub> pollution events. Figure 7  
588 shows the probability density function of observed and modeled MDA8 ozone at each  
589 monitoring site during July-August of 2004 and 2013, and the probability density function of  
590 modeled MDA8 ozone under a hypothetical scenario with another 40 % reduction in  
591 anthropogenic NO<sub>x</sub> emissions compared to 2013. We show that the lowest O<sub>3</sub>, about 20 ppb in  
592 current model simulations, remains invariant with NO<sub>x</sub> emission changes over the Southeast U.S.,

---

593 consistent with observations (Figure 7 (a)). Meanwhile, the high tail of MDA8 ozone events has  
594 shifted from more than 100 ppb in 2004 to about 85 ppb after the 40 % reduction of  
595 anthropogenic  $\text{NO}_x$  emissions from 2013. A similar shift is found in observations. The narrowing  
596 of the range of  $\text{O}_3$  with decreasing  $\text{NO}_x$  is consistent with the observed trends reported by Simon  
597 et al. (2015). We also find that further reductions of  $\text{NO}_x$  emissions will reduce both median  $\text{O}_3$   
598 values and the high tail, suggesting that fewer high ozone events will occur under continued  $\text{NO}_x$   
599 emission controls in the future.

## 600 **6 Conclusions and Discussions**

601 Near-surface ozone production over the Southeast U.S. is heavily influenced by both  
602 anthropogenic and biogenic emissions. We investigate the response of  $\text{NO}_y$  speciation to the  
603 significant  $\text{NO}_x$  emission controls (about 40 % reduction) in this region over the past decade, in  
604 light of the fast-evolving understanding of isoprene photooxidation. This knowledge is needed to  
605 predict nitrogen and ozone budgets in this region and elsewhere in the world with similar  
606 photochemical environments. Here we use extensive aircraft and ground observations, combined  
607 with a global chemistry-climate model (GFDL AM3), to examine decadal changes in  $\text{NO}_y$   
608 abundance and speciation as well as in surface  $\text{O}_3$  mixing ratios over the Southeast U.S. between  
609 the summers of 2004 and 2013. We then use the model to infer future  $\text{NO}_y$  speciation and surface  
610 ozone abundances in response to further  $\text{NO}_x$  emission controls in this region.

611 We first evaluate the model with aircraft and surface observations. When we apply the estimated  
612 40 % reductions in anthropogenic  $\text{NO}_x$  emissions from 2004 to 2013, our model reproduces the  
613 major features of vertical profiles of  $\text{NO}_x$ ,  $\text{HNO}_3$ , PAN,  $\Sigma\text{ANs}$  and  $\text{NO}_y$  observed during aircraft  
614 campaigns over the Southeast U.S. in the summers of 2004 and 2013. By including recent  
615 updates to isoprene oxidation, our model can largely reproduce the vertical profiles of  $\Sigma\text{ANs}$  and  
616 several speciated alkyl nitrates, as well as their correlations with  $\text{O}_x$  and HCHO, lending support  
617 to the model representation of isoprene oxidation. On the other hand, we show that a discrepancy  
618 between measured  $\Sigma\text{ANs}$  and speciated  $\text{RONO}_2$  can be explained by a combination of  
619 monoterpene nitrates, dinitrates and nighttime  $\text{NO}_3$  oxidation products from isoprene. We also  
620 show that modeled ozone appears to be insensitive to hydrolysis of ISOPNB, because its  
621 photooxidation, mainly by OH, also returns little  $\text{NO}_x$ .

622 Major RON decline proportionally as a result of  $\text{NO}_x$  emission reductions in the Southeast U.S.,  
623 except for a slower rate in  $\Sigma\text{ANs}$ . The slower decline of  $\Sigma\text{ANs}$  reflects the prolonged lifetime of  
624  $\text{NO}_x$  when it is decreasing. Our model suggests that summertime monthly averaged  $\text{NO}_x$ ,  $\text{HNO}_3$ ,  
625 PAN, and  $\text{NO}_y$  decline by 30 - 40 %, in response to 40 % reduction in anthropogenic  $\text{NO}_x$   
626 emissions from 2004 to 2013. This proportional decrease is likely driven by high concentrations  
627 of biogenic VOCs, the major precursor of PAN in this region that change little in magnitude  
628 from 2004 to 2013. In contrast, Pollack et al. (2013) find a faster PAN decrease than  $\text{HNO}_3$  in  
629 the LA basin over the past several decades, partly due to the decrease in anthropogenic VOC  
630 emissions that are major PAN precursors.

---

631 Deposited and exported  $\text{NO}_y$  decline with  $\text{NO}_x$  emission reductions. The model also shows a  
632 decrease of  $\text{NO}_3^-$  wet deposition flux by 29 % from 2004 to 2013, consistent with observations  
633 from the NADP network (- 24 %). We find from model calculations that the  $\text{NO}_y$  export  
634 efficiency remains at 12 % in both 2004 and 2013, leading to a proportional decrease of exported  
635  $\text{NO}_y$ . The dominant  $\text{NO}_y$  export terms include  $\text{NO}_x$  or  $\text{HNO}_3$ , each accounting for 6% of the total  
636 exported  $\text{NO}_y$ , followed by  $\Sigma\text{PNs}$  (4 %) and  $\Sigma\text{ANs}$  (2 %).

637 The response of surface ozone to  $\text{NO}_x$  emission reductions reveals a strong  $\text{NO}_x - \text{O}_3$  sensitivity  
638 in summertime over the Southeast U.S. Observations from EPA AQS surface network suggest  
639 that mean MDA8 ozone during July-August has decreased by 23%, from 48 ppb in 2004 to 37  
640 ppb in 2013. Despite a positive absolute bias of up to 12 ppb in boundary layer ozone and 16 ppb  
641 in surface MDA8 ozone, our model shows a 10 ppb decrease of surface MDA8 ozone from 2004  
642 to 2013, very close to the observed 11 ppb decrease from the EPA data. The bias of ozone in our  
643 model is not entirely attributed to uncertainties in  $\text{NO}_x$  emissions, as the overestimate suggested  
644 by earlier work would lead to an underestimate of  $\text{NO}_y$  (Travis et al., 2016). Care should be  
645 exercised in applying the modeling results for surface ozone regulation purposes, given the high  
646 ozone bias shown in our model. We find from model calculations that modeled MDA8  $\text{O}_3$  will  
647 continue to decrease by another 9 ppb assuming anthropogenic  $\text{NO}_x$  emissions are reduced by  
648 40 % from 2013 levels with meteorology and other emissions kept the same. In addition, further  
649  $\text{NO}_x$  emission reduction leads to less frequent high ozone events. This continued strong  
650 sensitivity of surface  $\text{O}_3$  to  $\text{NO}_x$  emissions can guide the development of effective emission  
651 control strategies for improving future air quality.

1133

1134 **Figure 1.** Mean vertical profiles of ozone and reactive oxidized nitrogen from observations  
 1135 during ICARTT (top row) and SENEX (bottom row) over SEUS (25 - 40° N, 100 - 75° W)  
 1136 during daytime, and model estimates from AM3 with hydrolysis of ISOPNB (red) and AM3  
 1137 without hydrolysis of alkyl nitrates (green). The solid and dashed black lines in the HNO<sub>3</sub> of  
 1138 ICARTT represent measurements collected using mist chamber/IC by University of New  
 1139 Hampshire (UNH) and Chemical Ionization Mass Spectrometer by California Institute of  
 1140 Technology (CIT), respectively. NO<sub>y</sub> from ICARTT is calculated as the sum of NO<sub>x</sub>, HNO<sub>3</sub> (w/  
 1141 UNH in the solid line and w/ CIT in the dashed line), PAN and total alkyl nitrates (ΣANs).  
 1142 ΣANs in the bottom row are from SEAC<sup>4</sup>RS.

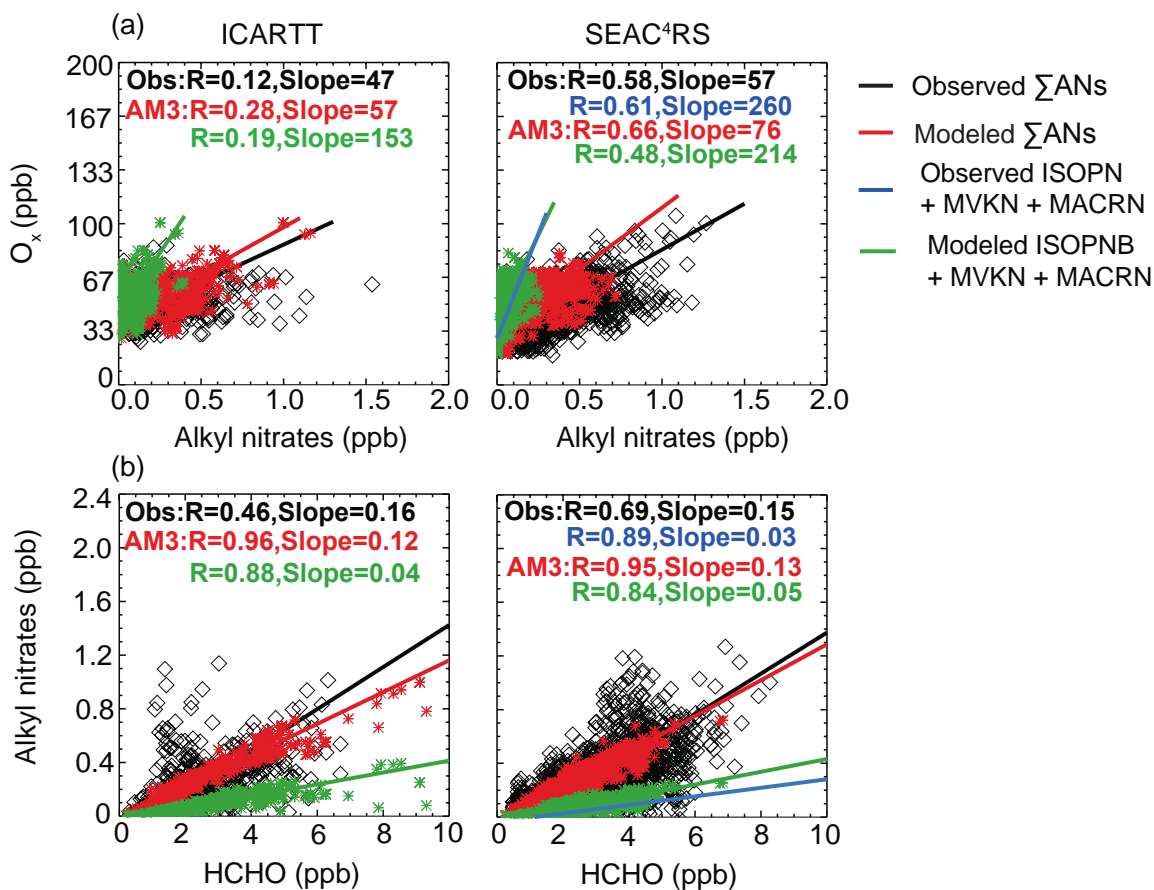

1143

1144 **Figure 2.** Mean vertical profiles of ISOPN and MVKN+MACRN during (a) SENEX and (b)  
 1145 SEAC<sup>4</sup>RS over SEUS (25 - 40° N, 100 - 75° W). Black lines are the mean of observations. Red  
 1146 and green lines are the mean of modeled results with hydrolysis of ISOPNB and without  
 1147 hydrolysis of alkyl nitrates respectively. Grey shades are the one standard deviation ( $\pm\sigma$ ) of  
 1148 averaged profiles of the measured tracers.

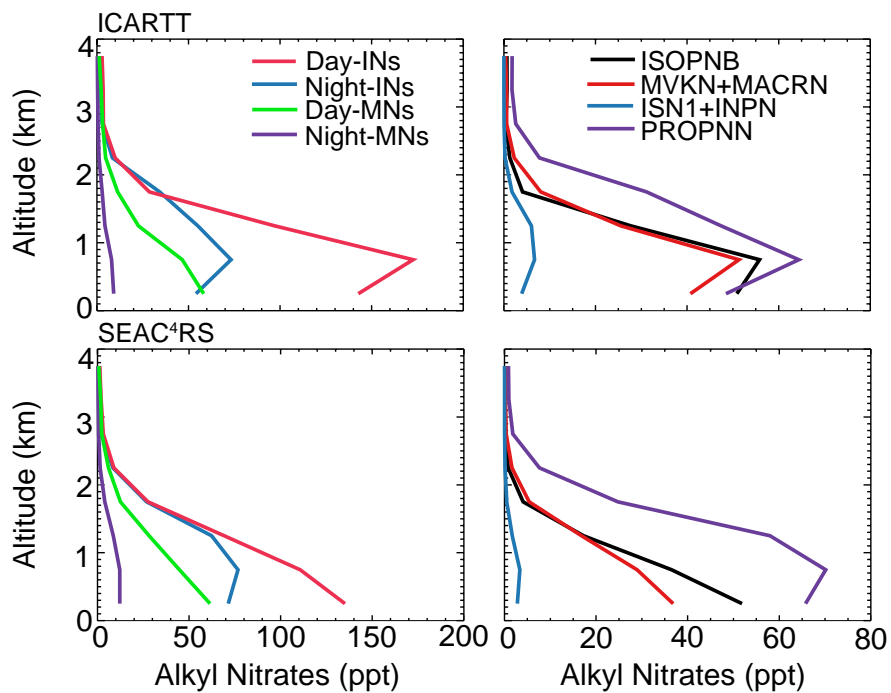

1149

1150 **Figure 3.** Nitrate wet deposition flux ( $\text{kg N ha}^{-1} \text{mon}^{-1}$ ) from NADP (circles) and AM3  
 1151 (background) during July - August of 2004 and 2013.

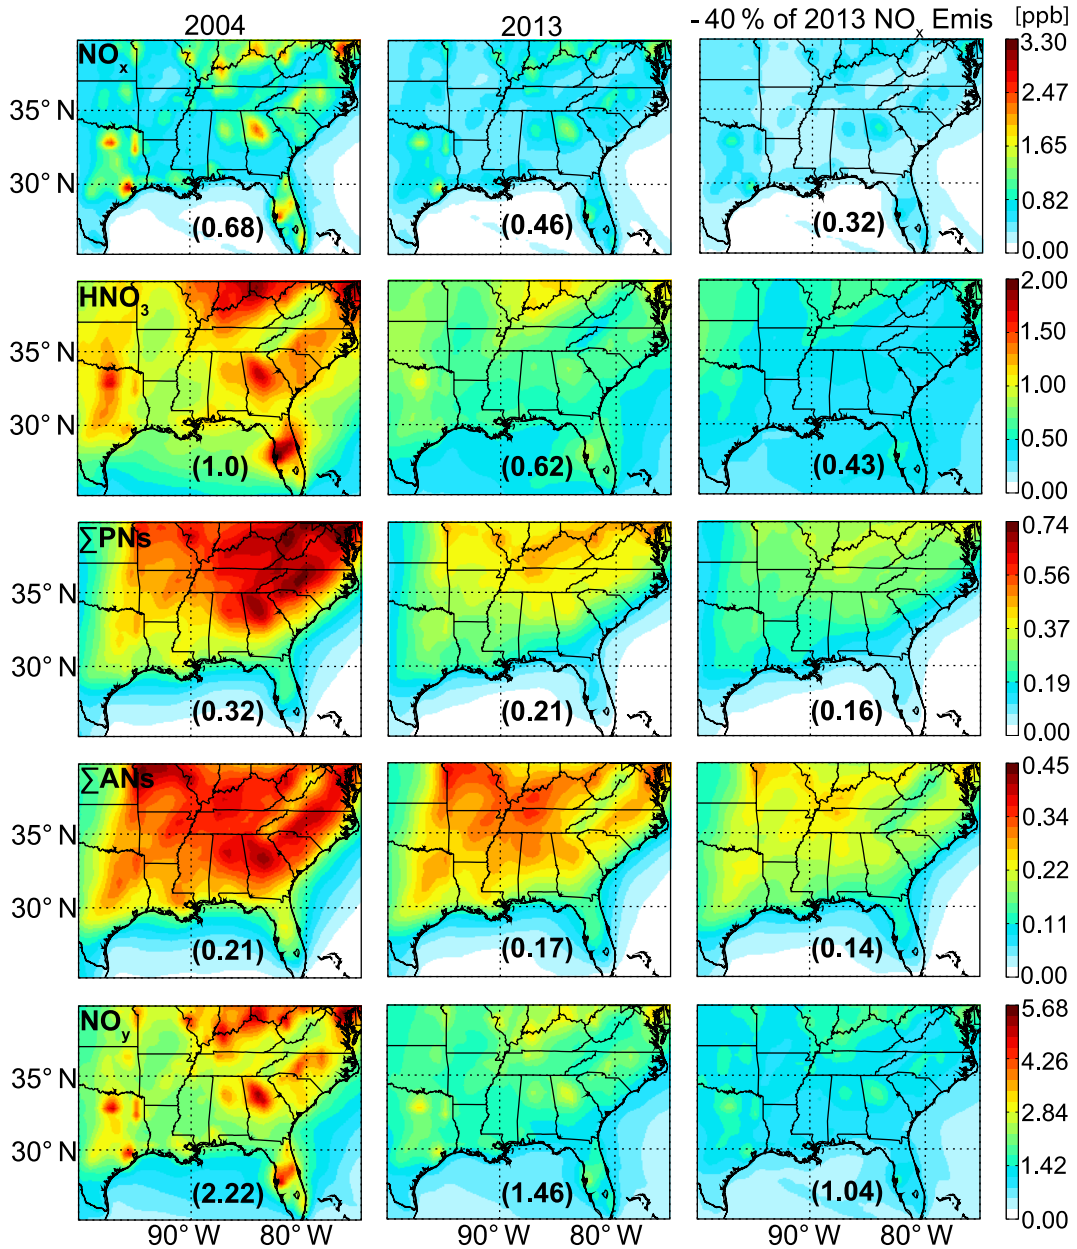

1152

1153 **Figure 4.**  $O_x$  versus  $\Sigma$ ANs correlation (top; (a)) and  $\Sigma$ ANs versus formaldehyde correlation  
 1154 (bottom; (b)) within the boundary layer (< 1.5 km) during ICARTT (left) and SEAC<sup>4</sup>RS (right).  
 1155 Observations are in black diamonds; model estimates from AM3 with ISOPNB hydrolysis are in  
 1156 red symbols. Green symbols represent the correlation using modeled ISOPN + MVKN +  
 1157 MACRN. Blue symbols represent the correlation using observed ISOPN + MVKN + MACRN  
 1158 from SEAC<sup>4</sup>RS. Solid lines are the reduced major axis regression lines.

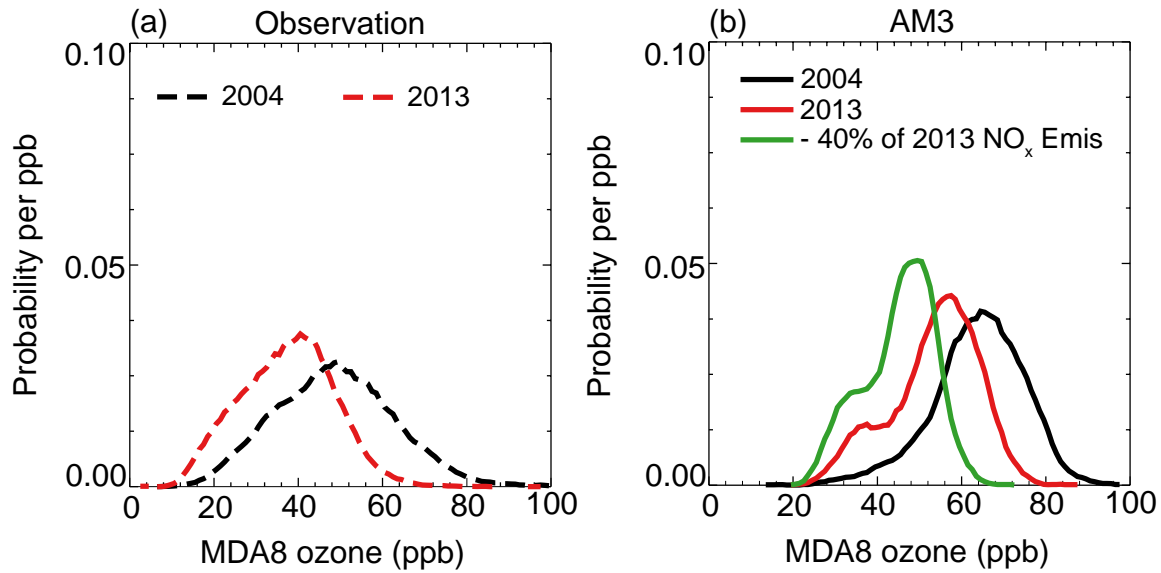

1159

1160 **Figure 5.** Mean vertical profiles of modeled alkyl nitrates from isoprene and monoterpene  
 1161 oxidation (left) and major isoprene nitrate species (right) during ICARTT (top row) and  
 1162 SEAC<sup>4</sup>RS (bottom row) from AM3 with hydrolysis of ISOPNB.

1163

1164 **Figure 6.** Modeled mean NO<sub>x</sub>, HNO<sub>3</sub>, total peroxy nitrates (ΣPNs), total alkyl nitrates (ΣANs)  
 1165 and NO<sub>y</sub> averaged over the boundary layer (< 1.5 km) of the Southeast U.S. during July - August  
 1166 of 2004 (left), 2013 (middle), and a scenario assuming 40 % reduction of 2013 anthropogenic  
 1167 NO<sub>x</sub> emissions (right). Numbers in parentheses indicate mean concentrations over the plotted  
 1168 region. Note different color scales represent the concentration of each species.

1169  
 1170 **7.** Observed (a) and simulated (b) probability density function of MDA8 ozone at AQS  
 1171 monitoring sites in Figure S3 during summer of 2004, 2013, and a scenario with 40 % reduction  
 1172 in the anthropogenic NO<sub>x</sub> emissions of 2013. **Figure**

1173

1174 **Table 1.** Monthly averaged NO<sub>x</sub> emissions in July-August of 2004 and 2013 over North America  
 1175 (25-50° N, 130-70° W) and over the Southeast US (25-40° N, 100-75° W) in brackets in AM3.

Source Type	2004 (Tg N)	2013 (Tg N)
Anthropogenic	0.42 (0.19)	0.25 (0.11)
Biomass Burning	$8.4 \times 10^{-3}$ ( $2.8 \times 10^{-3}$ )	$8.4 \times 10^{-3}$ ( $2.8 \times 10^{-3}$ )
Soils	$2.9 \times 10^{-2}$ ( $9.5 \times 10^{-3}$ )	$2.9 \times 10^{-2}$ ( $9.5 \times 10^{-3}$ )
Aircraft	$8.8 \times 10^{-3}$ ( $2.9 \times 10^{-3}$ )	$8.0 \times 10^{-3}$ ( $2.8 \times 10^{-3}$ )
Lightning	0.02 (0.01)	0.02 (0.01)
Total	0.49 (0.22)	0.32 (0.14)

1176

1177 **Table 2.** Case descriptions

Case name	Heterogeneous Loss of organic nitrates	NO <sub>x</sub> emissions	Meteorology
base	ISOPNB with a $\gamma$ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
no_hydro	—	2004 and 2013	2004 and 2013
hydro_full	ISOPNB and DHDN with a $\gamma$ of 0.005 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$ ; TERPN1 with a $\gamma$ of 0.01 and followed by a hydrolysis rate of $9.26 \times 10^{-5} \text{ s}^{-1}$	2004 and 2013	2004 and 2013
hypo	Same with the base case	40 % reduction of NO <sub>x</sub> emissions of 2013	2013

1178 **Table 3.** Monthly NO<sub>y</sub> budget in the boundary layer (< 1.5 km) of the Southeast United States for July-August of 2004, 2013 and a  
 1179 scenario with 40 % reduction of anthropogenic NO<sub>x</sub> emissions of 2013<sup>a</sup>.

Species	2004					2013					- 40 % of 2013 Anthropogenic NO <sub>x</sub> Emis				
	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export
<b>NO<sub>x</sub></b>	208.7	-172.4	21.8	–	14.5	132.6	-105	14.2	–	13.4	88.3	-69.6	9.2	–	9.5
<b>ΣPNs<sup>b</sup></b>		15.2	5.7	–	9.5		10.3	3.9	–	6.4		7.7	3.0	–	4.7

day <sup>c</sup>		13.8	8.7	3.6	1.5		12.0	7.5	3.0	1.6		10.2	6.3	2.6	1.3
night <sup>d</sup>		10.5	5.6	2.6	2.4		7.4	4.0	1.7	1.7		5.3	2.8	1.3	1.1
<b>HNO<sub>3</sub></b>		131.7	77.8	57.6	-3.7		74.2	45.6	35.1	-6.5		45.8	29.2	25.6	-9.0
<b>NO<sub>y</sub></b>					24.1					16.6					7.6

1180 <sup>a</sup>We define the boundary of Southeast US is 25-40° N, 100-75° W. All budget terms are in Gg N.

1181 <sup>b</sup>ΣPNs includes PAN, peroxyacetyl nitrate (MPAN), and a C5 hydroxy peroxyacyl nitrate (C5PAN1) produced by oxidation of  
 1182 ISN1.

1183 <sup>c</sup>Alkyl nitrates produced from oxidation of isoprene and monoterpenes by OH.

1184 <sup>d</sup>Alkyl nitrates produced from oxidation of isoprene and monoterpenes by NO<sub>3</sub>.

1185
