## 47 **Abstract**

48 Widespread efforts to abate ozone (O<sub>3</sub>) smog have significantly reduced nitrogen oxides  
49 (NO<sub>x</sub>) emissions over the past two decades in the Southeast U.S. (SEUS), a place heavily  
50 influenced by both anthropogenic and biogenic emissions. How reactive nitrogen  
51 speciation responds to the reduction in NO<sub>x</sub> emissions in this region remains to be  
52 elucidated. Here we exploit aircraft measurements from ICARTT (July-August, 2004),  
53 SENEX (June-July, 2013), and SEAC<sup>4</sup>RS (August-September, 2013) and long-term  
54 ground measurement networks alongside a global chemistry-climate model to examine  
55 decadal changes in summertime reactive nitrogen species and ozone over the Southeast  
56 U.S. We find that most reactive nitrogen species, including NO<sub>x</sub>, peroxyacetyl nitrate  
57 (PAN) and nitric acid (HNO<sub>3</sub>) decline proportionally with decreasing NO<sub>x</sub> emissions in  
58 this region, leading to a similar decline in exported NO<sub>y</sub>. This linear response is in part  
59 due to the nearly constant summertime supply of biogenic VOC emissions in this region.  
60 Our model captures the observed relative change of reactive nitrogen species and surface  
61 ozone from 2004 to 2013. Model sensitivity tests indicate that further reductions of NO<sub>x</sub>  
62 emissions will lead to a continued decline in surface ozone and less frequent extreme  
63 ozone events.

## 64 **1 Introduction**

65 Since the 1990s, the U.S.A. Environmental Protection Agency (U.S. EPA) has targeted  
66 emissions of nitrogen oxides (NO<sub>x</sub>) to improve air quality by lowering regional  
67 photochemical smog (The 1990 Clean Air Amendment). Satellite- and ground-based  
68 observations imply significant declines in U.S. NO<sub>x</sub> emissions, with a decreasing rate of  
69 roughly - 4 % yr<sup>-1</sup> after 2005 (Krotkov et al., 2016; Russell et al., 2012; Tong et al., 2015;  
70 Miyazaki et al., 2017; Lu et al., 2015; Lamsal et al., 2015). This has proven effective at  
71 lowering near-surface ozone (O<sub>3</sub>) in the past few decades (Cooper et al., 2012; Simon et  
72 al., 2015; Hidy and Blanchard, 2015; Stoeckenius et al., 2015; Xing et al., 2015; Yahya et  
73 al., 2016). According to U.S. EPA data, the average of the annual 4<sup>th</sup> highest maximum  
74 daily averaged maximum 8-hr (MDA8) ozone over 212 sites has decreased by 33 % from  
75 101 ppb in 1980 to 68 ppb in 2014 across the continental U.S., with more significant  
76 reductions in rural areas in summer (Simon et al., 2015; Cooper et al., 2012). Here we  
77 combine aircraft and ground-based datasets for both ozone and reactive nitrogen to  
78 evaluate a chemistry-climate model used to project future responses to changes in NO<sub>x</sub>  
79 emissions.

80 In the troposphere, ozone is produced through photochemical reactions involving NO<sub>x</sub>  
81 and volatile organic compounds (VOCs) in the presence of sunlight. During  
82 photooxidation, a large fraction of NO<sub>x</sub> is transformed into its reservoirs, including nitric  
83 acid (HNO<sub>3</sub>), peroxy nitrates (RO<sub>2</sub>NO<sub>2</sub>, dominated by peroxyacetyl nitrate (PAN)), and  
84 alkyl nitrates (RONO<sub>2</sub>). These species, together with NO<sub>x</sub>, are known as total reactive

85 nitrogen ( $\text{NO}_y = \text{NO}_x + \text{HNO}_3 + \text{HONO} + 2 \times \text{N}_2\text{O}_5 + \text{total peroxy nitrates } (\Sigma\text{PNs}) + \text{total}$   
86  $\text{alkyl nitrates } (\Sigma\text{ANs})$ ). Some of these reservoir species, particularly those with an  
87 organic component, tend to be less soluble and longer lived. They may carry reactive  
88 nitrogen far from the  $\text{NO}_x$  source region (Stohl et al., 2002; Parrish et al., 2004; Li et al.,  
89 2004) and thereby affect  $\text{NO}_x$  concentrations and  $\text{O}_3$  formation on a regional to global  
90 scale (Liang et al., 1998; Horowitz et al., 1998; Perring et al., 2013; Paulot et al., 2016;  
91 Hudman et al., 2004).

92  $\text{RONO}_2$  originating from biogenic VOCs (BVOCs) represents a major uncertainty in the  
93  $\text{NO}_y$  budget, as BVOC emissions account for more than 80 % of global VOC emissions  
94 (Millet et al., 2008). To a large extent, this is due to the uncertainties in current  
95 understanding of BVOC oxidation chemistry. Biogenic  $\text{RONO}_2$  species are mainly  
96 produced from the oxidation of BVOCs by OH in the presence of  $\text{NO}_x$  during daytime  
97 and by nitrate radical ( $\text{NO}_3$ ) during nighttime. Laboratory and field studies show a wide  
98 range of  $\text{RONO}_2$  yields from their BVOC precursors (Browne et al., 2014; Fry et al.,  
99 2014; Lockwood et al., 2010; Paulot et al., 2009; Rindelaub et al., 2015; Rollins et al.,  
100 2009; Lee et al., 2014; Xiong et al., 2015; Xiong et al., 2016; Teng et al., 2015). Another  
101 uncertainty lies in the fate of  $\text{RONO}_2$ , i.e. recycling  $\text{RONO}_2$  into  $\text{NO}_x$  versus converting it  
102 to  $\text{HNO}_3$  as a  $\text{NO}_x$  sink have important implications for the  $\text{NO}_y$  budget and thus  $\text{O}_3$   
103 production (Fiore et al., 2005; Horowitz et al., 2007; Ito et al., 2009; Perring et al., 2013;  
104 Paulot et al., 2012). In addition, recent field studies have shown that  $\text{RONO}_2$  is a  
105 potential source of secondary organic aerosol (SOA) over the Southeast U.S. (Xu et al.,  
106 2015; Lee et al., 2016). The fate of particle-phase  $\text{RONO}_2$  is unclear, with the possibility  
107 for removal by hydrolysis to form  $\text{HNO}_3$  (Jacobs et al., 2014; Hu et al., 2011; Darer et al.,  
108 2011; Rindelaub et al., 2015; Szmigielski et al., 2010; Sato, 2008; Romer et al., 2016;  
109 Wolfe et al., 2015), photochemical aging (Nah et al., 2016; Boyd et al., 2015), and  
110 deposition (Nguyen et al., 2015).

111 Over the Southeast U.S., photochemistry in summer is strongly influenced by both  
112 biogenic and anthropogenic emissions, implying strong sensitivity of  $\text{O}_3$  production to  
113 changes in anthropogenic  $\text{NO}_x$  emissions (Simon et al., 2015). Aircraft campaigns during  
114 the summers of 2004 and 2013 (i.e. the International Consortium for Atmospheric  
115 Research on Transport and Transformation (ICARTT) (Fehsenfeld et al., 2006; Singh et  
116 al., 2006), the Southeast Nexus (SENEX) (Warneke et al., 2016), and Studies of  
117 Emissions, Atmospheric Composition, Clouds and Climate Coupling by Regional  
118 Surveys (SEAC<sup>4</sup>RS) (Toon et al., 2016)) provide detailed characterization of tropospheric  
119 composition in this region separated by nearly a decade. Together with the wet deposition  
120 flux of nitrate ( $\text{NO}_3^-$ ) from the National Atmospheric Deposition Program (NADP) and  
121  $\text{NO}_y$  and  $\text{O}_3$  measurements from EPA Air Quality System (AQS) surface network, these  
122 aircraft datasets provide insights into changes in  $\text{O}_3$  pollution and  $\text{NO}_y$  speciation over a

123 decadal period when NO<sub>x</sub> emissions were declining rapidly as pollution control programs  
124 were implemented.

125 Here we use a high-resolution global 3D climate-chemistry model, the Geophysical Fluid  
126 Dynamics Laboratory (GFDL) AM3 model, with updated isoprene and organic nitrate  
127 chemistry to investigate decadal changes of NO<sub>y</sub> (and its specific constituents) and  
128 surface O<sub>3</sub> during summer between 2004 and 2013 over the Southeast U.S. We first  
129 evaluate the model with comprehensive measurements from three aircraft campaigns in  
130 the summer of 2004 (ICARTT) and 2013 (SETEX and SEAC<sup>4</sup>RS). The model estimates  
131 of nitrate wet deposition flux are also evaluated against measurements from the NADP;  
132 model estimates for NO<sub>y</sub> are compared against measurements from EPA AQS to provide  
133 an additional constraint on the fate of NO<sub>y</sub> species in the model. We then investigate the  
134 repartitioning of NO<sub>y</sub> species in response to NO<sub>x</sub> emission reductions from 2004 to 2013.  
135 From there, we examine the model estimate of decadal changes of summertime surface  
136 O<sub>3</sub> at 157 monitoring sites over the Southeast U.S. by comparing to the measurements  
137 from EPA AQS. Last, we demonstrate the sensitivity of MDA8 O<sub>3</sub> and NO<sub>y</sub> speciation to  
138 projected NO<sub>x</sub> emission decreases over the next decade (to 2022).

## 139 **2 Methodology**

### 140 **2.1 AM3 Model**

141 We apply a high-resolution (50 x 50 km<sup>2</sup>) version of the GFDL AM3 model to study  
142 decadal changes of O<sub>3</sub> and organic nitrates over the Southeast U.S. The model  
143 configuration is to a large extent similar to that used in a companion paper (Li et al.,  
144 2016); and a short summary is provided below. The dynamical core, physical  
145 parameterizations, cloud and precipitation processes, and cloud-aerosol interactions  
146 mainly follow Donner et al. (2011), except that convective plumes are computed on a  
147 vertical grid with finer resolution (Paulot et al., 2016). Dry deposition in the model has  
148 been updated to use dry deposition velocities calculated in the GEOS-Chem model  
149 (Paulot et al., 2016), to reflect rapid deposition of organic nitrates and oxidized volatile  
150 organic compounds (OVOCs) (Nguyen et al., 2015).

151 Isoprene emissions are computed in the model using the Model of Emissions of Gases  
152 and Aerosols from Nature (MEGAN). In July-August of 2004, the computed isoprene  
153 emissions over the continental U.S. (25-50° N, 130-70° W) are 8.0 Tg C and appear to be  
154 consistent with a previous model estimate of 7.5 Tg C by Mao et al. (2013) in the same  
155 region during this period. For 2013, we applied a 20 % reduction of MEGAN for  
156 isoprene emissions as described in Li et al. (2016). The resulting isoprene emission is 7.7  
157 Tg C in July-August over this region. Monoterpene emissions follow Naik et al. (2013)  
158 and do not vary interannually, with a total of 4.0 Tg C in July and August.

159 Anthropogenic emissions follow the Representative Concentration Pathway 8.5 (RCP 8.5)  
160 projection (Lamarque et al., 2011) for both 2004 and 2013, to compare the model to  
161 observations in a consistent fashion. As shown in Table 1, anthropogenic NO<sub>x</sub> emissions  
162 over the continental U.S. during July-August of 2004 amount to 0.42 Tg N mon<sup>-1</sup>,  
163 consistent with Hudman et al. (2007) but 11 % lower than EPA estimates of 0.47 Tg N  
164 mon<sup>-1</sup> (Granier et al., 2011). For the year of 2013, we apply a 25 % reduction to the  
165 anthropogenic NO<sub>x</sub> emissions from the RCP 8.5 projection (from base year 2010), to best  
166 reproduce the vertical profiles of NO<sub>y</sub> species during SENEX as shown below. This  
167 adjustment is also consistent with recent estimates of NO<sub>x</sub> emissions over the Southeast  
168 U.S. (Anderson et al., 2014). The resulting anthropogenic NO<sub>x</sub> emissions (0.25 Tg N  
169 mon<sup>-1</sup>) are 14 % lower than NEI11v1 emission inventory estimate (0.29 Tg N mon<sup>-1</sup>),  
170 although both inventories have a similar spatial distribution (Figure S1). Soil NO<sub>x</sub>  
171 emissions in our model, 3.6 Tg N yr<sup>-1</sup> globally (Naik et al., 2013), are considerably lower  
172 than other model estimates, including 5.5 Tg N yr<sup>-1</sup> in Yienger and Levy (1995) and 9.0  
173 Tg N yr<sup>-1</sup> in Hudman et al. (2012). Lightning NO<sub>x</sub>, calculated as a function of  
174 parameterized convection in the model following Price et al. (1997), is also lower than  
175 that of Hudman et al. (2007) by a factor of 8 over the U.S. As a result, the total NO<sub>x</sub>  
176 emissions over the continental U.S. are 0.98 Tg N for July-August of 2004, and 0.64 Tg  
177 N in July-August of 2013 (Table 1). The 40 % reduction of anthropogenic NO<sub>x</sub> emissions  
178 from 2004 to 2013 over the eastern U.S is consistent with EPA Air Pollutant Emissions  
179 Trends Data (<https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data>) and satellite observations (Krotkov et al., 2016; Lu et al., 2015).

## 181 2.2 Gas-phase chemistry

182 We apply the same isoprene mechanism as described by Li et al. (2016). A full list of the  
183 reactions can be found in Table S1. This mechanism is based on Mao et al. (2013), but  
184 has been significantly revised to incorporate recent laboratory updates on isoprene  
185 oxidation by OH and O<sub>3</sub> (Schwantes et al., 2015; Bates et al., 2016; Peeters et al., 2014;  
186 St. Clair et al., 2016; Bates et al., 2014; Praske et al., 2015; Müller et al., 2014; Lee et al.,  
187 2014; Crouse et al., 2011). One major feature is the suppression of  $\delta$ -isoprene hydroxyl  
188 peroxy radical ( $\delta$ -ISOPO<sub>2</sub>) and subsequent reaction pathways in the model, as these  
189 channels are considered to be of minor importance under ambient conditions (Peeters et  
190 al., 2014; Bates et al., 2014). The fraction of ISOPO<sub>2</sub> undergoing isomerization is  
191 calculated using bulk isomerization estimates (Crouse et al., 2011). As a result, the first-  
192 generation isoprene alkyl nitrate is assumed to be  $\beta$ -hydroxy nitrate (ISOPNB) in the  
193 model with a yield of 10 % from the ISOPO<sub>2</sub> + NO pathway. This differs from a recent  
194 GEOS-Chem study of organic nitrates over the Southeast U.S. that assumed 9 % yield of  
195 the first-generation isoprene alkyl nitrate comprised of 90 % ISOPNB and 10 %  $\delta$ -  
196 hydroxy nitrate (ISOPND) (Fisher et al., 2016). The treatment of  $\beta$ - and  $\delta$ -ISOPO<sub>2</sub> will  
197 not only affect the speciation of organic nitrates but also the production of O<sub>3</sub> due to

198 different NO<sub>x</sub> recycling efficiency in their secondary products. We also include updated  
199 chemistry for methylvinyl ketone (MVK) (Praske et al., 2015), an updated yield of  
200 hydroxy hydroperoxides (ISOPOOH) (Bates et al., 2016; St. Clair et al., 2016), fast  
201 photolysis of carbonyl organic nitrates (Müller et al., 2014), and an updated ozonolysis  
202 rate of ISOPNB (Lee et al., 2014). In addition, we reduce the yield of organic nitrates  
203 (MACRN) from methacrolein (MACR) oxidation from 15 % to 3 %, which is estimated  
204 from the measured yield of nitrate from MVK oxidation (Praske et al., 2015).

205 Another major model revision involves the treatment of the nighttime oxidation of  
206 isoprene. Instead of following Mao et al. (2013), we revised the nighttime oxidation of  
207 isoprene largely based on the Leeds Master Chemical Mechanism v3.2 (MCM v3.2),  
208 allowing a more complete description of isoprene oxidation by NO<sub>3</sub>. In particular, MCM  
209 v3.2 suggests significant production of propanone nitrate (PROPNN) from the  
210 photooxidation of the C<sub>5</sub> carbonyl nitrate, consistent with recent laboratory experiments  
211 (Schwantes et al., 2015). We also updated the products of the reaction of nitrooxy  
212 alkylperoxy radical (INO<sub>2</sub>), the peroxy radical from isoprene oxidation by NO<sub>3</sub>, with HO<sub>2</sub>  
213 to reflect a lower molar yield (0.77) of C<sub>5</sub> nitrooxy hydroperoxide (INPN) (Schwantes et  
214 al., 2015). The differences between MCM v3.2 and the most updated version, MCM  
215 v3.3.1, in isoprene nighttime chemistry appears to be small (Jenkin et al., 2015). We  
216 therefore use MCM v3.2 as the reference in this work.

217 We include a highly simplified chemistry for the oxidation of monoterpenes in this work,  
218 mainly to quantify their contribution to organic nitrates. Monoterpenes are lumped into  
219 one chemical species (C<sub>10</sub>H<sub>16</sub>) in our model. The organic nitrate yield is set to 26 % from  
220 OH-initiated oxidation (Rindelaub et al., 2015) and to 10 % from NO<sub>3</sub>-initiated oxidation  
221 (Browne et al., 2014). Details of the monoterpene chemistry can be found in Table S2.

### 222 **2.3 Heterogeneous loss of organic nitrates**

223 Field and laboratory studies have indicated a potential contribution to aerosol formation  
224 of organic nitrates from BVOC oxidation (Ayres et al., 2015; Fry et al., 2014; Nah et al.,  
225 2016; Rollins et al., 2009; Rindelaub et al., 2015; Boyd et al., 2015; Lee et al., 2016; Ng  
226 et al., 2008; Fry et al., 2009; Xu et al., 2015; Lee et al., 2014; Bean and Hildebrandt Ruiz,  
227 2016; Spittler et al., 2006). Aerosol yield depends on both the VOC precursor and the  
228 oxidant. For example, Δ-3-carene oxidation by NO<sub>3</sub> can produce a 38-65 % yield of  
229 organic aerosols in a smog chamber (Fry et al., 2014), which is much higher than the 1-  
230 24 % yield from NO<sub>3</sub>-initiated isoprene oxidation (Ng et al., 2008; Rollins et al., 2009;  
231 Ayres et al., 2015). Recent chamber studies indicate a very low aerosol yield from α-  
232 pinene oxidation by NO<sub>3</sub> (Nah et al., 2016; Fry et al., 2014), the aerosol yield increases to  
233 ~ 18 % when α-pinene is oxidized by OH (Rollins et al., 2010; Rindelaub et al., 2015). It  
234 should be noted that these results from laboratory experiments might not be

235 representative to atmospheric conditions in terms of the RO<sub>2</sub> reaction partner or RO<sub>2</sub>  
236 lifetime.

237 In the condensed phase, organic nitrates can undergo hydrolysis reactions to produce  
238 HNO<sub>3</sub> (Darer et al., 2011; Hu et al., 2011; Rindelaub et al., 2015; Boyd et al., 2015;  
239 Szmigielski et al., 2010; Sato, 2008; Jacobs et al., 2014; Bean and Hildebrandt Ruiz,  
240 2016). However, the hydrolysis rate varies greatly with the structure of nitrate, and for  
241 most species remains highly uncertain, though certain trends have been elucidated, e.g.  
242 tertiary nitrates favor hydrolysis while primary and secondary nitrates are more stable  
243 (Bean and Hildebrandt Ruiz, 2016; Darer et al., 2011; Hu et al., 2011; Boyd et al., 2015).  
244 Here we assume a first-order irreversible reactive uptake for the heterogeneous loss of  
245 organic nitrates onto aerosols (R1), followed by its hydrolysis reaction returning HNO<sub>3</sub>  
246 and alcohols (R2) (Fisher et al., 2016):

247 where RONO<sub>2</sub>, AONJ and ROH represent gas- and particle-phase organic nitrates and  
248 alcohols respectively. For the daytime isoprene organic nitrates (mainly from the ISOPO<sub>2</sub>  
249 + NO pathway), we only consider heterogeneous loss of ISOPNB to aerosols, since this  
250 has been detected in field and laboratory studies (Jacobs et al., 2014). Lee et al. (2014)  
251 hypothesized a significant amount of C<sub>5</sub> dinitrate (DHDN, with a molar yield of 21 % via  
252 the ISOPNB peroxy radical + NO pathway) produced from OH oxidation of ISOPNB.  
253 Since DHDN is highly functionalized and might partition to the condensed phase forming  
254 SOA, we test the impact of this process on the estimate of NO<sub>y</sub> speciation and O<sub>3</sub>  
255 concentration in a sensitivity study (AM3h, Figure S2). Aerosol formation from  
256 nighttime isoprene organic nitrates (from isoprene oxidation by NO<sub>3</sub>) are neglected due to  
257 the low mass yields. Information about hydrolysis of daytime monoterpene nitrates (from  
258 OH oxidation of monoterpenes) is quite sparse. Two chamber studies to date have  
259 examined the hydrolysis of nitrates from α-pinene oxidation by OH (Rindelaub et al.,  
260 2015; Bean and Hildebrandt Ruiz, 2016). They found that the hydrolysis rate is  
261 dependent on relative humidity (RH) and aerosol acidity. We also examine the hydrolysis  
262 of daytime monoterpene nitrates (TERPN1) in the above sensitivity study (AM3h, Figure  
263 S2). We do not consider heterogeneous loss of nighttime monoterpene nitrates in this  
264 work due to inadequate information.

265 We allow heterogeneous loss of organic nitrates to sulfate, black carbon, primary organic  
266 carbon, sea salt, mineral dust and SOA following Li et al. (2016). The first-order rate  
267 constant k<sub>1</sub> is determined using an effective uptake coefficient 0.005 for isoprene nitrates  
268 (ISOPNB in all hydrolysis cases and DHDN in AM3h, equivalent to 1.8-h lifetime in the  
269 atmosphere) and 0.01 for daytime monoterpene nitrates (TERPN1, in AM3h) following

270 Fisher et al. (2016), which are consistent with other estimates (Wolfe et al., 2015; Marais  
271 et al., 2016). Due to the large uncertainties of lifetimes against hydrolysis, we assume a  
272 3-h bulk lifetime for the three particle-phase nitrates following Pye et al. (2015),  
273 consistent with recent estimate of organic nitrate aerosol lifetime at a ground monitoring  
274 site in Centreville, Alabama (CTL) (Lee et al., 2016). We also conduct another sensitivity  
275 test (AM3 w/o hydro in Figure 1 and Figure 2) without accounting for the heterogeneous  
276 loss of organic nitrates.

### 277 3 Observational datasets

278 We use measurements from a series of field campaigns (2004 ICARTT, 2013 SENEX,  
279 and 2013 SEAC<sup>4</sup>RS) to evaluate the performance of the model in estimating O<sub>3</sub>, NO<sub>x</sub>,  
280 HNO<sub>3</sub>, PAN, ΣANs and NO<sub>y</sub> over the Southeast U.S. during summer.

281 The ICARTT aircraft campaign provided a detailed characterization of tropospheric  
282 chemistry over the eastern U.S. in the summer of 2004 (July 1-August 15, 2004). Two  
283 aircraft, the NASA DC-8 and the NOAA WP-3D, were deployed to collect measurements  
284 of ozone, NO<sub>y</sub> species, isoprene and its oxidation products. Here we focus on data  
285 including O<sub>3</sub>, NO<sub>x</sub>, HCHO (Tunable Diode Laser (TDL) absorption spectrometry), HNO<sub>3</sub>  
286 (mist chamber/IC by University of New Hampshire and Chemical Ionization Mass  
287 Spectrometer (CIMS) by California Institute of Technology), PAN and ΣANs (including  
288 gas and aerosol RONO<sub>2</sub>) from 11 science flights on the NASA DC-8 aircraft over the  
289 Southeast U.S. Details of the instrument operation and accuracy are summarized in Singh  
290 et al. (2006) and references therein.

291 SENEX was a NOAA aircraft campaign aimed to investigate the interaction between  
292 biogenic and anthropogenic emissions and the formation of secondary pollutants over the  
293 Southeast U.S. in summer 2013 (May 27-July 10, 2013). The NOAA WP-3D aircraft was  
294 launched to collect measurements of a variety of chemical compounds during 18  
295 scientific flights. Here we focus on data, including O<sub>3</sub>, NO<sub>x</sub>, HNO<sub>3</sub>, PAN and NO<sub>y</sub> from  
296 15 daytime flights only. We also used measurements of ISOPN, methylvinylketone  
297 nitrates (MVKN) and methacrolein nitrates (MACRN) taken by University of  
298 Washington from 10 daytime flights during June 3-July 3 of the campaign. Details of the  
299 instrument operation and accuracy are summarized in Warneke et al. (2016) and  
300 references therein.

301 Because ΣANs and several speciated RONO<sub>2</sub> were not measured on the NOAA WP-3D  
302 aircrafts during SENEX, we include another aircraft campaign for model evaluation  
303 despite that this campaign has a major coverage in September of 2013. SEAC<sup>4</sup>RS was a  
304 NASA aircraft campaign with the field mission based in Houston, Texas during August-  
305 September 2013, designed to examine vertical transport of atmospheric pollutants from  
306 the surface to the stratosphere. It provides comprehensive measurements of atmospheric

307 composition in the lower troposphere over North America. Here we use observations of  
308 O<sub>3</sub>, NO<sub>2</sub>, HCHO (laser-induced fluorescence, LIF), ΣANs (including gas and aerosol  
309 RONO<sub>2</sub>) and speciated RONO<sub>2</sub> from 20 NASA DC-8 science flights to evaluate the  
310 correlations of ΣANs and major RONO<sub>2</sub> originating from isoprene oxidation during  
311 daytime with O<sub>x</sub> (= O<sub>3</sub> + NO<sub>2</sub>) and with HCHO, respectively, as additional constraints to  
312 the model. Details of the instrument operation and accuracy are summarized in Toon et al.  
313 (2016) and references therein. We mainly focus on RONO<sub>2</sub> and related species from  
314 SEAC<sup>4</sup>RS in this work.

315 Besides these aircraft campaigns, we also use surface observations for model evaluation,  
316 including nitrate (NO<sub>3</sub><sup>-</sup>) wet deposition flux and concentration from the National Trend  
317 Network (NTN) of NADP (accessible at <http://nadp.sws.uiuc.edu/data/>) and surface O<sub>3</sub>  
318 from EPA AQS (accessible at  
319 [https://aq5.epa.gov/aq5web/documents/data\\_mart\\_welcome.html](https://aq5.epa.gov/aq5web/documents/data_mart_welcome.html)). NTN provides the  
320 monthly NO<sub>3</sub><sup>-</sup> concentration and precipitation so that the monthly mean concentration of  
321 NO<sub>3</sub><sup>-</sup> and wet deposition flux could be derived for model evaluation. The AQS database  
322 provides measurements of important ambient air pollutants (O<sub>3</sub>, NO<sub>x</sub>, SO<sub>2</sub>, PM<sub>2.5</sub> species,  
323 etc.) collected at monitoring sites across the continental U.S. We focus on NO<sub>3</sub><sup>-</sup> wet  
324 deposition fluxes at 53 sites (Figure 3) and MDA8 O<sub>3</sub> at 157 sites (Figure S3) located in  
325 the Southeast U.S. during July–August of 2004 and 2013.

#### 326 **4 Model evaluation of ozone and reactive nitrogen species**

327 We evaluate our model against observations from aircraft campaigns in 2004 and 2013.  
328 For each of the three field campaigns, all measurements are averaged to a 1-min time  
329 resolution. Data from biomass burning (CH<sub>3</sub>CN ≥ 225 ppt or HCN ≥ 500 ppt), urban  
330 plumes (NO<sub>2</sub> ≥ 4 ppb or NO<sub>x</sub>/NO<sub>y</sub> ≥ 0.4 (if NO<sub>y</sub> is available)), and stratospheric air  
331 (O<sub>3</sub>/CO > 1.25 mol mol<sup>-1</sup>) are excluded (Hudman et al., 2007) in all the analyses. We  
332 focus on the Southeast U.S. region, using only data within the domain of 25–40° N  
333 latitude and 100–75° W longitude for our analyses. A map of all the flight tracks of each  
334 campaign is shown in Figure S4. All model results for comparison with observations use  
335 model output sampled along the flight track with 1-min time resolution.

#### 336 **4.1 Mean vertical profiles of O<sub>3</sub> and reactive nitrogen species**

337 Figure 1 shows the observed and modeled mean vertical profiles of O<sub>3</sub>, NO<sub>x</sub>, HNO<sub>3</sub>, PAN,  
338 ΣANs and NO<sub>y</sub> during ICARTT and SENEX. We use ΣANs measurements from  
339 SEAC<sup>4</sup>RS to evaluate model performance during summer 2013, due to the lack of ΣANs  
340 measurements from SENEX. Our model results include both gas and aerosol RONO<sub>2</sub> in  
341 ΣANs, although aerosol RONO<sub>2</sub> accounts for 7–11% of ΣANs in the boundary layer (BL,  
342 < 1.5 km).

343 Mean observed O<sub>3</sub> in the surface layer decreased from 50 ppb during ICARTT to 35 ppb  
344 during SENEX, consistent with the decline in surface MDA8 ozone at AQS monitoring  
345 sites during July-August from 2004 to 2013 over the Southeast U.S. as shown below.  
346 Differences in meteorology may account for some of this decline as this region was cool  
347 and wet in Summer 2013 (Hidy et al., 2014), conditions that suppress ozone formation.  
348 We show below that this impact is relatively small compared to that from NO<sub>x</sub> emission  
349 reductions in this region. Our model can reproduce the vertical gradient of O<sub>3</sub> as well as  
350 the relative change from 2004 to 2013, but the model has a positive bias of upto 6 ppb  
351 and 12 ppb in the boundary layer during ICARTT and SENEX respectively. This  
352 overestimate of O<sub>3</sub> appears to be higher than that reported (3-5 ppb) by Mao et al. (2013)  
353 for their simulation of the ICARTT dataset, likely due to faster photolysis of carbonyl  
354 nitrates that increases the NO<sub>x</sub> recycling efficiency from isoprene oxidation. A recent  
355 study using the GEOS-Chem model (Travis et al., 2016) shows that this regional bias can  
356 be reduced (though not eliminated) with a 53 % reduction of anthropogenic NO<sub>x</sub>  
357 emissions from the 2011 EPA national emission inventory (NEI11v1). Despite some  
358 evidence of overestimated NO<sub>x</sub> emissions in NEI11v1 (Souri et al., 2016; Ahmadov et al.,  
359 2015), we find that such a reduction of NO<sub>x</sub> emissions would lead to a significant  
360 underestimate of the simulated vertical profiles of reactive nitrogen oxides in our model,  
361 as we show below. Therefore, we conclude that the bias in the vertical profile of O<sub>3</sub> in  
362 our model, even though the cause is not entirely understood so far, may not be solely due  
363 to biases in NO<sub>x</sub> emissions.

364 We further examine mean vertical profiles of NO<sub>x</sub> and its reservoirs in 2004 and 2013. In  
365 the boundary layer along the flight tracks (Figure 1), HNO<sub>3</sub> is the most abundant reactive  
366 nitrogen compound, accounting for 40-46 % of NO<sub>y</sub>, followed by NO<sub>x</sub> (18-23 %), PAN  
367 (21 %), and ΣANs (11-21 %). Between 2004 and 2013, mean observed NO<sub>y</sub> in the  
368 boundary layer decreased by 20 %, from 2.0 ppb to 1.6 ppb, a weaker change than the 35 %  
369 reduction of total NO<sub>x</sub> emissions (Table 1). This is likely due to the different sampling  
370 regions (Figure S4) from the two campaigns. We show later that regionally-averaged  
371 NO<sub>y</sub> indicates a 34 % reduction over the Southeast U.S. from 2004 to 2013, more  
372 consistent with the emission reductions (- 35 %). The responses of major reactive  
373 nitrogen compounds are mostly proportional to the change in NO<sub>x</sub> emissions, with the  
374 notable exception of ΣANs. We find significant decreases in NO<sub>x</sub> (- 35 %) and HNO<sub>3</sub> (-  
375 29 %) as well as a slight decrease in PAN (- 13 %) from observations. The relative trends  
376 of HNO<sub>3</sub> and PAN are opposite to those found in the Los Angeles (LA) basin, where  
377 PAN decreased much faster than HNO<sub>3</sub> (Pollack et al., 2013). This difference results  
378 mainly from the rapid decrease of anthropogenic VOC emissions in the LA basin that  
379 also serves as major precursors of PAN. In contrast, BVOC emissions show a constant  
380 supply (within 5 % differences over the two summers) over the Southeast U.S. ΣANs  
381 shows a different trend from the above compounds, increasing from 0.23 ppb to 0.27 ppb  
382 (+ 17 %) near the surface (Figure 1). As we show below, these changes (except for ΣANs)

383 are mostly consistent with model estimates on a regional average, despite possible  
384 representativeness errors from different sampling areas during the three aircraft  
385 campaigns (Figure S4).

386 The model can well reproduce all the  $\text{NO}_y$  species in the boundary layer but tends to  
387 underestimate them in the free troposphere. This is likely due to insufficient production  
388 of  $\text{NO}_x$  from lightning in the free troposphere in our model, which is 0.048 Tg N in total  
389 over North America during July-August of 2004, lower by almost a factor of 5 compared  
390 to the value (0.27 Tg N from July 1-August 15, 2004) reported by Hudman et al. (2007).  
391 Underestimate of  $\text{NO}_x$  in the free troposphere might also be due to rapid conversion of  
392  $\text{NO}_x$  to  $\text{HNO}_3$  (Henderson et al., 2011) in the model. However, we did not adjust the  
393 model due to the high uncertainty in the estimate of lightning  $\text{NO}_x$ . We find that if we  
394 reduce anthropogenic  $\text{NO}_x$  emission in our model by another 40 %, from 0.25 Tg N  $\text{mon}^{-1}$   
395 to 0.15 Tg N  $\text{mon}^{-1}$  as suggested by Travis et al. (2016), simulated  $\text{NO}_y$ ,  $\text{HNO}_3$  and  
396 PAN decrease by 30 %, 33 % and 30 % respectively, leading to a noticeable  
397 underestimate for these nitrogen reservoirs.

398 Hydrolysis of organic nitrates affects  $\text{RONO}_2$  significantly in the boundary layer. By  
399 introducing hydrolysis of ISOPNB, we find that model bias of  $\Sigma\text{ANs}$  in the boundary  
400 layer is reduced from + 20 % to + 2 % during ICARTT (Figure 1). However, the bias is  
401 increased in magnitude from - 9 % to - 24 % during SEAC<sup>4</sup>RS. This low bias can be  
402 partially due to neglecting small alkyl nitrates, which could contribute 20-30 ppt to  $\Sigma\text{ANs}$   
403 (Fisher et al., 2016). Hydrolysis of ISOPNB also impacts its product  $\text{HNO}_3$ . Although the  
404 change in  $\text{HNO}_3$  is not as evident as that of  $\text{RONO}_2$ , model bias is slightly increased  
405 during ICARTT but improved during SENEX. We find that the impact of hydrolysis of  
406 ISOPNB on boundary layer  $\text{O}_3$  appears to be small. This is mainly because without  
407 hydrolysis, the dominant loss of ISOPNB is oxidation by OH, which then leads to the  
408 formation of secondary organic nitrates including MVKN, MACRN and a C5 dihydroxy  
409 dinitrate (DHDN). The majority of these organic nitrates (MVKN and DHDN) return  
410  $\text{NO}_x$  slowly due to long lifetimes, resulting in a similar effect on ozone production as  
411 hydrolysis of ISOPNB. Besides the good agreement of  $\Sigma\text{ANs}$ , our model shows good  
412 agreement with speciated  $\text{RONO}_2$  measured during SENEX and SEAC<sup>4</sup>RS, including  
413 ISOPN and the sum of MVKN and MACRN (Figure 2). We find that the large  
414 discrepancy between  $\Sigma\text{ANs}$  and speciated alkyl nitrates (Figure S5) can be explained by  
415 a combination of terpene nitrates and the C5 dihydroxy dinitrate and nighttime  $\text{NO}_3$   
416 oxidation products from isoprene, accounting for 20-24 %, 14-17 % and 23-29 % of  
417  $\Sigma\text{ANs}$  in the boundary layer. Contribution of the three types of alkyl nitrates also show  
418 different vertical trend. For clarification, all model results discussed below are from AM3  
419 with hydrolysis of ISOPNB.

## 420 4.2 $\text{NO}_3$ wet deposition flux and concentration

421 Figure 3 shows a comparison of  $\text{NO}_3^-$  wet deposition flux between observations and  
422 model results during the summers of 2004 and 2013. The observed  $\text{NO}_3^-$  wet deposition  
423 flux is calculated by multiplying the measured  $\text{NO}_3^-$  concentration and precipitation at  
424 each monitoring site as  $F_{o,i} = C_{o,i} P_{o,i}$ , where  $F_{o,i}$  is the monthly-mean  $\text{NO}_3^-$  wet deposition  
425 flux,  $C_{o,i}$  and  $P_{o,i}$  are the monthly-mean observed  $\text{NO}_3^-$  concentration precipitation at  
426 monitoring site  $i$ . The modeled  $\text{NO}_3^-$  wet deposition flux includes  $\text{HNO}_3$  and all the alkyl  
427 nitrates. Observations indicate a 24 % reduction of  $\text{NO}_3^-$  wet deposition flux in summer  
428 from 2004 to 2013 over the Southeast U.S., likely due to  $\text{NO}_x$  emission reductions. This  
429 reduction in monthly averaged  $\text{NO}_3^-$  wet deposition flux is well captured by our model (-  
430 29 %), despite model has a low bias of 40 % in both years.

431 Since errors in modeled precipitation could strongly affect the modeled  $\text{NO}_3^-$  wet  
432 deposition flux (Appel et al., 2011; Grimm and Lynch, 2005; Metcalfe et al., 2005;  
433 Paulot et al., 2014; Tost et al., 2007), we also evaluate the modeled  $\text{NO}_3^-$  concentration  
434 ( $C_{p,i}$ ), which is calculated by using the modeled  $\text{NO}_3^-$  wet deposition flux ( $F_{p,i}$ ) and  
435 observed precipitation ( $P_{o,i}$ ;  $C_{p,i} = F_{p,i} / P_{o,i}$ ), as a separate constraint. The model shows a  
436 similar declining trend from the observations with a bias of - 18 % and - 40 % on  $\text{NO}_3^-$   
437 concentration for 2004 and 2013 respectively. Our results are consistent with the base  
438 case of Paulot et al. (2016), which showed that convective removal is likely insufficient  
439 in AM3, leading to underestimates of both  $\text{NO}_3^-$  wet deposition flux and concentrations.  
440 Our results are somewhat different from a recent GEOS-Chem study (Travis et al., 2016).  
441 They found that reducing anthropogenic  $\text{NO}_x$  emissions from NEI11v1 by 60 % can  
442 significantly improve the overestimate of 71 % on  $\text{NO}_3^-$  wet deposition flux in their model  
443 during August-September 2013. A further reduction of anthropogenic  $\text{NO}_x$  emission in  
444 our model (to  $0.15 \text{ Tg N mon}^{-1}$ ), as suggested in the previous study, would lead to an  
445 even greater negative bias compared to observations.

### 446 4.3 $\text{RONO}_2$ Chemistry

447  $\text{RONO}_2$  can serve as either a temporary  $\text{NO}_x$  reservoir by releasing  $\text{NO}_2$  via  
448 photooxidation or a permanent  $\text{NO}_x$  sink via hydrolysis to produce  $\text{HNO}_3$ . The modeled  
449 fate of  $\text{RONO}_2$  affects simulated  $\text{O}_3$ . Therefore, it is necessary to evaluate the  $\text{RONO}_2$   
450 chemistry and to understand its speciation.

451 The major pathway for the production of daytime  $\text{RONO}_2$  is the reaction of  $\text{NO}$  with  $\text{RO}_2$   
452 originating from VOC oxidation by  $\text{OH}$ :

453 where  $\alpha$  is the branching ratio for alkyl nitrate formation.  $\text{NO}_2$  subsequently further  
454 undergoes photolysis to produce  $\text{O}_3$ :

455 For isoprene,  $\alpha$  is  $9 \pm 4$  % (for ISOPN) according to a recent study (Xiong et al., 2015).  
456 For monoterpenes, specifically  $\alpha$ -pinene,  $\alpha$  ranges from 1 % to 26 % (Rindelaub et al.,  
457 2015; Nozière et al., 1999; Aschmann et al., 2002). Here, we use 10 % for isoprene and  
458 26 % for monoterpenes (Table S2), and take  $\alpha$  as an average of  $\text{RONO}_2$  from all the  
459 precursors. As  $\text{RONO}_2$  and  $\text{O}_3$  are both produced from (R4), a correlation between them  
460 is expected. We show that the model can roughly reproduce the correlation of  $\text{O}_x$  vs.  
461  $\Sigma\text{ANs}$  during both ICARTT and SEAC<sup>4</sup>RS (Figure 4), although the slope has a positive  
462 bias of about 21 % and 33 % respectively, largely due to an overestimate of  $\text{O}_3$  in the  
463 model. In particular, we find that the model shows better agreement with the observed  
464 correlation of  $\text{O}_x$  vs. daytime isoprene nitrates (the sum of ISOPN, MVKN and MACRN)  
465 than  $\text{O}_x$  vs.  $\Sigma\text{ANs}$  during SEAC<sup>4</sup>RS. This is expected since these three  $\text{RONO}_2$  species  
466 are directly coproduced with  $\text{O}_3$  from (R4), but only account for a small fraction of  $\Sigma\text{ANs}$   
467 (Figure S5). The good agreement between observed and modeled  $\text{O}_x$  vs. daytime  $\text{RONO}_2$   
468 provides additional support for our treatment of the yields and fate of these daytime  
469 isoprene nitrates.

470 Another metric to evaluate  $\text{RONO}_2$  chemistry is the correlation between  $\Sigma\text{ANs}$  and  
471 HCHO, as the latter is a coproduct from (R4). Since HCHO can be produced from other  
472 pathways of isoprene hydroxyl peroxy radicals (ISOPO<sub>2</sub>) besides (R4) (such as  
473 isomerization of ISOPO<sub>2</sub> and ISOPO<sub>2</sub> + HO<sub>2</sub>), changes in the slope of  $\Sigma\text{ANs}$  vs. HCHO  
474 may help to quantify decadal changes in isoprene oxidation pathways. We show in Figure  
475 4 that the model can roughly capture the observed  $\Sigma\text{ANs}$ -HCHO slope, with an  
476 underestimate by 25 % and 13 % during ICARTT and SEAC<sup>4</sup>RS, respectively. The  
477 underestimate is in part due to small alkyl nitrates that are neglected in the model, as  
478 mentioned above. During ICARTT, the slope estimated by AM3 is 0.12, similar to the  
479 value (0.15) from a previous GEOS-Chem study using a different isoprene oxidation  
480 mechanism that assumed a higher  $\alpha$  (of 11.7 % from both ISOPNB and ISOPND vs. 10 %  
481 of ISOPNB and zero ISOPND in AM3) and a lower yield of HCHO (66 % vs. 90 % in  
482 AM3) (Mao et al., 2013). The reason for such similarity between the two models might  
483 be two-fold: (a) the additional contribution of monoterpene nitrates to  $\Sigma\text{ANs}$  in AM3  
484 compensates for the decrease in  $\alpha$  from isoprene nitrates compared to GEOS-Chem and  
485 (b) the coarse grid resolution of that GEOS-Chem simulation ( $2^\circ \times 2.5^\circ$ ) may lead to a  
486 higher estimate of HCHO compared to the result from a finer grid resolution (Yu et al.,  
487 2016).

488 We find in Figure 4 that the observed slope of  $\Sigma$ ANs-HCHO shows very little change  
489 from 2004 to 2013. This is in part due to substantial HCHO production from isoprene  
490 oxidation under low  $\text{NO}_x$  conditions (Li et al., 2016), and in part due to the buffering of  
491  $\Sigma$ ANs in response to decreasing  $\text{NO}_x$ , as shown below. Our model is able to reproduce  
492 such behavior. We also find in our model that the branching ratios for the reactions of  
493  $\text{ISOPO}_2$  change marginally from 2004 to 2013 over the Southeast U.S. (Figure S6). The  
494 fraction of  $\text{ISOPO}_2 + \text{NO}$  has decreased from 81 % in 2004 to 66 % in 2013. The fraction  
495 of  $\text{ISOPO}_2 + \text{HO}_2$  has increased from 15 % to 28 %, and the fraction of  $\text{ISOPO}_2$   
496 isomerization has increased from 4 % to 6 %. Our result is slightly different from the  
497 results of GEOS-Chem, which found a lower contribution from the NO pathway (54 %)  
498 and higher from isomerization (15 %) during August-September of 2013 (Travis et al.,  
499 2016).

500 We also compare the correlation between major daytime isoprene nitrates and HCHO  
501 during 2013, which provides a constraint on the yield of these nitrates. Our model shows  
502 a slight overestimate on the slope (Figure 4 (b)), consistent with comparison of mean  
503 vertical profiles shown in Figure 2. The estimated slope (5 %) in this study is different  
504 from that (2.5 %) of a recent GEOS-Chem simulation by Fisher et al. (2016). This is  
505 partially due to the different treatment of  $\beta$ - and  $\delta$ - $\text{ISOPO}_2$  between GEOS-Chem and  
506 AM3. Another factor is that MVKN and MACRN are not allowed to hydrolyze in AM3,  
507 leading to a higher burden of these two nitrates.

508 Figure 5 shows the mean vertical profiles of modeled monoterpene nitrates (MNs) and  
509 isoprene nitrates (INs) during ICARTT and SEAC<sup>4</sup>RS. INs are the most abundant  
510  $\text{RONO}_2$ , accounting for 76-80 % below 3 km over the Southeast U.S., consistent with the  
511 large isoprene emissions in this region in summer (Palmer et al., 2003). In the  
512 measurements, ISOPN + MVKN + MACRN only contribute one third of the total INs  
513 (Figure S5). We show below that the discrepancy of  $\Sigma$ ANs and speciated  $\text{RONO}_2$  can be  
514 explained by other daytime and nighttime INs in the model. More than 60 % of modeled  
515 INs originate from isoprene oxidation during daytime. The first-generation nitrate ISOPN  
516 contributes slightly more (31 %) than the second-generation nitrates MVKN + MACRN  
517 (28 %) to the total daytime INs during ICARTT. This is different from Mao et al. (2013)  
518 who showed a higher contribution of MVKN + MACRN than the first-generation INs,  
519 due to the different treatment of  $\beta$ - and  $\delta$ - $\text{ISOPO}_2$ . We see more ISOPN (32 %) than  
520 MVKN + MACRN (26 %) from the daytime INs during SEAC<sup>4</sup>RS, consistent with  
521 Fisher et al. (2016). A large uncertainty in our model is attributed to DHDN, which  
522 contributes 32 % to the daytime INs. Fisher et al. (2016) showed less DHDN during  
523 SEAC<sup>4</sup>RS since it was removed rapidly by hydrolysis (1-h lifetime) in their model. Our  
524 sensitivity test (AM3h, Figure S2) indicates that AM3 would significantly underestimate  
525  $\Sigma$ ANs if we assume a similar heterogeneous loss as ISOPN. In fact, DHDN was  
526 hypothesized originally in Lee et al. (2014) for the imbalance of nitrogen in their lab

527 experiments, and may serve as a proxy for a large number of unidentified daytime INs. It  
528 remains unclear what the dominant loss of DHDN is. Daytime nitrates from monoterpene  
529 oxidation are another important source of  $\Sigma$ ANs in this region, accounting for 17-20 %  
530 (24-26 ppt) of the total. Fisher et al. (2016) estimate a smaller burden of MNs, of about  
531 10-20 ppt due to a lower molar yield (18 % vs. 26 % in AM3) and faster hydrolysis of  
532 MNs in their model.

533 Nighttime chemistry contributes about 30-36 % of  $\Sigma$ ANs, which is dominated by  
534 isoprene oxidation as well (Figure 5). 33-41 % of the INs are produced during night,  
535 similar to the value (44 %) reported by Mao et al. (2013) but with different speciation,  
536 due to the different treatment of chemistry. PROPNN contributes about 29-38 % of the  
537 total INs. PROPNN in this work is mainly produced from the oxidation of C5 carbonyl  
538 nitrate (ISN1) and C5 nitrooxy hydroperoxide (INPN) (dominantly by photolysis) that are  
539 generated from isoprene oxidation by  $\text{NO}_3$  during the nighttime. This is different from  
540 Fisher et al. (2016), who showed that PROPNN is partially from the  $\delta\text{-ISOPO}_2 + \text{NO}$   
541 pathway and partially from the oxidation of ISN1 and INPN. In our model, we see  
542 prompt production of PROPNN after sunrise in the boundary layer (Figure S7),  
543 consistent with observations at the Southern Oxidants and Aerosols Study (SOAS)  
544 ground site CTL (Schwantes et al., 2015). Our model overestimates the mean vertical  
545 profile of PROPNN by a factor of 3 (not shown). As our model may largely  
546 underrepresent the chemical complexity of nighttime isoprene oxidation as shown by  
547 Schwantes et al. (2015), we consider PROPNN as a proxy for other unspecified isoprene  
548 nighttime nitrates. As a result, PROPNN contributes a significant fraction of  $\Sigma$ ANs in the  
549 model.

## 550 **5 Decadal Change of PBL $\text{NO}_y$ species and surface ozone over SEUS**

### 551 **5.1 $\text{NO}_y$ species**

552 We examine the simulated decadal change of  $\text{NO}_y$  species in the boundary layer over the  
553 Southeast U.S. Figure 6 shows the mean modeled boundary layer concentrations of  $\text{NO}_x$ ,  
554  $\text{HNO}_3$ ,  $\Sigma$ PNs,  $\Sigma$ ANs and  $\text{NO}_y$  in the summer of 2004 and 2013 as well as a scenario with  
555 a further 40 % reduction from 2013 anthropogenic  $\text{NO}_x$  emissions to simulate possible  
556 future emission reductions. In summer 2004, modeled  $\text{NO}_y$  is mainly comprised of  $\text{HNO}_3$   
557 (45 %),  $\text{NO}_x$  (31 %),  $\Sigma$ PNs (14 %) and  $\Sigma$ ANs (9 %). In response to imposing a 40%  
558 reduction in anthropogenic  $\text{NO}_x$  emissions (35 % reduction in total  $\text{NO}_x$  emissions, Table  
559 1) from 2004 to 2013,  $\text{NO}_y$  declined by 34 %. This modeled response is consistent with  
560 long-term  $\text{NO}_y$  measurements from AQS dataset, which shows on average a 42 %  
561 decrease from 2004 to 2013 over the Southeast U.S. Most  $\text{NO}_y$  species are reduced  
562 proportionally, with decreases of 38 % for  $\text{HNO}_3$ , 32 % for  $\text{NO}_x$  and 34% for  $\Sigma$ PNs. The  
563 different change in  $\Sigma$ PNs and PAN (the majority of  $\Sigma$ PNs) in Figure 1 might be due to

564 the difference in sampling regions. The only exception is  $\Sigma\text{ANs}$ , with a smaller decline of  
565 19 %. It should be noted that the change of  $\Sigma\text{ANs}$  discussed here is different from the  
566 surface concentrations discussed in Section 4.1.

567 We conducted a sensitivity test with an additional 40 % reduction of anthropogenic  $\text{NO}_x$   
568 emissions from 2013 (Table 2). We find that  $\text{NO}_y$  decreases by 29 %, with a proportional  
569 decrease in  $\text{HNO}_3$ ,  $\text{NO}_x$ , and  $\Sigma\text{PNs}$ . Again, we find that  $\Sigma\text{ANs}$  decrease at a slower rate,  
570 becoming a larger fraction of total  $\text{NO}_y$ . The buffering of  $\Sigma\text{ANs}$  is consistent with  
571 previous studies (Browne and Cohen, 2012; Fisher et al., 2016), mainly due to decreasing  
572  $\text{NO}_x$  leading to lower OH (Figure S8) and thus a prolonged lifetime of  $\text{NO}_x$  and  $\Sigma\text{ANs}$   
573 (Browne and Cohen, 2012). As shown in Figure S8, averaged noontime OH decreases by  
574 11 % from 2004 to 2013 and by 29 % after we impose an additional 40 %  $\text{NO}_x$  emission  
575 reduction from 2013 levels.

576 The historical  $\text{NO}_x$  emission reduction also affects reactive nitrogen export out of the  
577 boundary layer. Here we define exported nitrogen as the difference of the sources  
578 (chemical production and emissions) and sinks (chemical loss, wet and dry deposition).  
579 As shown in Table 2, total summertime  $\text{NO}_y$  export from the Southeast U.S. boundary  
580 layer decreases proportionally, from 24.1 Gg N in 2004 to 16.6 Gg N in 2013. The  
581  $\text{NO}_y$  export efficiency, calculated as net exported nitrogen divided by total  
582  $\text{NO}_x$  emissions, remains roughly the same (12 %) for 2004 and 2013, consistent with  
583 previous studies (Fang et al., 2010; Li et al., 2004; Parrish et al., 2004; Mao et al., 2013;  
584 Sanderson et al., 2008; Hudman et al., 2007). Among all exported species,  
585  $\text{NO}_x$  contributes most of net export from the PBL (6 % of total  $\text{NO}_x$  emissions), followed  
586 by PAN (4 %) and  $\Sigma\text{ANs}$  (2 %). We emphasize in Table 2 that a major fraction of  $\text{NO}_x$  is  
587 exported through the top of the boundary layer (convection). From a budget calculation  
588 throughout the tropospheric column over the same region, we find that despite being the  
589 same  $\text{NO}_y$  export efficiency (12 %),  $\text{HNO}_3$  becomes the major exporter, accounting for  
590 half of  $\text{NO}_y$  export efficiency from the total column (6 %). The contributions from PAN  
591 and  $\Sigma\text{ANs}$  are roughly the same as their export from the boundary layer (4 % and 2 %).  
592 This suggests that surface  $\text{NO}_x$  ventilated through the boundary layer, converted to  
593  $\text{HNO}_3$  in the free troposphere and exported as  $\text{HNO}_3$  is likely the major  $\text{NO}_y$  export  
594 mechanism over the Southeast U.S. in our model, which is in agreement with previous  
595 observations (Parrish et al., 2004; Neuman et al., 2006). PAN and  $\Sigma\text{ANs}$  together account  
596 for another half of  $\text{NO}_y$  export efficiency. As PAN and  $\Sigma\text{ANs}$  are of biogenic origin and  
597 longer lived than  $\text{HNO}_3$ , they may play a key role in influencing reactive nitrogen and  
598 ozone in downwind regions (Moxim et al., 1996; Fischer et al., 2014).

## 599 5.2 Surface ozone

600 Understanding oxidation chemistry of NO<sub>x</sub> and VOCs is essential to improve surface  
601 ozone air quality by implementing effective control strategies. Since the mid-1990s, NO<sub>x</sub>  
602 emission controls have led to significant improvement on ozone air quality over the  
603 eastern U.S. (Simon et al., 2015; Cooper et al., 2012). As NO<sub>x</sub> emissions continue to  
604 decrease, ozone production efficiency (OPE) may increase due to the lower NO<sub>x</sub> removal  
605 rate by OH and to some extent may compensate the ozone reduction (Sillman, 2000).  
606 Meanwhile, surface ozone production may be further complicated by the increasing  
607 importance of ISOPO<sub>2</sub> isomerization (Peeters et al., 2014). Here we first evaluate our  
608 model against surface ozone observations in 2004 and 2013, and then project the future  
609 response of surface ozone to even lower NO<sub>x</sub> emissions to examine the efficacy of near-  
610 term NO<sub>x</sub> emission controls at lowering near-surface ozone levels.

611 We first examine the modeled surface ozone against observations at 157 EPA AQS  
612 monitoring sites over the Southeast U.S. in July-August of 2004 and 2013 (Figure S9). In  
613 general, AM3 overestimates surface MDA8 ozone in both years by about 16 ppb on  
614 average. This positive bias of summertime surface O<sub>3</sub> has been a common issue to a  
615 number of modeling studies of this region (Fiore et al., 2009; Canty et al., 2015; Brown-  
616 Steiner et al., 2015; Strode et al., 2015; Travis et al., 2016). This might be partially  
617 attributed to overestimated anthropogenic NO<sub>x</sub> emissions from non-power plant sectors,  
618 excessive vertical mixing in the boundary layer (Travis et al., 2016) or underestimates of  
619 O<sub>3</sub> dry deposition (Hardacre et al., 2015; Val Martin et al., 2014). Further studies are  
620 warranted to investigate the cause of this bias in AM3.

621 Surface O<sub>3</sub> concentrations over the Southeast U.S. decline substantially from 2004 to  
622 2013 in response to the large NO<sub>x</sub> emission reduction (Simon et al., 2015). MDA8 ozone  
623 averaged across all the monitoring sites is observed to decrease by 11 ppb (23 % of  
624 observed mean MDA8 ozone in July-August of 2004) resulting from approximately 40 %  
625 reductions of anthropogenic NO<sub>x</sub> emissions (35 % reduction in total NO<sub>x</sub> emissions)  
626 across the continental U.S. This strong sensitivity of surface ozone to NO<sub>x</sub> emission  
627 reflects the linear relationship between ozone production rate and NO<sub>x</sub> concentrations  
628 when NO<sub>x</sub> is low (Trainer et al., 2000). In contrast, the sensitivity of surface ozone to  
629 NO<sub>x</sub> emissions appears to be weaker in the 1980s. Jacob et al. (1993) found that  
630 summertime afternoon ozone over the eastern U.S. is only reduced by 15 % with a 50 %  
631 reduction of anthropogenic NO<sub>x</sub> emissions from 1985 levels, suggesting a lower OPE  
632 when NO<sub>x</sub> concentrations were high. We attribute this transition from a low OPE in the  
633 1980s to high OPE in 2000s to the extended lifetime of NO<sub>x</sub> resulting from NO<sub>x</sub> emission  
634 reductions. Our model is able to capture this strong NO<sub>x</sub>-O<sub>3</sub> sensitivity, with the mean  
635 MDA8 ozone reduced by 10 ppb from 2004 to 2013. We find that a further 40 %  
636 reduction of anthropogenic NO<sub>x</sub> emissions with identical meteorological conditions and  
637 non-anthropogenic emissions in 2013 could lead to an additional 9 ppb decrease, a  
638 similar magnitude to the change from 2004 to 2013. Meanwhile, any increase in OPE

639 over the past decade appears to be small and to have little impact on net ozone production,  
640 leading to a continued high sensitivity of surface ozone to  $\text{NO}_x$  emission reductions in the  
641 near future.

642 We further investigate the impact of temperature and moisture on surface  $\text{O}_3$  from 2004  
643 to 2013. While several studies suggest that surface  $\text{O}_3$  increases with ambient temperature  
644 (Jacob and Winner, 2009; Bloomer et al., 2010; Wu et al., 2008; Steiner et al., 2010),  
645 Cooper et al. (2012) showed that this temperature related impact is weak during the  
646 period of 1990-2010 across the USA. Recent studies suggest that relative humidity (RH)  
647 or vapor pressure deficit (VPD) may play an important role in ozone variability through  
648 soil-atmosphere or biosphere-atmosphere coupling (Kavassalis and Murphy, 2017;  
649 Camalier et al., 2007; Tawfik and Steiner, 2013). Our model shows marginal differences  
650 in RH and temperature over the Southeast U.S. between the summers of 2004 and 2013,  
651 consistent with climatology data (Hidy et al., 2014). Using the same model but with the  
652 standard AM3 chemical mechanism, Lin et al. (2017) found that meteorology changes  
653 would have caused surface ozone over the eastern U.S. to increase in the absence of  
654 emission controls from 1999 to 2014. Therefore, we conclude that the impact of climate  
655 variability and change on  $\text{O}_3$  is relatively small compared to  $\text{NO}_x$  emission reductions  
656 over the Southeast U.S., consistent with previous studies (Lam et al., 2011; Hidy et al.,  
657 2014; Lin et al., 2017; Rieder et al., 2015)

658 Decreasing  $\text{NO}_x$  emission also reduces the frequency of extreme  $\text{O}_3$  pollution events.  
659 Figure 7 shows the probability density function of observed and modeled MDA8 ozone at  
660 each monitoring site during July-August of 2004 and 2013, and the probability density  
661 function of modeled MDA8 ozone under a future scenario with another 40 % reduction in  
662 anthropogenic  $\text{NO}_x$  emissions compared to 2013. We show that the lowest  $\text{O}_3$ , about 20  
663 ppb in current model simulations, remains invariant with  $\text{NO}_x$  emission changes over the  
664 Southeast U.S., consistent with observations (Figure 7 (a)). Meanwhile, the high tail of  
665 MDA8 ozone events has shifted from more than 100 ppb in 2004 to about 85 ppb after  
666 the 40% reduction of anthropogenic  $\text{NO}_x$  emissions from 2013. A similar shift is found in  
667 observations. The narrowing of the range of  $\text{O}_3$  with decreasing  $\text{NO}_x$  is consistent with  
668 the observed trends reported by Simon et al. (2015). We also find that further reductions  
669 of  $\text{NO}_x$  emissions will reduce both median  $\text{O}_3$  values and the high tail, suggesting that  
670 fewer extreme ozone events will occur under continued  $\text{NO}_x$  emission controls in the  
671 future.

## 672 **6 Conclusions and Discussions**

673 Near-surface ozone production over the Southeast U.S. is heavily influenced by both  
674 anthropogenic and biogenic emissions. We investigate the response of  $\text{NO}_y$  speciation to  
675 such  $\text{NO}_x$  reduction to the significant  $\text{NO}_x$  emission controls (about 40 % reductions) in  
676 this region over the past decade, in light of the fast-evolving understanding of isoprene

677 photooxidation. This knowledge is needed to predict nitrogen and ozone budgets in this  
678 region and elsewhere in the world with similar photochemical environments. Here we use  
679 extensive aircraft and ground observations, combined with a global chemistry-climate  
680 model (GFDL AM3), to examine decadal changes in  $\text{NO}_y$  abundance and speciation as  
681 well as in surface  $\text{O}_3$  mixing ratios over the Southeast U.S. between the summers of 2004  
682 and 2013. We then use the model to infer future  $\text{NO}_y$  speciation and surface ozone  
683 abundances in response to further  $\text{NO}_x$  emission controls in this region.

684 We first evaluate the model with aircraft and surface observations. When we apply the  
685 estimated 40 % reductions in anthropogenic  $\text{NO}_x$  emissions from 2004 to 2013, our  
686 model reproduces the vertical profiles of  $\text{NO}_x$ ,  $\text{HNO}_3$ , PAN,  $\Sigma\text{ANs}$  and  $\text{NO}_y$  observed  
687 during aircraft campaigns over the Southeast U.S. in the summers of 2004 and 2013. By  
688 including recent updates on isoprene oxidation, our model can largely reproduce the  
689 vertical profiles of  $\Sigma\text{ANs}$  and several speciated alkyl nitrates, as well as their correlations  
690 with  $\text{O}_x$  and  $\text{HCHO}$  (Figure 4), lending support to the model representation of isoprene  
691 oxidation. On the other hand, we show that the discrepancy between measured  $\Sigma\text{ANs}$  and  
692 speciated  $\text{RONO}_2$ , can be explained by a combination of terpene nitrates, dinitrates and  
693 nighttime  $\text{NO}_3$  oxidation products from isoprene. We also show that modeled ozone  
694 appears to be insensitive to hydrolysis of ISOPNB, because its photooxidation, mainly by  
695 OH, also returns little  $\text{NO}_x$ .

696 Major  $\text{NO}_y$  species decline proportionally as a result of  $\text{NO}_x$  emission reductions in the  
697 Southeast U.S., except that  $\Sigma\text{ANs}$  decline at a slower rate. Our model suggests that  
698 summertime monthly averaged  $\text{NO}_x$ ,  $\text{HNO}_3$ , PAN, and  $\text{NO}_y$  decline by 30-40 %, in  
699 response to 40 % reductions in anthropogenic  $\text{NO}_x$  emissions from 2004 to 2013. The  
700 slower decline of  $\Sigma\text{ANs}$  reflects the prolonged lifetime of  $\text{NO}_x$  with decreasing  $\text{NO}_x$ .  
701 This proportional decrease is to a large extent driven by high concentrations of biogenic  
702 VOC in this region that change little in magnitude from 2004 to 2013. In contrast,  
703 Pollack et al. (2013) find a faster PAN decrease than  $\text{HNO}_3$  in the LA basin over the past  
704 several decades, partly due to the decrease in anthropogenic VOC emissions that are  
705 major PAN precursors.

706 Deposited and exported  $\text{NO}_y$  decline with  $\text{NO}_x$  emission reductions. The model also  
707 shows a decrease of  $\text{NO}_3^-$  wet deposition flux by 29 % from 2004 to 2013, consistent with  
708 observations from the NADP network (- 24 %). We find from model calculations that the  
709  $\text{NO}_y$  export efficiency remains at 12 % in both 2004 and 2013, leading to a proportional  
710 decrease of exported  $\text{NO}_y$ . The dominant  $\text{NO}_y$  export terms include  $\text{NO}_x$  or  $\text{HNO}_3$ , each  
711 accounting for 6% of the total exported  $\text{NO}_y$ , followed by  $\Sigma\text{PNs}$  (4 %) and  $\Sigma\text{ANs}$  (2 %).

712 Response of surface ozone to  $\text{NO}_x$  emission reductions reveals a strong  $\text{O}_3$ - $\text{NO}_x$   
713 sensitivity in summertime over Southeast U.S. Observations from EPA AQS surface

714 network suggest that mean MDA8 ozone during July-August has decreased from 48 ppb  
715 in 2004 to 37 ppb in 2013, a 23 % decrease. Despite a positive bias of upto 12 ppb in  
716 boundary layer ozone and a bias of 16 ppb in surface MDA8 ozone, our model shows a  
717 10 ppb decrease of surface MDA8 ozone from 2004 to 2013, very close to the observed  
718 11 ppb decrease from the EPA data. The bias of ozone in our model is not entirely  
719 attributed to uncertainties in NO<sub>x</sub> emissions, as the overestimate suggested by earlier  
720 work would lead to underestimate of NO<sub>y</sub>. More importantly, we find from model  
721 calculations that modeled MDA8 O<sub>3</sub> will continue to decrease by another 9 ppb assuming  
722 anthropogenic NO<sub>x</sub> emissions are decreased by 40 % from the 2013 level with  
723 meteorology and other emissions kept constant. In addition, further NO<sub>x</sub> reduction leads  
724 to less frequent extreme ozone events (Figure 7). This continued strong sensitivity of  
725 surface O<sub>3</sub> to NO<sub>x</sub> emissions can guide the development effective emission control  
726 strategies for improving future air quality.

1199

1200 **Figure 1.** Mean vertical profiles of ozone and reactive nitrogen species from observations  
1201 during ICARTT (top row) and SENEX (bottom row) over SEUS (25-40° N, 100-75° W)  
1202 during daytime, and model estimates from AM3 with hydrolysis of alkyl nitrates (red)  
1203 and AM3 without hydrolysis of alkyl nitrates (green). The dashed and solid black lines in  
1204 the HNO<sub>3</sub> of ICARTT represent measurements collected using mist chamber/IC by  
1205 University of New Hampshire (UNH) and Chemical Ionization Mass Spectrometer by  
1206 California Institute of Technology (CIT), respectively. NO<sub>y</sub> from ICARTT is calculated  
1207 as the sum of NO<sub>x</sub>, HNO<sub>3</sub> (w/ UNH in the solid line and w/ CIT in the dashed line), PAN  
1208 and total alkyl nitrates (ΣANs). ΣANs in the bottom row are from SEAC<sup>4</sup>RS.

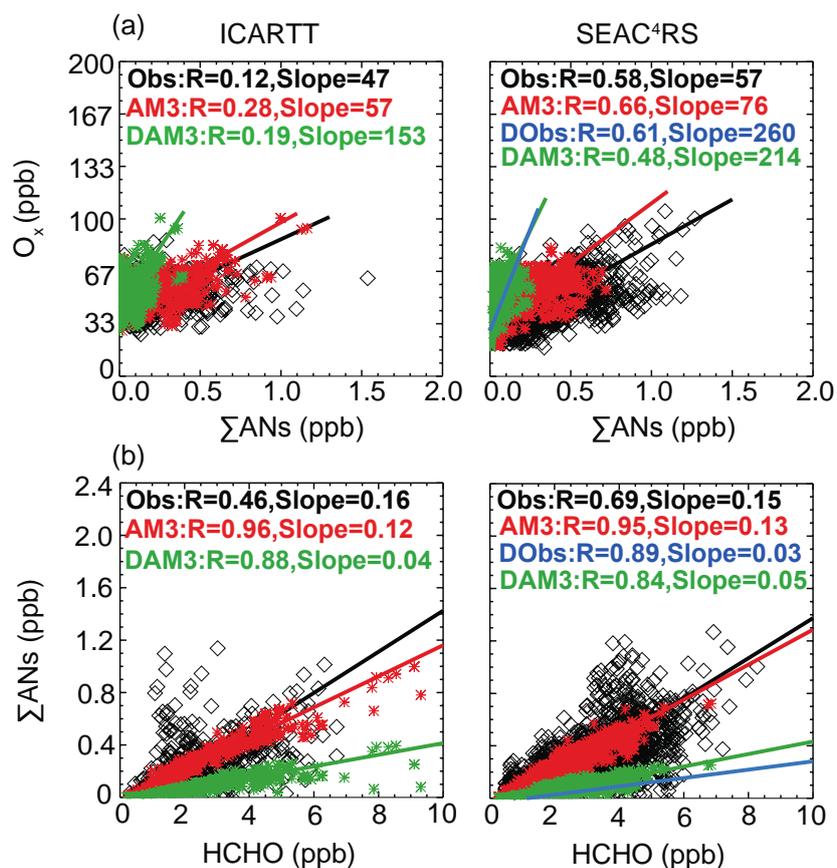

1209

1210 **Figure 2.** Mean vertical profiles of ISOPN and MVNKN+MACRN during (a) SENEX and  
1211 (b) SEAC<sup>4</sup>RS over SEUS (25-40° N, 100-75° W). Black lines are the mean of  
1212 observations. Red and green lines are the mean of modeled results with hydrolysis of  
1213 ISOPNB and without hydrolysis of alkyl nitrates respectively. Grey shades are the one  
1214 standard deviation ( $\pm\sigma$ ) of averaged profiles of the measured tracers.

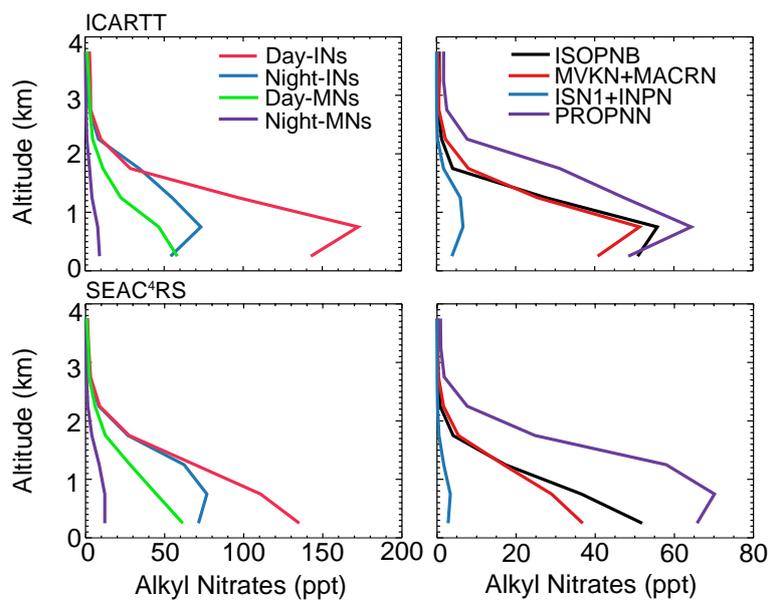

1216 **Figure 3.** Nitrate wet deposition flux ( $\text{kg N ha}^{-1} \text{mon}^{-1}$ ) from NADP (circles) and AM3  
1217 (background) during July-August of 2004 and 2013.

1218

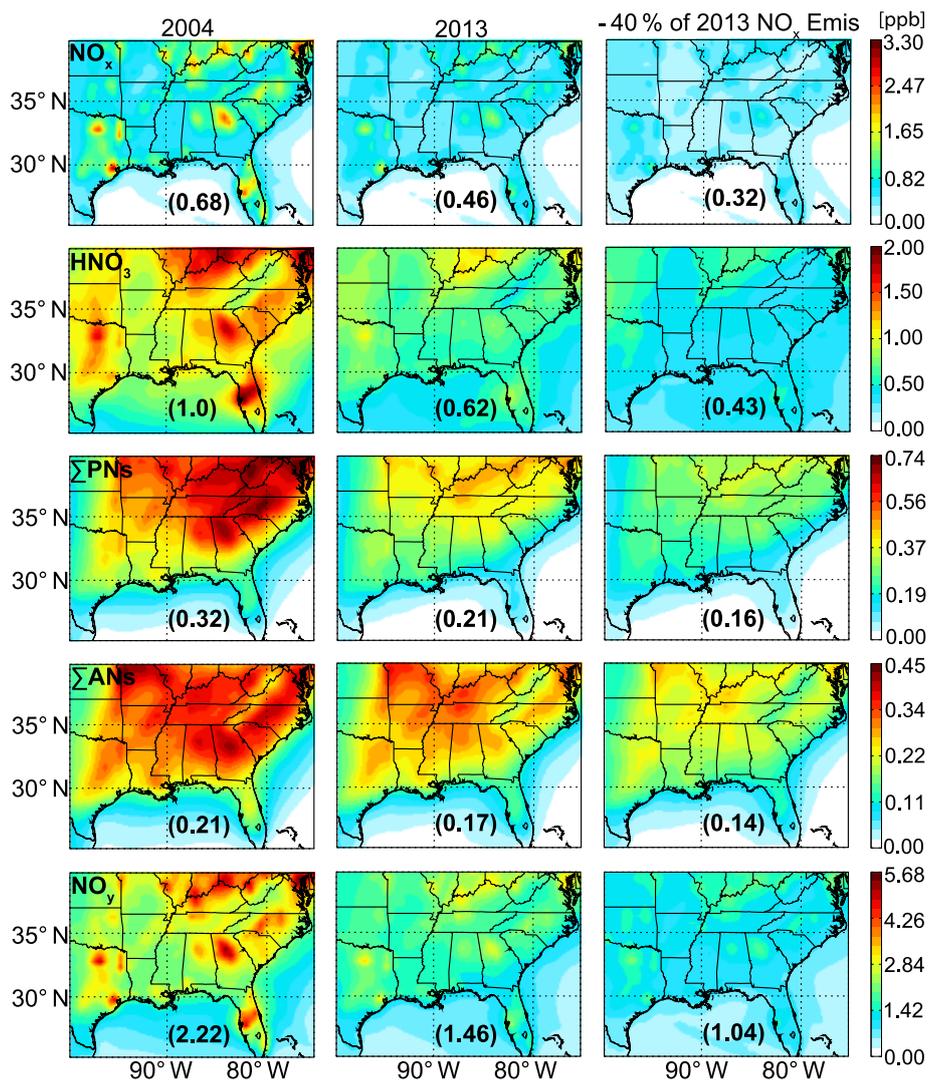

1219 **Figure 4.**  $O_x$  versus  $\sum ANs$  correlation (top; (a)) and  $\sum ANs$  versus formaldehyde  
 1220 correlation (bottom; (b)) within the boundary layer (< 1.5 km) during ICARTT (left) and  
 1221 SEAC<sup>4</sup>RS (right). Observations are in black diamonds; model estimates from AM3 with  
 1222 ISOPNB hydrolysis are in red symbols. Green symbols (DAM3) represent the correlation  
 1223 using modeled ISOPN + MVKN + MACRN. Blue symbols (DObs) represent the  
 1224 correlation using observed ISOPN + MVKN + MACRN from SEAC<sup>4</sup>RS. Solid lines are  
 1225 the reduced major axis regression lines.

1226

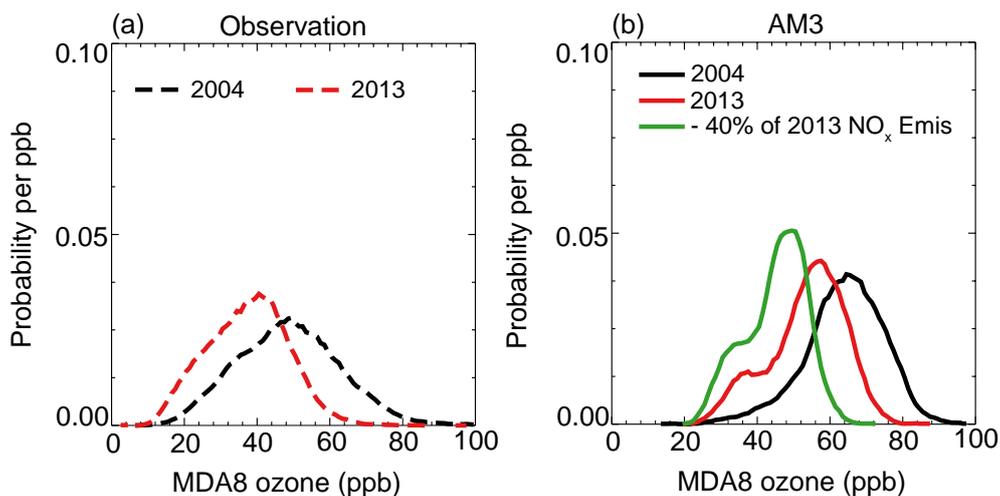

1227

1228 **Figure 5.** Mean vertical profiles of modeled alkyl nitrates from isoprene and  
1229 monoterpene oxidation (left) and major isoprene nitrate species (right) during ICARTT  
1230 (top row) and SEAC<sup>4</sup>RS (bottom row) from AM3 with hydrolysis of ISOPNB.

1231

1232 **Figure 6.** Modeled mean NO<sub>x</sub>, HNO<sub>3</sub>, total peroxy nitrates (ΣPNs), total alkyl nitrates  
1233 (ΣANs) and NO<sub>y</sub> averaged over the boundary layer (< 1.5 km) of the Southeast U.S.  
1234 during July-August of 2004 (left), 2013 (middle), and a scenario assuming 40 %  
1235 reduction of 2013 anthropogenic NO<sub>x</sub> emissions (right). Numbers in parentheses indicate  
1236 mean concentrations over the plotted region. Note different color scales represent the  
1237 concentration of each species.

1238

1239

1240 **Figure 7.** Observed (a) and simulated (b) probability density function of MDA8 ozone at  
1241 AQS monitoring sites in Figure S3 during summer of 2004, 2013, and a scenario with 40 %  
1242 reduction in the anthropogenic NO<sub>x</sub> emissions of 2013.

1242

1243 **Table 1.** Monthly averaged NO<sub>x</sub> emissions in July-August of 2004 and 2013 over North  
1244 America (25-50° N, 130-70° W) in AM3.

Source Type	2004 (Tg N)	2013 (Tg N)
Anthropogenic	0.42	0.25
Biomass Burning	$8.4 \times 10^{-3}$	$8.4 \times 10^{-3}$
Soils	$2.9 \times 10^{-2}$	$2.9 \times 10^{-2}$
Aircraft	$8.8 \times 10^{-3}$	$8.0 \times 10^{-3}$
Lightning	0.02	0.02
Total	0.49	0.32

1245

1246 **Table 2.** Monthly  $\text{NO}_y$  budget in the boundary layer (< 1.5 km) of the Southeast United States for July–August of 2004, 2013 and a  
 1247 scenario with 40 % reduction of anthropogenic  $\text{NO}_x$  emissions of 2013<sup>a</sup>.

Species	2004				2013				- 40 % of 2013 Anthropogenic $\text{NO}_x$ Emis						
	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export	Emission	Chem (P-L)	Dry Dep	Wet Dep	Net Export
$\text{NO}_x$	208.7	-172.4	21.8	-	14.5	132.6	-105	14.2	-	13.4	88.3	-69.6	9.2	-	9.5
$\Sigma\text{PNs}^b$		15.2	5.7	-	9.5		10.3	3.9	-	6.4		7.7	3.0	-	4.7
$\Sigma\text{ANs}$		24.3	14.3	6.2	3.8		19.4	11.4	4.7	3.3		15.4	9.1	3.9	2.4
day <sup>c</sup>		13.8	8.7	3.6	1.5		12.0	7.5	3.0	1.6		10.2	6.3	2.6	1.3
night <sup>d</sup>		10.5	5.6	2.6	2.4		7.4	4.0	1.7	1.7		5.3	2.8	1.3	1.1
$\text{HNO}_3$		131.7	77.8	57.6	-3.7		74.2	45.6	35.1	-6.5		45.8	29.2	25.6	-9.0
$\text{NO}_y$					24.1					16.6					7.6

1248 <sup>a</sup>We define the boundary of Southeast US is 25–40° N, 100–75° W. All budget terms are in Gg N.

1249 <sup>b</sup> $\Sigma\text{PNs}$  include PAN, peroxyacetyl nitrate (MPAN), and a C5 hydroxy peroxyacetyl nitrate (C5PAN1) produced by oxidation of  
 1250 ISN1.

1251 <sup>c</sup>Alkyl nitrates produced from oxidation of isoprene and monoterpenes by OH.

1252 <sup>d</sup>Alkyl nitrates produced from oxidation of isoprene and monoterpenes by  $\text{NO}_3$ .
