9  
10 **Abstract**

11 Downdrafts and cold pool characteristics for strong mesoscale convective systems  
12 (MCSs) and isolated, unorganized deep precipitating convection are analyzed using multi-  
13 instrument data from the DOE Atmospheric Radiation Measurement (ARM) GoAmazon2014/5  
14 campaign. Increases in column water vapor (CWV) are observed leading convection, with higher  
15 CWV preceding MCSs than for isolated cells. For both MCSs and isolated cells, increases in  
16 wind speed, decreases in surface moisture and temperature, and increases in relative humidity  
17 occur coincidentally with system passages. Composites of vertical velocity data and radar  
18 reflectivity from a radar wind profiler show that the downdrafts associated with the sharpest  
19 decreases in surface equivalent potential temperature ( $\theta_e$ ) have a probability of occurrence that  
20 increases with decreasing height below the freezing level. Both MCSs and unorganized  
21 convection show similar mean downdraft magnitudes and probabilities with height. Mixing  
22 computations suggest that, on average, air originating at heights greater than 3 km must undergo  
23 substantial mixing, particularly in the case of isolated cells, to match the observed cold pool  $\theta_e$ ,  
24 implying a low typical origin level. Precipitation conditionally averaged on decreases in surface  
25 equivalent potential temperature ( $\Delta\theta_e$ ) exhibits a strong relationship because the most negative  
26  $\Delta\theta_e$  values are associated with a high probability of precipitation. The more physically motivated  
27 conditional average of  $\Delta\theta_e$  on precipitation shows that decreases in  $\theta_e$  level off with increasing  
28 precipitation rate, bounded by the maximum difference between surface  $\theta_e$  and its minimum in

29 the profile aloft. Robustness of these statistics observed across scales and regions suggests their  
30 potential use as model diagnostic tools for the improvement of downdraft parameterizations in  
31 climate models.

## 32 **1 Introduction**

33 Convective downdrafts involve complex interactions between dynamics,  
34 thermodynamics, and microphysics across scales. They form cold pools, which are evaporatively  
35 cooled areas of downdraft air that spread horizontally and can initiate convection at their leading  
36 edge (Byers and Braham 1949; Purdom 1976; Wilson and Schreiber 1986; Rotunno et al. 1988;  
37 Fovell and Tan 1998; Tompkins 2001; Khairoutdinov and Randall 2006; Lima and Wilson 2008;  
38 Khairoutdinov et al. 2009; Böing et al. 2012; Rowe and Houze 2015). The boundary between the  
39 cold pool and the surrounding environmental air, known as the outflow boundary or gust front, is  
40 key to sustaining multi-cellular deep convection (e.g. Weisman and Klemp 1986). It has also  
41 been shown to trigger new convective cells in marine stratocumulus clouds (Wang and Feingold  
42 2009; Terai and Wood 2013) and in trade-wind cumulus (Zuidema et al. 2012; Li et al. 2014).  
43 Downdrafts also have implications for new particle formation in the outflow regions, which  
44 contribute to maintaining boundary layer CCN concentrations in unpolluted environments (Wang  
45 et al. 2016).

46 Precipitation-driven downdrafts are primarily a result of condensate loading and the  
47 evaporation of hydrometeors in unsaturated air below cloud base (e.g. Houze 1993), with  
48 evaporation thought to be the main driver (Knupp and Cotton 1985; Srivastava 1987). It was  
49 originally suggested by Zipser (1977) that the downdrafts in the convective part of a system,  
50 referred to in the literature as convective-scale downdrafts, are saturated and the downdrafts in  
51 the trailing stratiform region (referred to as mesoscale downdrafts) are unsaturated. Studies with  
52 large-eddy simulations (LES; Hohenegger and Bretherton 2011; Torri and Kuang 2016) indicate,  
53 however, that most convective downdrafts are unsaturated, consistent with evidence that the  
54 evaporation of raindrops within the downdraft likely does not occur at a sufficient rate to  
55 maintain saturation (Kamburova and Ludlam 1966).

56 More recently, studies have shown the importance of downdraft parameters in  
57 maintaining an accurate simulation of tropical climate in global climate models (GCMs;  
58 Maloney and Hartmann 2001; Sahany and Nanjundiah 2008; Del Genio et al. 2012;

59 Langenbrunner and Neelin 2017). Accurate simulation of MCSs in continental regions (Pritchard  
60 et al. 2011) was also shown to be sensitive to downdraft–boundary layer interactions, with  
61 significantly improved representation of MCS propagation in the central US once such  
62 interactions were resolved. Additionally, representing the effects of downdrafts and cold pools in  
63 models has been shown to have positive effects on the representation of the diurnal cycle of  
64 precipitation (Rio et al. 2009; Schlemmer and Hohenegger 2014).

65 This study aims to characterize downdrafts in a comprehensive way in the Amazon for  
66 both isolated and mesoscale convective systems, and to provide useful guidance for downdraft  
67 parameterization in GCMs. Data from the DOE–Brazil Green Ocean Amazon (GOAmazon)  
68 campaign (2014–2015; Martin et al. 2016) provide an unprecedented opportunity to evaluate  
69 downdraft characteristics in the Amazon with sufficiently large datasets for quantifying robust  
70 statistical relationships describing leading order processes for the first time. Relationships  
71 explored previously, primarily in tropical oceanic (Barnes and Garstang 1982; Feng et al. 2015;  
72 de Szoke et al. 2017) or mid-latitude regions (Charba 1974; Engerer et al. 2008), such as time  
73 composites of wind and thermodynamic quantities relative to downdraft precipitation, are also  
74 revisited and compared to our findings over the Amazon. Downdrafts in MCSs and isolated cells  
75 are compared to inform decisions concerning their unified or separate treatment in next  
76 generation models. The effect of downdrafts on surface thermodynamics and boundary layer  
77 recovery are examined, and the origin height of the downdrafts explored, combining inferences  
78 from radar wind profiler data for vertical velocity and thermodynamic arguments from simple  
79 plume models. Lastly, statistics describing cold pool characteristics at the surface are presented  
80 and discussed for possible use as model diagnostics.

## 81 **2 Data and Methods**

82 Surface meteorological values (humidity, temperature, wind speed, precipitation) were  
83 obtained from the Aerosol Observing meteorological station (AOSMET) at the DOE ARM site  
84 in Manacapuru, Brazil, established as part of the GoAmazon2014/5 campaign. The record used  
85 in this study spans 10 Jan 2014–20 Oct 2015. Values in this study are averaged at 30-min  
86 intervals. Equivalent potential temperature is computed following Bolton (1980).

87 Thermodynamic profiles are obtained from radiosonde measurements within 6 h of a  
88 convective event. Radiosondes are launched at approximately 01:30, 7:30, 13:30, and 19:30 LT  
89 each day, with occasional radiosondes at 10:30 LT in the wet season. Profiles of vertical velocity

90 and radar reflectivity are obtained from a 1290 MHz radar wind profiler (RWP) reconfigured for  
91 precipitation modes. It has a beam width of  $6^\circ$  ( $\sim 1$  km at 10 km AGL), a vertical resolution of  
92 200 m, and a temporal resolution of 6 seconds (Giangrande et al. 2016).

93 Precipitation data at 25 km and 100 km, as well as convection classifications, are derived  
94 from an S-Band radar located approximately 67 km to the northeast of the primary  
95 GoAmazon2014/5 site (T3) at the Manaus Airport. Composite constant altitude low-level  
96 gridded reflectivity maps (constant altitude plan position indicators, CAPPIs) were generated,  
97 and the radar data were gridded to a Cartesian coordinate grid with horizontal and vertical  
98 resolution of 2 km and 0.5 km, respectively. Rain rates were obtained from the 2.5 km  
99 reflectivity using the reflectivity-rain rate (Z-R) relation  $Z=174.8R^{1.56}$  derived from disdrometer  
100 data. The spatially averaged rainfall rate over a 25 km and 100 km grid box were used in this  
101 study. The center of the 100 km grid box is shifted slightly to the right of center with respect to  
102 the T3 site due to reduced data quality beyond a 110 km radius.

103 All MCSs and isolated cells composited produce downdrafts that create a subsequent  
104 drop in  $\theta_e$  at the surface of more than 5 K in a 30-min period and have precipitation rates  
105 exceeding  $10 \text{ mm h}^{-1}$  within that same period. These criteria were chosen to examine the most  
106 intense downdraft events with the most well-defined vertical velocity signatures in the RWP  
107 data. Only data for events with complete vertical velocity data coverage over the 1 h period  
108 spanning the passage of the convective cells and centered around the maximum precipitation  
109 were composited and evaluated.

110 Isolated convective cells were identified by S-Band composite reflectivity, as in Fig. 1,  
111 and are defined as being less than 50 km in any horizontal dimension (contiguous pixels with  
112 reflectivity  $> 30$  dBZ) with a maximum composite reflectivity of greater than or equal to 45 dBZ.  
113 Following the criteria defined above, this resulted in the selection of 11 events, all of which were  
114 in the late morning or afternoon hours between 11:00 and 18:00 LT. Mesoscale convective  
115 systems follow the traditional definition of regions of contiguous precipitation at scales of 100  
116 km or greater (contiguous pixels with reflectivity  $> 30$  dBZ) in any horizontal dimension (e.g.  
117 Houze 1993; Houze 2004). All of the events sampled are characterized by a leading edge of  
118 convective cells with a trailing stratiform region (Fig. 1), which is the most common MCS type  
119 (Houze et al. 1990). The above criteria yielded 18 events: 11 in the late morning and early

120 afternoon hours (11:00-18:00 LT) and 6 in the late evening/early morning hours (22:00-11:00  
121 LT).

122 In Sect. 6, statistics are presented using nearly the entire two-year timeseries of  
123 meteorological variables at the GoAmazon2014/5 site, as well as 15 years of data (1996–2010)  
124 from the DOE ARM site at Manus Island in the tropical western Pacific. One-hour averages are  
125 computed in  $\Delta\theta_e$  and precipitation.

### 126 **3 Surface Thermodynamics**

127 Composites of surface meteorological variables are displayed in Fig. 2 for the 11 isolated  
128 cellular deep convective events coinciding with drops in equivalent potential temperature of 5 K  
129 or greater and precipitation rates greater than 10 mm h<sup>-1</sup> (see Sect. 2). The composites are  
130 centered 3 h before and after the 5-min interval marking the sharpest decrease in surface  $\theta_e$  in  
131 the mean timeseries (time 0). All timeseries averaged in the composites are shifted to the mean  
132 value at the  $\theta_e$  minimum and shading on the composites shows +/- 1 standard deviation for  
133 anomalies with respect to the  $\theta_e$  minimum to provide a sense of the variability. All differences  
134 quoted are the differences between the maximum and minimum values within the 1 h timeframe  
135 of convective cell passage (+/- 30 min of time 0), unless noted otherwise. Recovery percentages  
136 are computed as the difference between the minimum and maximum values between time 0 and  
137 some specified time afterwards, divided by the difference between the minimum and maximum  
138 values within 30 minutes of time 0.

139 In the two hours leading isolated convection, the CWV increases by 4.5 mm. The mean  
140 value of  $\theta_e$  30 minutes before the minimum recorded  $\theta_e$  are 353.7 K. As the systems pass, the  $\theta_e$   
141 mean value drops by an average 9.6 K to an average value of 344.2 K. Since the isolated  
142 convective cells observed occur in the daytime hours, the relative humidity is seen to drop  
143 steadily throughout the 3 h period leading the convection following the rise in temperatures with  
144 the diurnal cycle. The mean relative humidity (RH) rises to 82.3% within 30 minutes of system  
145 passage, which indicates that the downdrafts are sub-saturated when they reach the surface.  
146 Within the hour, temperatures drop by 4.2 K to 24.7 K, which is a smaller decrease than observed  
147 over mid-latitude sites (see Table 2 in Engerer et al. 2008 for a review of mid-latitude case  
148 studies) and specific humidity drops by 1.5 g kg<sup>-1</sup> to 15.7 g kg<sup>-1</sup>. Mean winds reach 6.4 m s<sup>-1</sup>,  
149 consistent with previous studies that document strong horizontal winds associated with the

150 leading edges of cold pools (e.g. Fujita 1963; Wakimoto 1982), but are lower than the observed  
151 values for mid-latitude storms (Engerer et al. 2008). Additionally, surface pressure often  
152 increases with the existence of a cold pool and is referred to as the meso-high (Wakimoto 1982).  
153 Here, it increases marginally by 0.6 hPa, but this value is much less than the typical values  
154 observed in mid-latitudes (e.g. Goff 1976; Engerer et al. 2008). Lastly, 32.7% (52.4%) of the  
155 temperature and 88.8% (88.9%) moisture depleted by the downdraft recovers within one (two)  
156 hour(s) of cell passage, with moisture recovering more quickly and by a greater percentage than  
157 temperature. It is likely that moisture recovers more quickly than temperature because of  
158 increased evaporation, while cloud cover persistence may continue to affect temperature. It is  
159 difficult to observe heat fluxes using eddy covariance techniques during precipitation, however,  
160 so we are unable to properly quantify this. Nevertheless, we include measurements of heat fluxes  
161 in Supplementary Figs. S1 and S2 to assess general trends.

162 Composites of surface meteorological variables are also shown in Fig. 2 for the 17 MCSs  
163 with surface  $\theta_e$  depressions of 5 K or greater and coincident precipitation rates of 10 mm h<sup>-1</sup> or  
164 greater. On average, the environment is more humid for MCSs than for the isolated cases, as is  
165 seen in the CWV composite. CWV between hours -3 and -1 leading the MCSs is higher on  
166 average than that observed leading the isolated cells, but increases to a comparable magnitude of  
167 ~59 mm within the hour. CWV increases by an average of 1.5 mm in the 2 h leading the passage  
168 of MCSs, which is slightly lesser than the increases reported in Taylor et al. 2017 (~4 mm) in the  
169 Sahel, though the Amazon is a more humid environment. Values of  $\theta_e$  leading the passage of  
170 MCSs (350.3 K) are 3.4 K lower than the  $\theta_e$  values leading the isolated cells (353.7 K), mostly  
171 due to lower surface temperatures (27.0 K for MCSs vs. 28.9 K for isolated cells). The  
172 precipitation occurs over a longer period than in the cases of isolated cells, as there is often  
173 stratiform rain trailing the leading convective cells. The stratiform rain and associated  
174 downdrafts also sustain the cooling and drying of the near surface layers for many hours lagging  
175 the precipitation maximum. The relative humidity maximum in the cold pool is 90.2% ( $\Delta RH =$   
176 13.3%), the specific humidity minimum is 15.4 g kg<sup>-1</sup> ( $\Delta q = 1.6$  g kg<sup>-1</sup>), and the temperature  
177 minimum is 22.8° C ( $\Delta T = 4.2$  K), with winds gusting to an average of 7.8 m s<sup>-1</sup> with the passage  
178 of the leading convective cells. The cold pools are thus cooler, drier, and nearer to saturation for  
179 the MCSs than for the isolated cells. It is worth noting that these statistics for MCSs are not  
180 greatly affected by the inclusion of nighttime events; composites for afternoon only MCSs yield

181 similar results. Overall, on average, the environments in which MCSs live are moister, they have  
182 colder, drier cold pools that are nearer to saturation, the winds at their leading edges are gustier,  
183 and the boundary layer recovers more slowly than for isolated cells.

184 Here, we composite events based on strict criteria identifying the strongest convective  
185 events (see Table S1 for dates/times of events composited in Figs. 2-6). In Supplemental Figs. S1  
186 and S2, we instead composite based on either a minimum  $\theta_e$  decrease or a minimum  
187 precipitation rate to test the sensitivity of the results presented here and include additional events.  
188 We also examine the sensitivity to averaging by compositing timeseries of meteorological  
189 variables averaged at 30-min intervals and plot results for 6 h leading and lagging the  
190 convection. The features discussed above associated with the passage of isolated systems and  
191 MCSs are generally robust to averaging and the choice of imposed criteria.

#### 192 **4 Downdraft Origin and the Effects of Mixing**

193 Many previous studies of moist convective processes use  $\theta_e$  as a tracer since it is  
194 conserved in the condensation and evaporation of water and for dry and moist adiabatic  
195 processes (e.g., Emanuel 1994). Tracing surface  $\theta_e$  to its corresponding value aloft has been used  
196 in many studies of tropical convection to examine potential downdraft origin heights (e.g. Zipser  
197 1969; Betts 1973, 1976; Betts and Silva Dias 1979; Betts et al. 2002). This assumes that  
198 downdraft air conserves  $\theta_e$  to a good approximation and that downdraft air originates at one  
199 height above ground level. Neither of these assumptions is likely to be true, as mixing is likely  
200 occurring between the descending air and the environmental air and thus originating from  
201 various levels. However, it can provide a useful reference point for further considerations.

202 We examine the mean  $\theta_e$  profiles to place bounds on mixing and downdraft origin with  
203 simple thermodynamic arguments and plume computations. The profiles composited in Fig. 3  
204 were measured within the 6 hours prior to the same MCSs and isolated events composited in Fig.  
205 2, less two MCS events that did not have corresponding radiosonde measurements. Simply  
206 matching the mean of the minimum  $\theta_e$  value within the cold pools to the minimum altitude at  
207 which those values are observed yields 2.1 km for MCSs (left panel, Fig. 3) and 1.5 km for  
208 isolated cells (right panel, Fig. 3). Again, this assumes that  $\theta_e$  is conserved and that the air  
209 originates at one altitude. If instead we assume that substantial mixing occurs with the  
210 surrounding environment and that air originates at multiple levels in the lower troposphere, it

211 would be plausible for more of the air reaching the surface to originate at altitudes greater than  
212 1.5 and 2.1 km for isolated cells and MCSs, respectively. This has been alluded to in previous  
213 studies (e.g. Zipser 1969; Gerken et al. 2016), which provide evidence that air originates in the  
214 middle troposphere.

215 To examine this, we mix air from above the altitude where the  $\theta_e$  matched the surface  
216 value (shown in the composites in Fig. 2) downward towards the surface, varying the  
217 entrainment rate (constant in pressure coordinates). To start, we use a mixing of  $0.001 \text{ hPa}^{-1}$ , as  
218 this is the constant entrainment value used in Brown and Zhang (1997) and Holloway and Neelin  
219 (2009), which can produce realistic updraft buoyancy profiles over tropical oceans given  
220 simplified assumptions about freezing (no freezing) and condensate loading (all condensate  
221 retained). For the MCS case, it is plausible that a downdraft could originate at a height of 2.5 km  
222 given this rate of mixing to reach the surface with characteristics given by Fig. 2. If instead the  
223 air were coming from the level of minimum  $\theta_e$  ( $\geq 3.2$  km, on average), an assumption similar to  
224 that made by many downdraft parameterizations (e.g. Zhang and McFarlane 1995; Tiedtke 1989;  
225 Kain and Fritsch 1990), mixing would need be 2 times greater. For the isolated cells, mixing  
226 rates appear to need to be greater in order to produce results consistent with cold pool  
227 characteristics at the surface. If we start out at  $0.002 \text{ hPa}^{-1}$ , the rate sufficient for a minimum  $\theta_e$   
228 origin for the MCSs, this only yields an origin height of 1.7 km. If instead we assume the air  
229 originates somewhere near the level of minimum  $\theta_e$ , mixing would need to be at least  $0.004 \text{ hPa}^{-1}$   
230 <sup>1</sup>. For simplicity the discussion above is in terms of mean profiles – the standard error of the  
231 profiles is shown at 50 mb intervals – but computation based on individual profiles yields a  
232 standard error in the inferred mixing up about  $0.0005 \text{ hPa}^{-1}$ . For reference, in the European  
233 Center for Medium Range Weather Forecasting Integrated Forecasting System (ECMWF IFS)  
234 and Goddard Institute for Space Studies (GISS) Model E2 GCM (Kim et al. 2013), downdrafts  
235 mix at a rate of  $2 \times 10^{-4} \text{ m}^{-1}$  (roughly equivalent to  $0.002 \text{ hPa}^{-1}$  in pressure coordinates in the  
236 lower troposphere).

237 To summarize, this analysis is suggestive of bounds on mixing coefficients for downdraft  
238 parameterizations. If downdrafts of both convective types mix at similar rates, these results  
239 suggest that downdrafts from isolated cells originate at lower levels than MCSs, on average. If  
240 instead downdrafts originate from the level of minimum  $\theta_e$ , mixing rates of  $0.002 \text{ hPa}^{-1}$  for  
241 MCSs and  $0.004 \text{ hPa}^{-1}$  for isolated convection would be consistent with mean thermodynamic

242 conditions. In Sections 5 and 6, we provide a complementary probabilistic perspective on levels  
243 of origin.

## 244 **5 Vertical Velocity and Downdraft Probability**

245 Figure 4 composites reflectivity ( $Z$ ), vertical velocity ( $w$ ), and the probability of  
246 observing downdrafts ( $w < 0 \text{ m s}^{-1}$ ) for the 11 cases of isolated cellular convection meeting the  
247 minimum  $\Delta\theta_e$  criteria of -5 K and minimum precipitation criteria of  $10 \text{ mm h}^{-1}$ . Time 0 is the  
248 time right before the sharpest decrease in  $\theta_e$  and maximum precipitation (slightly offset from the  
249 composites in Fig. 2). A 3 h window is composited for reference, but the interval of primary  
250 interest is the 1 h window within which the minimum  $\Delta\theta_e$  and maximum precipitation are  
251 observed. To highlight the interval of interest, the 1 h intervals leading and lagging this period  
252 are masked out.

253 The drop in  $\theta_e$  is coincident with the passage of the isolated cell and its main updraft and  
254 precipitation-driven downdraft. Mean reflectivity exceeding 40 dBZ is observed during this  
255 period, as are strong updrafts in the middle-upper troposphere. The cell then dissipates and/or  
256 moves past the site within an hour. A downdraft is observed directly below and slightly trailing  
257 the updraft core. This is the downdraft that is associated with the largest drop in surface  $\theta_e$ . As is  
258 suggested in the literature, these are mainly driven by condensate loading and evaporation of  
259 precipitation and are negatively buoyant. The probability of observing negative vertical velocity  
260 (threshold  $< 0 \text{ m s}^{-1}$ ) within the 30 minutes of minimum  $\Delta\theta_e$  and maximum precipitation is  
261 highest in the lower troposphere (0-2 km), consistent with precipitation-driven downdrafts  
262 observed in other studies (Sun et al. 1993; Cifelli and Rutledge 1994).

263 There is also a high probability of downdrafts in air near the freezing level (masked out in  
264 the vertical velocity retrievals, as there is large error associated with retrievals near the freezing  
265 level; Giangrande et al. 2016). It appears likely, however, that these downdrafts are  
266 discontinuous in height more often than not, as high probabilities are not observed coincidentally  
267 in the lowest levels beneath these downdrafts. These mid-upper level downdrafts are documented  
268 in previous studies of MCSs, which suggest that they form in response to the pressure field (e.g.  
269 Biggerstaff and Houze 1991), can occur quite close to the updraft (Lily 1960; Fritsch 1975), and  
270 are positively buoyant (Fovell and Ogura 1988; Jorgensen and LeMone 1989; Sun et al. 1993).  
271 These motions produce gravity waves in the stratosphere, as is discussed in Fovell et al. (1992).

272 Figure 5 shows the same composites for the 18 MCSs observed. They, too, have high  
273 reflectivity (mean > 40 dBZ) in the 30 minutes coincident with the minimum  $\theta_e$  and a defined  
274 updraft extending up to the upper troposphere. Downdrafts occurring coincident with the  
275 minimum  $\theta_e$  are observed directly below the updraft signature in the mean vertical velocity  
276 panel, and the probabilities are greatest below the freezing level. There are likely also mesoscale  
277 downdrafts in the trailing stratiform region of the MCSs, although difficult to discern here, which  
278 Miller and Betts (1977) suggest are more dynamically driven than the precipitation-driven  
279 downdrafts associated with the leading-edge convection. These likely sustain the low  $\theta_e$  air in  
280 the boundary layer for hours after the initial drop, observed in Fig. 2. Vertical motions in the  
281 stratiform region are weaker than in the convective region, and on average, as in Cifelli and  
282 Rutledge (1994), rarely exceed  $1 \text{ m s}^{-1}$ .

283 Figure 6 is a concise summary of the results presented in Figs. 4 and 5, showing the mean  
284 vertical velocity within the 30-min of sharpest  $\Delta\theta_e$  for MCSs and isolated cells. Means are for  $w$   
285  $> 0 \text{ m s}^{-1}$  only (updrafts) or  $w < 0 \text{ m s}^{-1}$  only (downdrafts) at each height (as in Giangrande et al.  
286 2016) and are thus characteristic of magnitudes rather than bulk air motions. Updraft and  
287 downdraft strength increases with height, consistent with results from previous studies evaluating  
288 a broader range of conditions (May and Rajopadhyaya 1999; Kumar et al. 2015; Giangrande et  
289 al. 2016). The corresponding mean probability of observing such motions at each height is  
290 shown in the right panel. Probabilities, which can be interpreted loosely as convective area  
291 fractions (Kumar et al. 2015; Giangrande et al. 2016), are largest below the freezing level for  
292 downdrafts and in the 3-7 km region for updrafts. The probability of downdrafts for both isolated  
293 cells and MCSs increases nearly linearly towards the surface below the freezing level. Thus, this  
294 behavior in the lowest 3 km summarizes our results from the previous two figures and suggests  
295 that the mean properties of downdrafts are such that air accumulates along descent – analogous  
296 to mixing. The probability and vertical velocity for both MCSs and isolated cells correspond to  
297 mass flux profiles that increase nearly linearly throughout the lower troposphere for updrafts and  
298 that decrease nearly linearly throughout the lower troposphere for downdrafts, as seen in  
299 Giangrande et al. (2016) over a broader range of convective conditions. To give some sense of  
300 the error in these estimates, Wilson score intervals (lower bound/upper bound) for the 18 MCSs  
301 cases are roughly 0.16/0.23 for a probability of 0.7, 0.21/0.21 for a probability of 0.5, and  
302 0.23/0.16 for a probability of 0.3; for 11 events (as in the isolated cases), the intervals are

303 roughly 0.19/0.28 for a probability of 0.7, 0.25/0.25 for a probability of 0.5, and 0.28/0.19 for a  
304 probability of 0.3.

305         These results, and those presented in the previous section, suggest a range of downdraft  
306 origin levels throughout the lowest few kilometers within both organized and unorganized  
307 convective systems. Several observational studies corroborate the evidence presented here that a  
308 majority of the air reaching the surface in deep convective downdrafts originates at low-levels  
309 (Betts 1976; Barnes and Garstang 1982; Betts et al. 2002; de Szoke et al. 2017). Betts (1976)  
310 concluded that the downdraft air descends approximately only the depth of the subcloud layer  
311 (~150 mb). Betts et al. (2002) cited a range of 765-864 hPa for the first levels at which the  
312 surface  $\theta_e$  values matched those of the air aloft. Additionally, there are many modeling studies  
313 that provide evidence of these low-level origins (Moncrieff and Miller, 1976; Torri and Kuang,  
314 2016). Recently, Torri and Kuang (2016) used a Lagrangian particle dispersion model to show  
315 that precipitation-driven downdrafts originate at very low levels, citing an altitude of 1.5 km  
316 from the surface, with the mode of the distribution nearer to 1 km. These conclusions are  
317 consistent with our results here, suggesting that downdraft parameterizations substantially weight  
318 the contribution of air from the lower troposphere (e.g. with substantial mixing and/or modifying  
319 the height of downdraft origin).

## 320 **6 Relating Cold Pool Thermodynamics to Precipitation**

321         As seen in previous sections, the passage of both organized and unorganized convection  
322 can lead to substantial decreases in  $\theta_e$  resulting mainly from precipitation-driven downdrafts  
323 formed from the leading convective cells. In this section, we search for robust statistical  
324 relationships between key thermodynamic variables for potential use in improving downdraft  
325 parameterizations in GCMs. These statistics differ from those presented in Figs. 2-6, as these  
326 statistics are not conditioned on convection type and sample both precipitating and non-  
327 precipitating points within the timeseries analyzed. All data available at the surface  
328 meteorological station during the GoAmazon2014/5 campaign from 10 Jan 2014–20 Oct 2015  
329 are included in these statistics.

330         The first of these statistics conditionally averages precipitation rate by  $\Delta\theta_e$  (Fig. 7),  
331 variants of which have been discussed in previous studies (Barnes and Garstang 1982; Wang et  
332 al. 2016). Our statistics mimic those shown in previous work relating column-integrated moisture

333 to deep convection over tropical land (Schiro et al. 2016) and ocean (Neelin et al. 2009;  
334 Holloway and Neelin 2009). The direction of causality in the CWV-precipitation statistics,  
335 however, is the opposite of what is presented here. CWV is thought to primarily be the cause of  
336 intense precipitation and deep convection, while here the  $\Delta\theta_e$  observed is a direct result of the  
337 precipitation processes and associated downdraft. Nevertheless, examining the distribution of  
338  $\Delta\theta_e$  observed at the surface and magnitudes of the rain rates associated with the largest drops in  
339  $\Delta\theta_e$  across different regions in the tropics can place bounds on downdraft behavior. We will also  
340 conditionally average  $\Delta\theta_e$  by precipitation rate, a more physically consistent direction of  
341 causality.

342 Figure 7 shows precipitation rates binned by  $\Delta\theta_e$  for in-situ and radar-derived  
343 precipitation. Bins are 1 K in width (bins with less than 5 observations are eliminated from the  
344 analysis) and precipitating events are defined as having rain rates greater than 2 mm h<sup>-1</sup>. This  
345 threshold is chosen based on results from Barnes and Garstang (1982), who suggested it as a  
346 minimum precipitation rate for observing coincident decreases in  $\theta_e$  at the surface. These  
347 statistics mainly suggest that a majority of the substantial decreases in  $\theta_e$  at the surface occur  
348 coincidentally with heavy precipitation, which is particularly evident from the sharp increase in  
349 probability of precipitation (middle panel).

350 S-Band radar data are averaged in 25 km and 100 km grid boxes surrounding the  
351 GoAmazon2014/5 site to examine the precipitation- $\Delta\theta_e$  relation with model diagnostics in mind  
352 (Fig. 7). The  $\Delta\theta_e$  shown is in situ, since we do not have spatial information in the moisture and  
353 temperature fields at a high enough temporal frequency to match the radar data. Out to 25 km,  
354 the statistics are very similar to those observed using in situ precipitation. Theoretical (Romps  
355 and Jevanjee 2015), modeling (Tompkins 2001; Feng et al. 2015), and observational (Feng et al.  
356 2015) studies have all examined typical sizes of cold pools, which can be on the order of 25 km  
357 in diameter for any one cell. Cold pools can combine, however, to form a larger, coherent  
358 mesoscale-sized cold pool (radius of 50 km or greater), as is commonly associated with  
359 mesoscale convective systems (Fujita 1959; Johnson and Hamilton 1988). Therefore, it is likely  
360 that our use of the in situ  $\Delta\theta_e$ , assuming cold pool properties are somewhat homogeneous in  
361 space, is appropriate for scales up to 25 km. Beyond this scale, it is likely that the  $\Delta\theta_e$  would be  
362 smoothed by averaging, particularly for the smaller isolated cells, as would precipitation. For the  
363 conditional average precipitation (Fig. 7), this effect may be seen at the 100 km averaging scale.

364 The probabilities are, however, robust to averaging. This suggests that when drops in  $\theta_e$  occur  
365 locally, there tends to be good correspondence to precipitation both locally and in the  
366 surrounding 25 and 100 km averaging areas.

367 The width of the distribution of precipitating points is of greatest interest here. The  
368 distribution of precipitating points peaks just shy of a  $\Delta\theta_e$  of 0 K, indicating that most  
369 precipitation events have low rain rates and do not occur coincidentally with an appreciable drop  
370 in  $\theta_e$ . The frequency of precipitation drops off roughly exponentially towards lower  $\Delta\theta_e$ . An  
371 interesting feature is the lower bound observed in  $\Delta\theta_e$  near -15 K. The mean profiles in Fig. 3  
372 show that, on average, this value of -15 K would be consistent with air originating from the level  
373 of minimum  $\theta_e$  and descending undiluted to the surface. The frequency of observing these values  
374 suggests that air very rarely reaches the surface from these altitudes (3 km or higher) undiluted.  
375 The  $\theta_e$  probability distribution is consistent with the results of Sect. 5, indicating that the  
376 probability of air from a given level of origin reaching the surface increases toward the surface  
377 through the lowest 3 km.

378 Figure 8 shows remarkable similarity in these statistics when comparing across regions to  
379 a DOE ARM site at Manus Island in the tropical western Pacific. As  $\Delta\theta_e$  decreases, in situ  
380 precipitation rates sharply increase. The PDFs, as well as the steepness and locations of the  
381 pickups, are remarkably consistent. Again, the sharpness of these curves is a result of the  
382 strongest precipitation events coinciding with the strongest decreases in  $\theta_e$ , shown in the middle  
383 panels in Fig. 8, where the probability of observing coincident precipitation is greatest at low  
384  $\Delta\theta_e$ .

385 It is then of interest to see if for a given precipitation rate we can expect a particular  $\Delta\theta_e$ ,  
386 as this is the proper direction of causality. Figure 9 conditionally averages  $\Delta\theta_e$  by precipitation  
387 rate (1-h averages). The minimum  $\Delta\theta_e$  and maximum precipitation within a 3-h window are  
388 averaged to minimize the effects of local precipitation maxima occurring slightly before or after  
389 the maximum in  $\Delta\theta_e$ . Comparing Fig. 8 and Fig. 9 shows that there can be strong precipitation  
390 events without large, corresponding decreases in surface  $\theta_e$ , but that large decreases in surface  $\theta_e$   
391 are almost always associated with heavy precipitation. Beyond about  $10 \text{ mm h}^{-1}$  there is a high  
392 probability of observing large, negative  $\Delta\theta_e$  and an apparent limit in mean  $\theta_e$  decreases with rain  
393 rate. This makes physical sense, as discussed above (see also Barnes and Garstang 1982), since  
394 cooling is limited by the maximum difference between the surface  $\theta_e$  and the  $\theta_e$  minimum aloft.

395           The average  $\Delta\theta_e$  for rain rates exceeding  $10 \text{ mm h}^{-1}$  is about  $-5 \text{ K}$  for the Amazon and  $-4$   
396  $\text{K}$  for Manus Island (Fig. 9). This statistic could be of use in constraining downdraft parameters  
397 to be consistent with surface cooling and drying observed in nature. The results for  $100 \text{ km}$   
398 overlaid in Fig. 9 suggest that even though precipitation rates at  $100 \text{ km}$  are not simply  
399 proportional to in situ rain rates, the main feature of the statistic is robust to averaging  
400 precipitation out to a typical GCM grid scale. There are still, however, open questions about  
401 scale dependence and how much cooling or drying should be observed for varying space and  
402 time scales, given that we are using in situ  $\Delta\theta_e$  for all of the statistics presented. Overall, if  
403 convective precipitation is present in a GCM grid, a corresponding  $\Delta\theta_e$  should result within a  
404 range consistent to those observed here, subject to scale dependence.

405           To summarize the results from Figs. 7-9 and provide additional diagnostics, we can ask  
406 what fraction of precipitation occurs within a given time window of an appreciable drop in  $\theta_e$ ,  
407 and how this fraction changes with precipitation intensity. At the GoAmazon2014/5 site, for  
408  $\Delta\theta_e \leq -2 \text{ K}$ , the fraction of precipitation events within the same hour exceeding  $1, 5, 10 \text{ mm h}^{-1}$ ,  
409 respectively, is  $43\%$ ,  $63\%$ , and  $74\%$ . Similar fractions (though smaller) are found at Manus Isl.:  
410  $37\%$ ,  $53\%$ , and  $63\%$ , respectively. Increasing the required value of  $\Delta\theta_e$  yields smaller fractions –  
411 e.g., for  $\Delta\theta_e \leq -4 \text{ K}$ , corresponding fractions at the GoAmazon2014/5 site are about  $75\%$  of the  
412 above values ( $37\%$ ,  $53\%$ , and  $62\%$ , respectively). Based on arguments presented above about  
413 typical cold pool sizes, these result are likely applicable to GCM grid scales of  $0.25^\circ$  or less, with  
414 evidence of consistency out to  $1^\circ$ .

## 415 **7 Conclusions**

416           Convective events sampled during the GoAmazon2014/5 campaign compare downdraft  
417 characteristics between MCSs and isolated cells and examine their respective effects on surface  
418 thermodynamics. All events included in the analysis passed directly over the GoAmazon2014/5  
419 site with minimum precipitation rates of  $10 \text{ mm h}^{-1}$  and  $\Delta\theta_e$  less than or equal to  $-5 \text{ K}$ . The  
420 isolated events sampled occurred in the afternoon hours only and were characterized by average  
421 decreases of  $1.5 \text{ g kg}^{-1}$  in specific humidity,  $4.2 \text{ K}$  in temperature, and  $9.6 \text{ K}$  in  $\theta_e$ , with an  
422 increase of  $4.2 \text{ m s}^{-1}$  in wind speed at the surface. More than half ( $59\%$ ) of the deficit in  $\theta_e$   
423 observed with the passage of the cells recovers within  $1 \text{ h}$ , on average, with the moisture  
424 recovering faster than temperature and constituting a larger fraction of the total  $\theta_e$  recovered.

425 MCSs show similar decreases in temperature (4.2 K), moisture (1.6 g kg<sup>-1</sup>), and thus  $\theta_e$  (9.7 K)  
426 at the surface. The  $\theta_e$  recovers more slowly for MCSs due to the mesoscale downdrafts and  
427 associated precipitation in their trailing stratiform regions.

428 Vertical velocity profiles from a radar wind profiler show that the probability of  
429 observing downdraft air during the 30 minutes of observed minimum  $\Delta\theta_e$  increases with  
430 decreasing height in the lowest 3 km for both isolated cells and MCSs. This vertical structure of  
431 the downdraft probability is consistent with negative vertical velocities originating at various  
432 levels within this layer and continuing to the surface. Considering complementary  
433 thermodynamic arguments, without mixing, profiles of  $\theta_e$  suggest that origin levels at average  
434 altitudes of 1.4 and 2.1 km for isolated cells and MCSs, respectively, would be consistent with  
435 average cold pool  $\theta_e$  for these cases. A minimum in  $\theta_e$  is observed between 3 and 7 km, on  
436 average, so for air to originate above 3 km, simple plume calculations suggest that downdrafts in  
437 MCSs would have to be mixing with environmental air at an approximate rate of 0.002 hPa<sup>-1</sup>  
438 along descent and at a rate roughly 2 times greater (0.004 hPa<sup>-1</sup>) for isolated cells. This would  
439 imply mass entering the downdraft throughout the lowest few kilometers. Overall the vertical  
440 velocity and thermodynamic constraints are consistent in suggesting a spectrum of downdraft  
441 mass origin levels throughout the lowest few kilometers.

442 Robust statistical relationships between  $\Delta\theta_e$  and precipitation are examined from nearly  
443 two years of data at the GoAmazon2014/5 site and 15 years of data at the DOE ARM site at  
444 Manus Island in the tropical western Pacific. We conditionally average precipitation by  $\Delta\theta_e$ ,  
445 similar to the statistics of precipitation conditioned on a thermodynamic quantity we consider for  
446 convective onset statistics. Here, however, the most likely direction of causality differs in that  
447 the  $\theta_e$  drop is caused by the downdraft that delivers the precipitation (as opposed to the  
448 thermodynamic profile providing convective available potential energy for an updraft). For in  
449 situ precipitation, the conditional average precipitation exhibits a sharp increase with decreasing  
450  $\Delta\theta_e$ , which is similar in magnitude over land and ocean, reaching roughly 10 mm hour<sup>-1</sup> at a  $\Delta\theta_e$   
451 of -10 K. For area-averaged precipitation on scales typical of GCM grids, precipitation  
452 magnitudes are smaller for strong, negative  $\Delta\theta_e$ , consistent with events with large  $\Delta\theta_e$  occurring  
453 at localized downdraft locations within a larger system with smaller area-average precipitation.  
454 The probability distributions of  $\Delta\theta_e$  (for precipitating and non-precipitating points) over land and  
455 ocean are also remarkably similar. Distributions show exponentially decreasing probability with

456 decreasing  $\Delta\theta_e$ , providing additional evidence that downdraft plumes originating in the lowest  
457 levels are orders of magnitude more likely than plumes descending with little mixing from the  
458 height of minimum  $\theta_e$ . Conditionally averaging  $\Delta\theta_e$  by precipitation (the most likely direction of  
459 causality) suggests an average limit in  $\Delta\theta_e$  of -4 K to -5 K given high precipitation typical of  
460 downdraft conditions. The corresponding 90<sup>th</sup> percentile yields  $\Delta\theta_e$  of roughly -10 K, consistent  
461 with results obtained from compositing strong downdrafts. The robustness of these statistics over  
462 land and ocean, and to averaging in space at scales appropriate to a typical GCM resolution,  
463 suggests possible use of these statistics as model diagnostic tools and observational constraints  
464 for downdraft parameterizations.

690 **Figures**

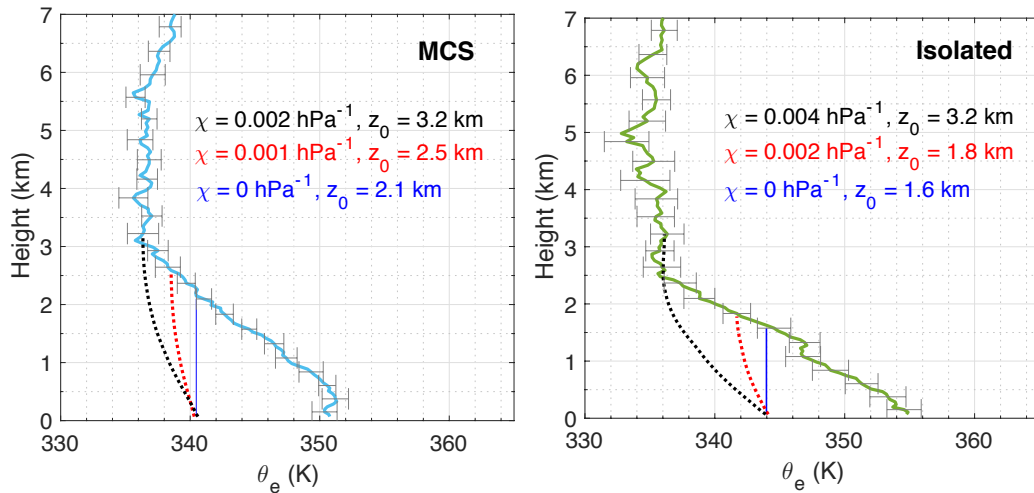

691  
 692 **Figure 1: Reflectivity (dBZ) from S-Band Radar on 01 Apr 2014 at 15:00 UTC (11:00 LT)**  
 693 **before the passage of an MCS, and at 17 Jul 2017 at 21:24 UTC (17:24 LT) after the**  
 694 **passage of an isolated cell. The red dot indicates the location of the S-Band radar, and the**  
 695 **blue dot indicates the location of the main GOAmazon site (T3).**

696  
 697 **Figure 2: Composites of meteorological variables from the AOSMET station at site T3 3 h**  
 698 **leading and 3 h lagging the minimum in equivalent potential temperature (0 h; 2<sup>nd</sup> panel)**  
 699 **coincident with the passage of isolated cells (green) and MCSs (blue). Shading denotes +/- 1**  
 700 **standard deviation of anomalies with respect to 0 h; bars on precipitation are +/- 1**

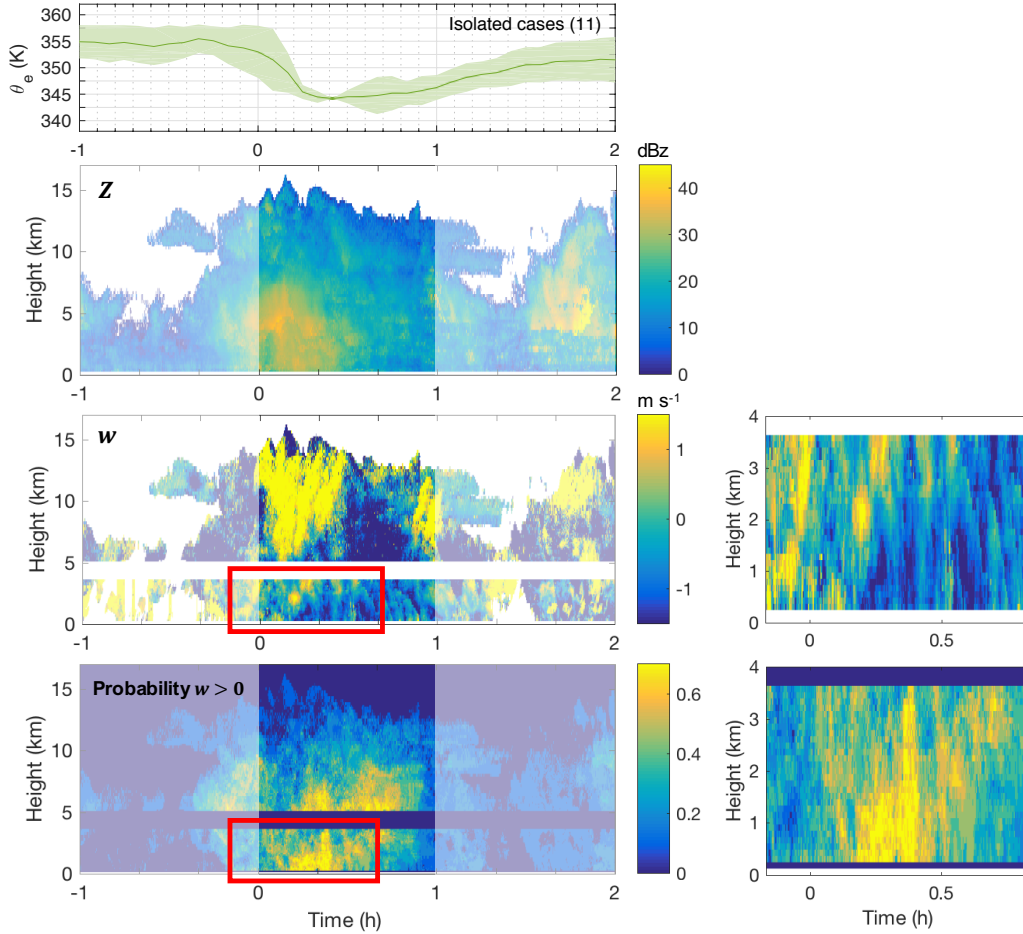

701 standard deviation for each time interval. Standard errors would be smaller by a factor of  
702 0.3 for isolated cells and 0.2 for MCSs.

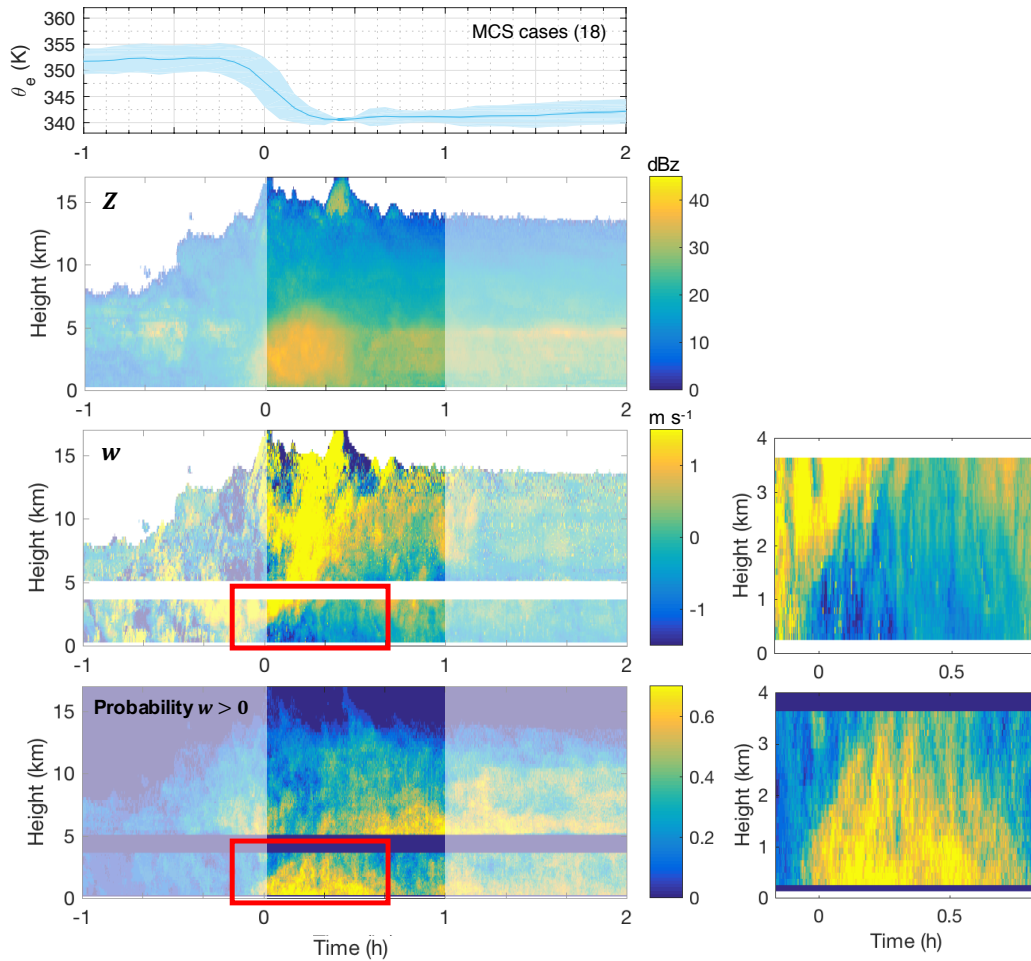

703  
704 **Figure 3: Mean profiles of  $\theta_e$  within 6 h leading the passage of a deep convective event for**  
705 **MCSs (16 profiles; left) and isolated cells (11 profiles; right). Dashed lines indicate the**  
706 **mean descent path for plumes originating at various altitudes and mixing with the**  
707 **environment at various rates; solid blue line shows mean descent without mixing. Error**  
708 **bars are +/- 1 standard error.**

709

710

711 **Figure 4: The composite  $\theta_e$  (K; top panel), mean reflectivity (dBZ; second panel), mean**  
 712 **vertical velocity (third panel;  $\text{m s}^{-1}$ ), and probability of  $w < 0 \text{ m s}^{-1}$  (bottom panel) observed**  
 713 **by the radar wind profiler at T3 leading and lagging the passage of isolated cells. Plots of  $w$**   
 714 **and probability zoomed in time and height (as outlined in red) are shown to the right of the**  
 715 **corresponding plots for visual clarity.**

716

717 **Figure 5: Same as Fig. 5, but leading and lagging the passage of MCSs.**

718

719

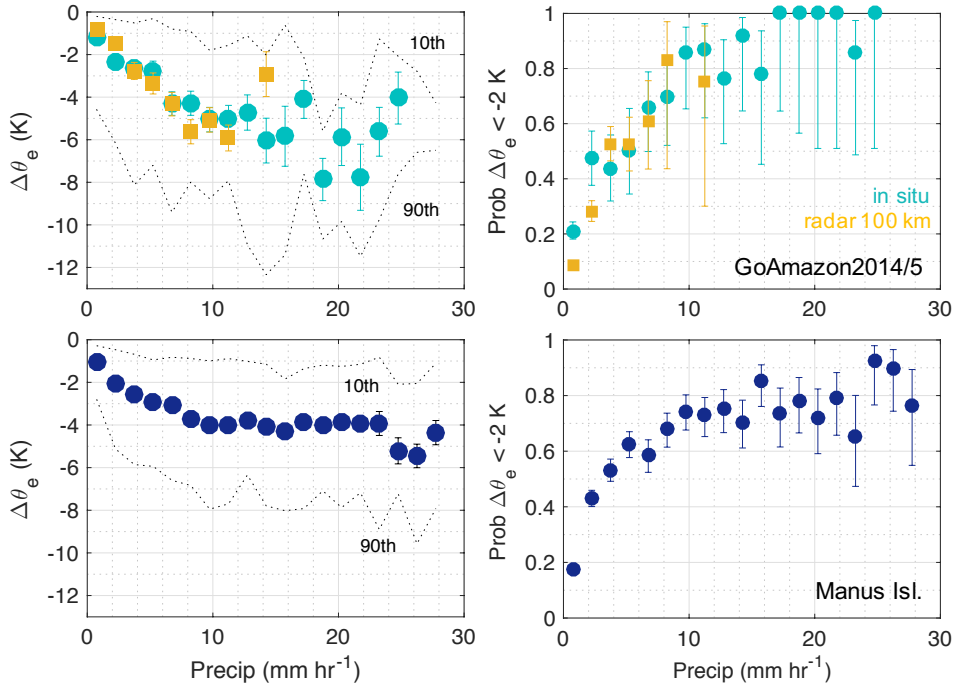

720 **Figure 6: (left) Mean vertical velocity profiles for MCSs and isolated cells for downdrafts**  
 721 **( $w < 0 \text{ m s}^{-1}$ ; dashed) and updrafts ( $w > 0 \text{ m s}^{-1}$ ; solid). (right) Mean probability of**  
 722 **observing updrafts or downdrafts as a function of altitude. Means are composited from**  
 723 **data in the 30 minutes of largest drop in  $\Delta\theta_e$  (0-0.5 h in Figs. 4 and 5).**  
 724

725  
 726 **Figure 7: (left) Precipitation (1-h averages) conditionally averaged by coincident changes in**  
 727 **equivalent potential temperature ( $\Delta\theta_e$ ) at the GOAmazon site. Precipitation values**  
 728 **corresponds to the  $\theta_e$  values at the end of each differencing interval. Bins are a width of  $1^\circ$**   
 729 **and error bars represent the standard error. (middle) The probability of precipitation ( $> 2$**   
 730  **$\text{mm h}^{-1}$ ) occurring for a given  $\Delta\theta_e$ . Error bars represent Wilson score intervals from 5-**  
 731 **95%. (right) The frequency of occurrence of  $\Delta\theta_e$  and precipitation for a given  $\Delta\theta_e$**   
 732 **(precipitation  $> 2 \text{ mm h}^{-1}$ ). Precipitation derived from S-Band radar reflectivity at spatial**  
 733 **averages over 25 km and 100 km grid boxes surrounding the GOAmazon site are included**  
 734 **for comparison to the in situ precipitation.**  
 735

736  
 737 **Figure 8: Same as Fig. 7, except comparing results from in situ data only at the**  
 738 **GoAmazon2014/5 site (aqua) and the DOE ARM site at Manus Island (navy).**

739

740

741 **Figure 9:  $\Delta\theta_e$  conditionally averaged by coincident precipitation (1-h averages) at the**  
 742 **GOAmazon site (top) and at Manus Island (bottom). Precipitation values corresponds to**  
 743 **the  $\theta_e$  values at the end of each differencing interval. Bins are a width of  $1.5 \text{ mm hr}^{-1}$ . Error**  
 744 **bars represent the standard error (left panels), and the 10<sup>th</sup> and 90<sup>th</sup> percentile values for**  
 745 **each bin are drawn for reference (right panels). Error bars on the probability represent**  
 746 **Wilson score intervals from 5-95%.**
