**Abstract.** The framework of universal multifractals (UM) characterizes the spatio-temporal variability of geophysical data over a wide range of scales with only a limited number of scale-invariant parameters. This work aims to clarify the link between multifractals and more conventional weather descriptors and to show how they can be used to perform a multi-scale evaluation of model data.

5 The first part of this work focuses on a multifractal analysis of the climatology of precipitation intensities simulated by the COSMO numerical weather prediction model. Analysis of the spatial structure of the multifractal parameters and their correlations with external meteorological and topographic descriptors reveals that simulated precipitation tends to be smoother at higher altitudes, and that the mean intermittency is mostly influenced by the latitude. A hierarchical clustering was performed on the external descriptors, yielding three different classes, which correspond  
10 roughly to Alpine/continental, Mediterranean and temperate regions. Distributions of multifractal parameters within these three classes are shown to be statistically significantly different, indicating that the multifractal signature of rain is indeed climate-dependent.

The second part of this work is event based and focuses on the smaller scales. The multifractal parameters of precipitation intensities at the ground are compared with those obtained from the Swiss radar composite during  
15 three events corresponding to typical synoptic conditions over Switzerland. The results of this analysis show that the COSMO simulations exhibit spatial scaling breaks that are not present in the radar data, indicating that the model is not able to simulate the observed variability at all scales. Comparison of the operational one-moment microphysical parameterization scheme of COSMO with a more advanced two-moment scheme reveals that, while  
20 no scheme outperforms systematically the other, the two-moment scheme tends to produce larger extreme values and more discontinuous precipitation fields which agree better with the radar composite .

## 1 Introduction

Validation of precipitation fields simulated by a numerical weather prediction model is a delicate task as reference data (rain gauges, radar scans) are typically available at a different spatial and temporal resolution than the model. Traditional point-based verification scores are generally unable to provide sufficient information about the forecast quality, as they do not [take into consideration](#) the spatial structure and are affected by the so-called “double penalty” (Gilleland et al., 2009). Indeed, small displacements in the simulated forecast features will be penalized twice, once for missing the observation and again for giving a false alarm. The impact of this double penalty is related to the variability of the simulated fields, which tends to increase with the resolution of the model. Numerous methods have been proposed in recent years to address this issue. Some methods rely on the use of traditional scores but applied on filtered fields, estimating the forecast performance as a function of scale and precipitation intensity (e.g., Ebert, 2008; Mittermaier et al., 2013) while others detect specific features on forecast and verification fields and compare these features based on their attributes (e.g., Davis et al., 2006; Wernli et al., 2008). [Yet another type of validation techniques relies](#) on the separation of scales with the use of space-frequency tools such as the 2D wavelet transform (Vasić et al., 2007).

Multifractals (MF) offer a convenient way to [analyse](#) the variability of complex geophysical systems globally over a wide range of scales. In the context of multifractals, the statistical properties of a field are related to the resolution by a power-law (Schertzer and Lovejoy, 1987). Universal Multifractals (UM) are a framework [of multifractals](#) based on the concept of multiplicative cascades, which allows [for analysis and simulation of](#) a high variability across scales with only a small number of parameters with physical meaning (e.g., Schertzer and Lovejoy, 1987; Lovejoy and Schertzer, 2007). In meteorology, UM have been used to study a large variety of complex natural phenomena such as the distribution of rainfall intensities at the ground (e.g., Marsan et al., 1996; Gires et al., 2015a, b), atmospheric turbulence (e.g., Parisi and Frisch, 1985a; Schertzer and Lovejoy, 2011) or climate change (e.g., Schmitt et al., 1995; Royer et al., 2008).

Gires et al. (2011) used the UM framework to compare simulations of Meso-NH, a non-hydrostatic numerical weather prediction (NWP) model developed by Météo-France, with composite radar images during a heavy convective rainfall event. This comparison showed that the radar quantitative precipitation estimation (QPE) and the model simulations were generally characterized by similar ranges of scaling and agreed quite well with a simple space-time scaling model.

Gires et al. (2011)~~'s work~~ focused on a rather flat area and a single event. It is therefore relevant to study [the](#) multifractal behavior of model simulations and radar observations over a more complex terrain [and](#) in a broader synoptic context. This work is thus divided in two parts. The first part aims to illustrate the use of multifractals for characterizing regional patterns of precipitation and to relate multifractals to synoptic and topographic features. To this end a [large-scale](#) analysis of five years of simulated precipitation intensities from the COSMO numerical weather prediction model is conducted. The multifractal properties of the corresponding climatology of precipitation

intensities are then studied and related to several regional and synoptic descriptors. The second part of this paper extends the work of Gires et al. (2011) over Switzerland for three different synoptic situations (snowstorm, convective summer precipitation and stratiform rainfall) by using simulated precipitation intensities from the COSMO model run with different microphysical parameterizations.

5 This article is structured as follows: in Section 2, the COSMO model as well as the Swiss radar composite are briefly described. The studied events as well as the radar data sets and model variables are then described in detail. Section 3 provides a short summary of the UM framework. In Section 4, a climatological analysis of precipitation intensities simulated by COSMO is performed with the UM framework in relation with external geographical and meteorological descriptors. In Section 5, a spatial and temporal analysis of precipitation intensities on the ground  
 10 simulated by COSMO is performed during three characteristic events. The results are then compared with the UM analysis of the radar composite. Finally, Section 6 gives a summary of the main results and concludes this work.

## 2 Description of the data

### 2.1 The COSMO model

The COSMO model is a mesoscale limited area numerical weather prediction model initially developed as the  
 15 Lokal Modell (LM) at the Deutscher Wetterdienst (DWD). It is now operated and developed by various weather services in Europe, including Switzerland. Besides its operational applications it is also used for scientific purposes in weather prediction and for regional climate simulations. The COSMO model is a non-hydrostatic model based on the fully compressible primitive equations integrated using a split-explicit third-order Runge–Kutta scheme (Wicker and Skamarock, 2002). The spatial discretization is based on a fifth-order upstream advection scheme on  
 20 an Arakawa C-grid with Lorenz vertical staggering. Height-based Gal-Chen coordinates are used in the vertical (Gal-Chen and Somerville, 1975). The model uses a rotated coordinate system where the pole is displaced to ensure approximately horizontal resolution over the model domain. Sub-grid scale processes are taken into account with parameterizations. In particular, grid-scale clouds and precipitation are parameterized operationally with a one-moment scheme similar to Rutledge and Hobbs (1983) and Lin et al. (1983), with five hydrometeor categories: rain,  
 25 snow, graupel, ice crystals and cloud droplets. Snow is assumed to be in the form of rimed aggregates of ice-crystals that have become large enough to have an appreciable fall velocity. Cloud ice is assumed to be in the form of small hexagonal plates that are suspended in the air and have no appreciable fall velocity. The particle size distributions (PSD) are assumed to be exponential for all hydrometeors except for rain where a gamma PSD is used:

$$N(D) = N_0 D^\mu \exp(-\lambda \cdot D) \quad \text{m}^{-3} \text{mm}^{-1} \quad (1)$$

30 where  $D$  is the equivolume diameter,  $N_0$  is the intercept parameter ( $\text{m}^{-3} \text{mm}^{-1}$ ),  $\lambda$  the slope parameter ( $\text{mm}^{-1}$ ) and  $\mu$  the dimensionless shape parameter.

In the [operational](#) one-moment scheme the only free parameter of the PSDs is the slope parameter  $\lambda$  which can be obtained from the prognostic moment of order three (mass [concentrations](#)). The intercept parameter  $N_0$  is either assumed to be constant, or in the case of snow, to be temperature dependent. The scale parameter  $\mu$  is [set](#) to zero (exponential PSDs) for all hydrometeors except for rain where it [can be chosen a-priori](#) and is set to 0.5 by default.

5 A more advanced two-moment scheme, [which adds hail as](#) a sixth hydrometeor category, was developed for COSMO by Seifert and Beheng (2006). In this scheme all PSDs are assumed to be gamma distributions where the intercept and slope parameters are free parameters that can be obtained from the prognostic moments of order zero ([number concentrations](#)) and order three (mass [concentrations](#)). As this scheme significantly increases the overall computation time, it is currently not used operationally.

10 In COSMO, the interaction of various microphysical processes and their feedback on the simulated flow fields are represented by a system of budget equations for  $q^x$ , the specific mass fraction in  $\text{kg}_x$  per  $\text{kg}_{\text{air}}$  of hydrometeor  $x$ .

$$\frac{\partial q^x}{\partial t} + \mathbf{v} \cdot \nabla q^x - \frac{1}{\rho} \frac{\partial P^x}{\partial z} = S^x - \frac{1}{\rho} \nabla \cdot \mathbf{F}^x \quad (2)$$

where  $S^x$  [represents](#) the microphysical sources and sink per unit mass of moist air,  $\mathbf{F}^x$  the turbulent fluxes and  $P^x$  the precipitation or sedimentation fluxes defined by  $P^x = \rho q^x v_T^x$ , where  $v_T^{(j)}$  is the terminal fall velocity of hydrometeor  $j$ . The precipitation intensity at the ground is then simply the sum of the sedimentation fluxes of all hydrometeors at the lowest model level. In terms of terminal velocities COSMO [generally](#) assumes power-laws:  $v_T = aD^b$ , where  $D$  is the particle equivolume diameter. [Note that in the two-moments scheme a more refined empirical relation by Rogers et al. \(1993\) is used for raindrops.](#)

Numerically, this system of differential equations is treated with a time splitting method, in which the advection terms  $\mathbf{v} \cdot \nabla q^x$  are first integrated over a COSMO time step (20 sec.) and the budget equations are then solved for the microphysical source terms and sedimentation only. In the operational microphysical scheme the source terms include (1) *nucleation and depositional growth of cloud ice*, (2) *autoconversion of cloud water to rain*, (3) *collection mechanisms*, (4) *diffusional growth of rain and snow* and (5) *melting and freezing mechanisms*. Details about the parameterization of all these source terms can be found in Doms et al. (2011).

25 In the operational set-up, the COSMO model uses a prognostic turbulent kinetic energy (TKE) closure at level 2.5 for the parametrization of atmospheric turbulence. This scheme is similar to Mellor and Yamada (1982), the main difference being the use of variables that are conserved under moist adiabatic processes: total cloud water and liquid water potential temperature. Additionally, a so-called ‘‘circulation term’’ is included which describes the transfer of non-turbulent sub-grid kinetic energy from larger-scale circulation [towards](#) TKE. The reader is referred to Baldauf et al. (2011) and the model documentation (Doms et al., 2011) for a more in-depth description of the various COSMO sub-grid parameterizations.

Name	Description	Unit
Average altitude	average altitude	m
Midpoint latitude	latitude of the center of the square	degree <a href="#">north</a>
Midpoint longitude	longitude of the square center	degree <a href="#">east</a>
Total precipitation	Total precipitation during all years	mm
Standard deviation of precipitation	Average standard deviation during timesteps with precip.	mm
Wet fraction	Fraction of simulated precipitation amounts that exceed a threshold of 0.1 mm per hour	-
Geopotential	average geopotential height at 850 hPa	m
Wind <a href="#">speed</a>	average <a href="#">wind speed</a> at 850 hPa	$\text{m s}^{-1}$
Wind direction	average wind direction at 850 hPa	degree
Temperature	average temperature at 850 hPa	K
Potential vorticity	average potential vorticity at 850 hPa	$\text{m}^2 \text{kg}^{-1} \text{s}^{-1}$

**Table 1.** List and description of all [synoptical](#) and [topographical](#) descriptors used in the multifractal characterization of the [climatology](#) of precipitation [intensities](#).

## 2.2 Climatological study

In the first part of this work, a multifractal characterization of all precipitation intensities simulated by COSMO during five years is performed. The computed multifractal parameters are then compared with various descriptors. A total of 43115 hourly timesteps of COSMO simulations in analysis mode covering a period of 5 years (2011 to 2016) were retrieved from the MeteoSwiss archives. [These data are](#) available at a 2 km resolution ( $0.02^\circ$  angular resolution) using a set-up known operationally as “COSMO-2” (COSMO, 2015), which was used for forecast and analysis until [the](#) beginning of 2016. The first and last 100 kilometers of the COSMO-2 domain along both longitudinal and latitudinal directions were discarded from the analysis in order to avoid border effects. The remaining area is shown in Figure 2 (Domain 1). This area was then divided into 209 sub-squares of size  $64 \times 64$  ( $128 \times 128 \text{ km}^2$ ), with an overlap of  $2/3$  between consecutive squares. This ratio has been chosen as a trade-off between representativity (total number of squares) and computation time.

Besides the multifractal parameters, which will be described later on, 11 local descriptors of the geography and meteorology were computed from the COSMO data within every square (Table 1). [Spatial maps of all descriptors are given in Appendix A.](#)

Day	Timeline	Number of time steps	Description
26 March 2010	08:00 - 18:00	144 (12 h)	Crossing of a strong cold front causing sudden drop of temperature followed by heavy graupel and snowfall as well as strong winds
8 April 2014	02:00 - 10:00	144 (12 h)	Stationary front with widespread stratiform precipitation over Switzerland
13 August 2015	12:00 - 24:00	144 (12 h)	Strong summer convection triggered by the presence of very warm and wet subtropical air over Switzerland

**Table 2.** Short description of the three ~~considered~~ precipitation events.

## 2.3 QPE comparison

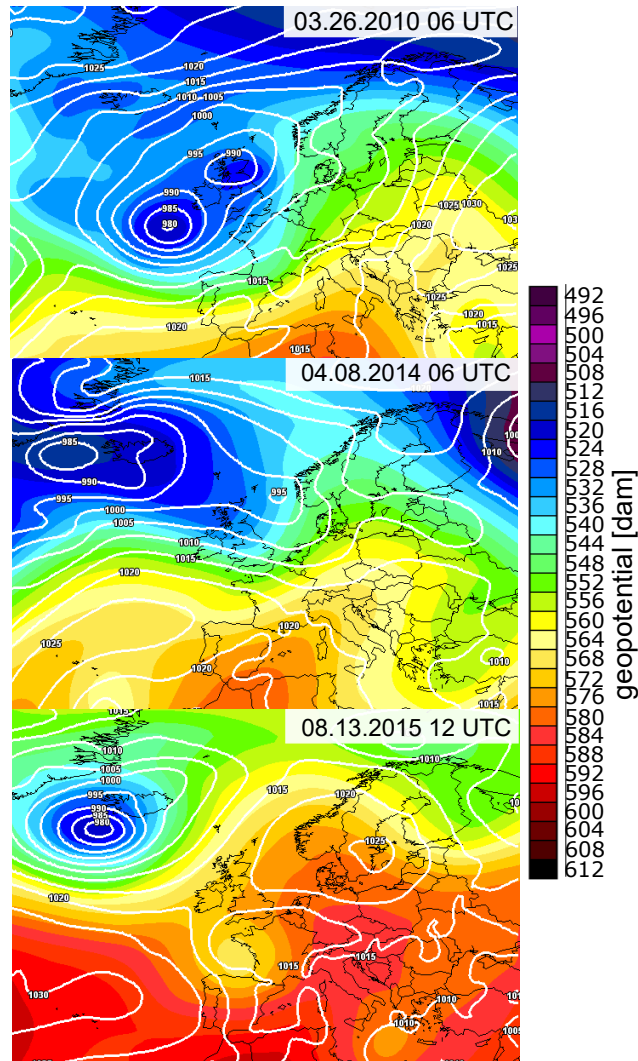

### 2.3.1 Simulation of events

In the second part of this work, three precipitation events were simulated with COSMO and compared to the radar QPE in terms of the multifractal properties of their rainfall intensity fields. These events correspond to three typical synoptic situations observed over Switzerland. A brief description of the events is given in Table 2, and 500 hPa geopotential and temperature charts are shown in Figure 1. To simulate these events, COSMO was used in its version 5.01 with the standard “COSMO-2” set-up (COSMO, 2015). As was done in similar studies (Bohme et al., 2009), a spin-up time of 12 hours was used to account for the cold start of the model. For the initial and boundary conditions, analysis forcings of MeteoSwiss, obtained with the COSMO-7 model run at a 7 km spatial resolution, were used. This allows for forcing the model with the most accurate information available at the time of simulation. In addition, the events were also simulated using the non-operational two-moment scheme, while keeping all other namelist parameters unchanged. For all simulations, model outputs were written every 5 minutes of simulated time, which corresponds to the temporal resolution of the Swiss radar composite.

### 2.3.2 QPE data

In Section 5, precipitation intensities at the ground simulated by the COSMO are compared with the QPE product from the Swiss operational radar composite. The Swiss radar composite consists of the plane position indicator (PPI) measurements of the four <sup>1</sup> operational polarimetric C-band radars. The QPE product of MeteoSwiss is computed in the following way: the linear equivalent radar reflectivity measurements at up to six  $1^\circ \times 1^\circ \times 83\text{m}$  clutter-free radar bins are corrected for partial beam-blocking and averaged to derive polar  $1^\circ \times 1^\circ \times 500\text{m}$  radar bins. Reflectivity measurements are then converted to equivalent precipitation intensity with a Marshall and Palmer (1948)  $Z - R$  relationship. The precipitation estimation at the ground is extrapolated from multi-radar observations aloft using

<sup>1</sup>The Weissfluhgipfel radar was not yet installed at the time of the considered events

**Figure 1.** 500 hPa geopotentials and pressure at mean sea level for the three considered events.

a weighting function that depends on the altitude above the ground and the radar visibility. The correction for the vertical profile of reflectivity (VPR) is done with an average profile based on aggregation over a few hours and over the visible part of the area located less than 70 km from the radar. More information on the MeteoSwiss QPE estimation can be found in Germann et al. (2006). Note that the Plaine-Morte radar was only installed in 2014 and was thus not available during the first event (26 March 2010). The Swiss radar composite extends radially up to 250 km from every single radar (Figure 2). However, the quality of the product improves with the proximity to the radar and in the areas where the radar scanning domains overlap. To perform a comparison of rain intensities a smaller field of 128x128 km<sup>2</sup> was chosen in the center of the domain where the quality of the product is optimal (Domain 2

**Figure 2.** Situation map showing the theoretical maximum extent of available QPE (light blue), the location of the Swiss operational radars (blue dots), the region used for the climatological study of COSMO precipitation intensities (domain 1) as well as the sub-regions centered over the precipitation events used in the QPE analysis (domains 2 and 3).

in Figure 2). For the second event (8 April 2014) the domain was moved slightly to the left in order to better follow the evolution of the precipitation event (Domain 3 in Figure 2).

### 3 The UM framework

#### 3.1 Multifractality

Let  $\epsilon$  be a normalized (divided by its mean) conservative field, which can be one or two dimensional (time series or spatial map). The field  $\epsilon$  also needs to be have the same length in all dimensions, and this length must be a power of two.

The fractal dimension  $D_f$  of  $\epsilon$  indicates how a corresponding binary field (where all values larger than a given threshold are set to 1) scales with the resolution. The resolution is defined by the ratio between outer scale  $L$  and observation scale  $l$  ( $\lambda = L/l$ ).

$$N_\lambda = \lambda^{-D_f} \tag{3}$$

where  $N_\lambda$  is the number of positive samples (rainy pixels for example) at a given resolution, which can be obtained with the help of box counting.

It is possible to interpret this result in a probabilistic way. Indeed, let's consider a line or cube of size  $l$ ,  $p$  is the probability that it intersects the field. This probability scales with the resolution:

$$p = \frac{\lambda^{D_f}}{\lambda^D} = \lambda^{-c_F} \tag{4}$$

where  $D$  is the dimension of the field (1 for a time series, 2 for a spatial field) and  $c_F = D - D_f$  is called the fractal codimension of the field.

It is clear that the values of  $D_f$  (and  $c_F$ ) depend on the threshold that is used. Several thresholds and corresponding values of  $D_f$  are thus required to characterize the field. In the multifractal framework this characterization is performed with scale-independent thresholds (Schertzer and Lovejoy, 1987), which yields a multifractal version of Equation 4.

$$p(\epsilon_\lambda \leq \lambda^\gamma) \approx \lambda^{-c(\gamma)} \tag{5}$$

where  $c(\gamma)$  is the co-dimension function which is convex and increasing,  $\gamma$  is a so-called singularity, which is independent of scale.  $\lambda^\gamma$  can thus be seen as a scale invariant threshold. Since  $c(\gamma)$  takes several values, multifractals can be understood as a hierarchy of embedded fractal sets.

It can be shown that Equation 5 implies that the statistical moments  $q$  of the field scale with the resolution (Schertzer and Lovejoy, 1987):

$$\langle \epsilon_\lambda^q \rangle \approx \lambda^{K(q)} \tag{6}$$

where  $K(q)$  is the moment scaling function which is related to  $c(\gamma)$  by a Legendre transform (Parisi and Frisch, 1985b). For a conservative field  $\langle \epsilon_\lambda \rangle = 1$ .

The quality of the scaling can be studied with the Trace Moment (TM) method which consists of a log-log plot of the up-scaled fields as a function of the resolution  $\lambda$  for each moment  $q$ ; the slope being the moment scaling function.

5 In the universal multifractal framework (Schertzer and Lovejoy, 1987), the moment scaling function for a conservative field  $K_c(q)$  can be fully characterized with only two parameters,  $\alpha$  and  $C_1$ .

$$K_c(q) = \frac{C_1}{\alpha - 1} (q^\alpha - q) \quad (7)$$

$C_1$  is the mean intermittency co-dimension and measures the clustering of the average intensity at increasing scales.  $C_1$  is equal to zero when the field is homogeneous.  $\alpha$  is the multifractality index and measures the clustering variability with respect to the intensity level;  $\alpha \in [0, 2]$ .

The size of the sample limits the insight one can get of a statistical process. For a multifractal processes, if  $N_s$  samples are available this will result in a maximum singularity  $\gamma_s$  (and corresponding moment order  $q_s$ ) beyond which the values of the statistical estimates of the co-dimension and moment scaling function are not considered as reliable (e.g., Schertzer and Lovejoy, 1987; Lovejoy and Schertzer, 2007). It can be shown that in the multifractal framework,  $q_s$  and  $\gamma_s$  are equal to:

$$q_s = \left( \frac{D + D_s}{C_1} \right)^{\frac{1}{\alpha}} \quad \text{and} \quad \gamma_s = \alpha' C_1 \left( \frac{D + D_s}{C_1} \right)^{\frac{1}{\alpha'}} \quad (8)$$

where  $\frac{1}{\alpha} + \frac{1}{\alpha'} = 1$  and  $D_s$  is the sampling dimension defined by  $N_s = \lambda^{D_s}$ .

An example of the use of  $\gamma_s$  can be found in Royer et al. (2008) who investigated the impact of climate change on rainfall extremes with a climate model. They observed an increase of  $\gamma_s$  over time which could result in a possible increase in the intensity of rainfall extremes over the next hundred years. Douglas and Barros (2003) and Hubert et al. (1993) also used the maximum singularity  $\gamma_s$  in the estimation of probable maximum precipitation.

In this work, the UM parameters are estimated with the Double Trace Moment (DTM) method (Lavallée et al., 1993). This method relies on the fact that, in the context of UM, the moment scaling function  $K(q, \eta)$  of the field  $\epsilon_\lambda^{(\eta)}$ , obtained by raising the field  $\epsilon$  at a power  $\eta$  and up-scaled at resolution  $\lambda$ , can easily be expressed as a function of  $\alpha$  (Lavallée et al., 1993).

$$\langle (\epsilon_\lambda^{(\eta)})^q \rangle \approx \lambda^{K(q, \eta)} = \lambda^{\eta^\alpha K(q)} \quad (9)$$

$\alpha$  is thus the slope of the linear part of  $K(q, \eta)$  as a function of  $\eta$  in a log-log plot.

### 3.2 Non-conservative fields

In the case of a non-conservative field  $\phi$ , we have  $\langle \phi_\lambda \rangle \neq 1$ .

One way to consider non-conservative fields within the UM framework it to assume that they can be expressed as:

$$\phi_\lambda = \epsilon_\lambda \lambda^{-H} \quad (10)$$

where  $H$  is the non-conservation parameter ( $H = 0$  for conservative fields) and  $\epsilon$  is a conservative field characterized by a moment scaling function  $K_c(q)$  with parameters  $C_1$  and  $\alpha$ .

5 The moment scaling function of the non-conservative field  $\phi_\lambda$  is then given by:

$$K(q) = K_c(q) - Hq \quad (11)$$

$H$  can be related to the spectral slope  $\beta$  by:

$$\beta = 1 + 2H - K_c(2) \quad (12)$$

10 where  $\beta$  is the exponent of the power law that characterizes the relation between power spectrum and wave numbers:

$$E(k) \propto k^{-\beta} \quad (13)$$

Hence the larger the value of the slope  $\beta$ , the shorter the decorrelation range. If  $\beta$  is larger than the dimension of the field, the field is non-conservative.

15  $\epsilon_\lambda$  can be estimated from  $\phi_\lambda$  with a fractional integration (for  $H < 0$ ) or differentiation (for  $H > 0$ ) of order  $H$ , which is equivalent to a multiplication by  $k^H$  in the Fourier space. In practice however, for  $H > 0$ , particularly when  $H > 0.5$ ,  $\epsilon_{\lambda_{\max}}$  (the field  $\epsilon$  at the maximum resolution) is often approximated by the renormalized absolute fluctuations of the field.

$$\epsilon_{\lambda_{\max}}(i) = \frac{|\phi_{\lambda_{\max}}(i+1) - \phi_{\lambda_{\max}}(i)|}{\langle |\phi_{\lambda_{\max}}(i+1) - \phi_{\lambda_{\max}}(i)| \rangle}, \quad i = 1, 2, \dots, N \quad (14)$$

20 Table 3 provides an overview of all multifractal parameters as well as their interpretation, while Appendix B provides some visual examples of how varying the multifractal parameters affects the spatial structure of randomly generated multifractal fields.

### 3.3 Spatio-temporal analysis

The multifractal analysis of time series of two-dimensional fields, such as the ones considered in this study, can be performed both in space, by considering an ensemble of two-dimensional fields (one sample for every time step),

Parameter	Name	Interpretation
$\alpha$	multifractality index	When $\alpha = 0$ , the field is mono-fractal which means that a single fractal dimension is sufficient to fully characterize the field. The higher $\alpha$ , the larger the variability within areas with precipitation.
$C_1$	mean intermittency	Measures how concentrated the average field is, $C_1 = 0$ for a uniform field. The larger $C_1$ , the larger the intermittency of the field. High $C_1$ associated with high $\alpha$ implies strong extremes.
$\beta$	Negative of the spectral slope	The larger $\beta$ the shorter the decorrelation range of the data. If $\beta = 0$ , the power spectral density is the one of white noise, meaning there is no decorrelation. When $\beta$ is large, large scale phenomena have a large contribution to the variability of the data, which means that the fields have a larger correlation range (smoother fields).
$H$	non-conservation parameter	Scale-independent proportionality factor relating a conservative field to the non-conservative field (a field for which the average is not scale independent). Can be seen as a smoothing factor. If $H$ is positive, the field is too smooth and one needs to differentiate it to retrieve a conservative field. If $H$ is negative, the field is too discontinuous and one needs to integrate it to retrieve a conservative field.
$\gamma_s$	maximum singularity	Maximum observable singularity (scale independent threshold) from the data. Large $\gamma_s$ implies that stronger extremes are present in the data.
$R^2$	TM coefficient of determination	Coefficient of determination of the relation between a given moment of order $q$ and the scale (Equation 6) on a loglog plot. If the field is multifractal the plot is a straight line with slope $K(q)$ . In practice, $q = 1.5$ is often used as a reference to determine $R^2$ . $R^2$ can be seen as an estimation of the quality of scaling and of the viability of the multifractal approach for the data.
$D_f$	Fractal dimension	Factor relating the number of rainy observations at a given scale to the <a href="#">corresponding</a> scale. The larger $D_f$ , the more uniform the binary precipitation field ( <a href="#">obtained with</a> a threshold of zero) is.

**Table 3.** Overview of all multifractal parameters

or in time, by considering an ensemble of one-dimensional time series (one sample for every coordinate in the two-dimensional field).

A simple spatio-temporal scaling model (e.g., Marsan et al., 1996; Deidda, 2000; Macor et al., 2007; Radkevich et al., 2008) is based on the hypothesis of an anisotropy coefficient between space and time:

$$5 \quad K_{\text{space}}(q) = \frac{K_{\text{time}}(q)}{1 - H_t} \quad (15)$$

where  $H_t$  is the anisotropy coefficient between space and time, which in the theory of Kolmogorov (e.g., Kolmogorov, 1962; Marsan et al., 1996) is equal to  $1/3$ . This result implies identical  $\alpha$  and proportional  $C_1$  and  $H$  parameters.

$$\frac{C_{1,\text{space}}}{C_{1,\text{time}}} = \frac{H_{\text{space}}}{H_{\text{time}}} = \frac{1}{1 - H_t} \quad (16)$$

## 4 Climatological analysis of multifractal parameters

Within all 209 selected squares (Section 2.2), the multifractal parameters  $\alpha$ ,  $C_1$ ,  $\beta$ ,  $H$ ,  $\gamma_s$ ,  $R^2$  and  $D_f$  were computed both in time and in space by performing an ensemble average, i.e. by taking the mean parameters over all the available realizations of the process. In space, every timestep is considered as a realization of a two-dimensional geophysical process, while in time every COSMO gridpoint is considered as a realization of a one-dimensional geophysical process (time series). For the analysis in space, this implies 43115 realizations of a 64x64 2D field and for the analysis in time, 64x64 (= 4096) realizations of a time series of length 32768 ( $2^{15}$  which is the closest power of 2 of 43115). Analysis of the overall temporal power spectrum (not displayed) revealed the presence of a strong peak centered around a resolution of 3 hours, which is very likely to be caused by the nudging scheme of COSMO (assimilation within the model is performed every 3 hours). To remove the effect of the nudging in the estimation of multifractal parameters, only the larger time scales (from 8 hours to 5 years) were considered. Even though some areas are characterized by values of  $H > 0.5$  (non-conservative fields), it was decided to treat all areas in a consistent way, by working on the original fields instead of the fluctuations. Indeed, it was observed that using fluctuations for areas where  $H > 0.5$ , was causing important discontinuities in the spatial structure of MF parameters. Indeed, using fluctuations is only a crude way to address the non-conservativity of the fields. A proper correction using fractional integration, would allow for a much smoother correction, since it is proportional to  $H$ , but is computationally intractable for the very large dataset that is used.

In order to test the effect of zeros on the overall analysis, the multifractal parameters were also estimated in space<sup>2</sup> by using only the fields where there is precipitation over at least 50% of the surface. This did however not impact the main conclusions in terms of correlations and spatial structure of the multifractal parameters. Hence the subsequent study was performed on the raw precipitation fields without any kind of filtering.

### 4.1 Correlation study

In a first step, the relationships between MF parameters evaluated in time and space and the descriptors detailed in Table 1 were analysed by looking at the non-parametric (Spearman) correlations. Figure 3 displays the correlation plots for the MF parameters in space and time.

The following conclusions can be drawn from the correlation plots.  $D_f$  is strongly correlated with the latitude, indicating that the fractal dimension of rain is larger at higher latitudes (i.e. cooler climates).  $D_f$  is also quite strongly correlated to the wet fraction: the more often it rains, the higher the fractal dimension. Similarly  $C_1$  also has a strong latitudinal trend and tends to decrease in regions with a high wet fraction (less intermittency), which is typically the case in cooler climates.  $\alpha$  also seems to show a latitudinal trend, though not as strong as for  $C_1$  and  $D_f$ . The link between  $\alpha$  and the standard deviation is not obvious since the standard deviation is a second-order statistic, while the UM parameters are based on all moments.  $C_1$  and  $\gamma_s$  tend to decrease with the altitude while  $\beta$

---

<sup>2</sup>In time, it would not be possible to filter out non rainy timesteps, as it would break the continuity of the time series.

**Figure 3.** Correlation plots showing the Spearman (rank) correlation between MF parameters and descriptors. On **top**, with MF parameters estimated in space, and **at the bottom**, with MF parameters estimated in time. Note that the part on the right of the correlation plot in time has been truncated since it is the same as on the correlation plot in space. Correlations that are not statistically significant (for a significance level of 5%) and correlations which are not consistent in sign between time and space are left in white.

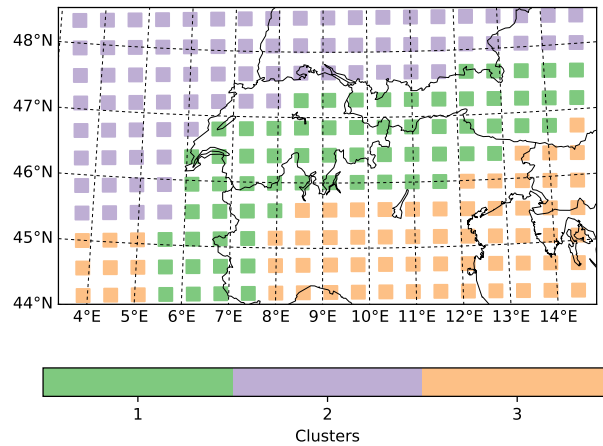

and  $H$  tend to increase. This could be due to orographic effects, precipitation over mountains being both dominated by large-scale circulations and generally abundant.

The correlation values are roughly consistent in time and in space, although the ones in time are generally higher. In time the correlation between  $\beta$  and  $H$  is lower than in space. This can be explained by the lower values of  $\beta$  in time. Because of this and as a consequence of Equation 12,  $H$  becomes more correlated with  $\alpha$  and  $C_1$ .

## 4.2 Hierarchical clustering

- 5 A hierarchical clustering of all 209 areas was performed based on the value of their descriptors (Table 1), using the Ward linkage method (Ward, 1963). Investigation of the dendrogram gives an optimal number of classes of either 3 or 6. Figure 4 shows the resulting classification for 3 different classes.

**Figure 4.** Hierarchical clustering of the 209 regions into three classes based on the synoptical and topographical descriptors listed in Table 1.

As could be expected, the clustering of the synoptical and topographical descriptors results in a meaningful spatial distribution. Indeed, all classes are spatially very coherent, with class 1 corresponding mostly to the Alpine regions, from the Mediterranean Sea to Austria, class 2 corresponding mostly to the cooler temperate regions in the east of France and south of Germany, and class 3 corresponding to the warmer Mediterranean regions in the south of France, in Italy and the Balkans. Note that over land areas a somewhat similar classification can be obtained by aggregating classes of the famous Köppen (1936) climate classification. A comparison between the synoptical classification and the Köppen classification is performed in Appendix C.

- 15 The distributions of MF parameters within these clusters, as illustrated in Figure 5, highlight some obvious discrepancies in MF parameters between clusters. In space,  $\alpha$ ,  $H$ ,  $\beta$  and  $D_f$  seem to be lower in cluster 3 than in the others, while  $C_1$  and  $\gamma_s$  are higher. Clusters 1 and 2 do not exhibit such marked differences but differ nonetheless by stronger values of  $D_f$  and slightly larger values of  $H$ ,  $\beta$  and  $\alpha$ . In time, cluster 1 (Alpine regions) is characterized by high values of  $\alpha$  and  $\beta$  and low values of  $C_1$ , which indicates frequent rainfall and a large variability in intensities.

**Figure 5.** Boxplots showing the distributions of MF parameters within the clusters. MF parameters estimated in time are shown with a dashed pattern. Note that the left  $y$ -axis applies to MF parameters in space and the right  $y$ -axis (in red) to MF parameters in time (the boxplots indicated with a red hatch).

Cluster 2 differs by its low values of  $\beta$  and  $H$ , indicating that small temporal frequencies play a bigger role in the overall [variability of precipitation](#).

The statistical significance of these discrepancies was confirmed both with the MANOVA (multivariate [analysis of variance](#)), and the non-parametric Kruskal-Wallis [statistical tests](#). All [tests](#) were performed with a significance level of 2.5%. The MANOVA reveals that the multivariate means of MF parameters (both in time and space) are significantly different between the three clusters, as well as between all three pairs of clusters taken separately (1 vs 2, 2 vs 3 and 1 vs 3). The non-parametric Kruskal-Wallis test, performed separately for all MF parameters, reveals that distributions of all MF parameters are significantly different between the three clusters. A pairwise comparison (1 vs 2, 2 vs 3 and 1 vs 3) reveals that, [in time](#), all MF parameters are significantly different between all pairs of clusters, except for  $H$  which is not statistically different between clusters 1 and 2. In space, the situation is similar, but this time it is  $C_1$  and  $\gamma_s$  which are not significantly different between clusters 1 and 2.

To summarize, the statistical analysis shows that the multifractal parameters of precipitation intensities are significantly different within the three climatological clusters.

### 4.3 Spatial structure of MF parameters

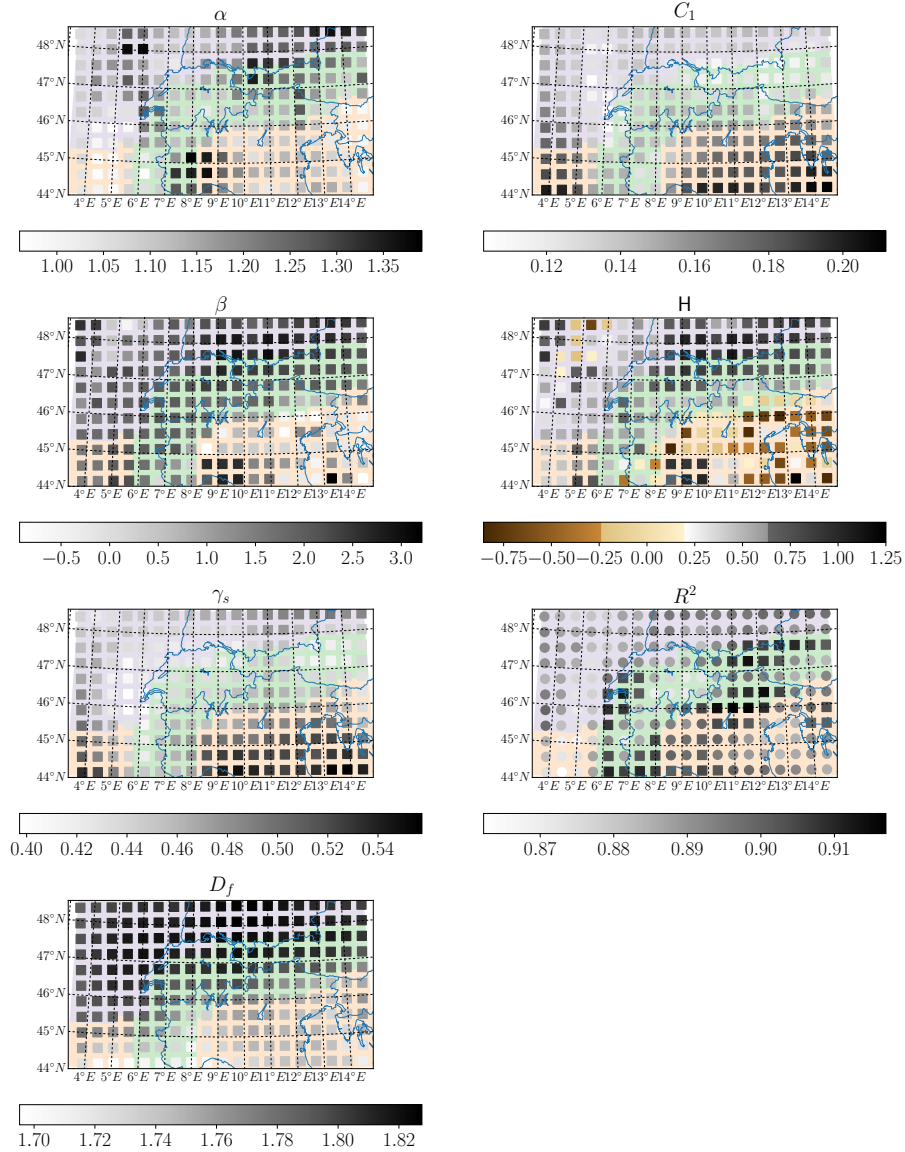

Figure 6 shows the spatial structure of MF parameters in space and reveals that  $\alpha$  is particularly large over Bavaria, the Piedmont region of Italy and the Champagne region of France. However these “clusters” of large values are quite difficult to relate to other trends, especially in terms of descriptors. Generally, the Swiss Alps are characterized by relatively low values of  $\alpha$ . In terms of  $C_1$ , there is a clearer trend, with a strong latitudinal and elevational negative gradient, which can be related to an increase in overall precipitation amounts. In terms of  $\beta$ , the regions over Italy show smaller values, which tend to indicate that precipitation events exhibit strong high-frequency components (such as for example short convective storms). Over the Alps and the more continental regions, where the precipitation systems are mostly frontal,  $\beta$  increases. The trend is similar for  $H$  which is related to  $\beta$ . For  $\gamma_s$ , we observe a similar trend to  $C_1$  with a decrease with altitude and elevation. This indicates that precipitation extremes are stronger in southern regions. For  $R^2$  it is difficult to identify a proper spatial structure, except that the foothill regions of the Alps generally have large  $R^2$  values. Finally for  $D_f$ , there is mostly a latitudinal trend: the value of  $D_f$  increases with the latitude, which can be related to a decrease in the number of zeros (smaller  $C_1$  and generally larger  $\alpha$ ).

In time, similar conclusions can be drawn for  $C_1$ ,  $D_f$ ,  $\gamma_s$  and  $\beta$ . For the other parameters, the latitudinal trend seems to be much more visible than in space, especially for  $H$  and  $R^2$ .  $R^2$  seems to be generally larger in time than in space. Unlike in space, for  $\alpha$  in time there is a clearer dependency on the altitude.  $\alpha$  in time tends to be larger in mountainous regions, indicating a larger temporal variability of precipitation intensities in these regions.

To summarize, the multifractal signature of precipitation is related both to the topography, the climate and the typical synoptical conditions. As such, multifractals can be used as a way to characterize precipitation fields and assess the realism of simulated atmospheric variables.

## 5 Comparison of simulated precipitation with radar QPE

The previous section presented the MF approach in a climatological context, which helps to link meteorological and geographical parameters to MF parameters. In the present section, we evaluate the quality of the precipitation simulated by COSMO with two different microphysical schemes, by comparing it with quantitative precipitation estimations from the Swiss radar network using the universal multifractal framework. This comparison requires the COSMO model to be run at the radar temporal resolution (5 minutes) in a very expensive setup (two-moments scheme). As such, a climatological comparison over several years is not feasible from a computational point of view. Hence, the comparison is now conducted at the event scale, which also makes the intercomparison of the microphysical parameterizations easier.

**Figure 6.** Spatial representation of the MF parameters estimated in space for all areas. The special colormap for  $H$  has been chosen to separate positive and negative values and highlight non-conservative areas where  $|H| > 0.5$ . For  $R^2$ , circles represent all zones where  $R^2 < 0.9$ , whereas squares represent all zones with good scaling ( $R^2 \geq 0.9$ ). As previously mentioned, the size of the represented squares is not to scale. The colors in the background correspond to the hierarchical classification.

The power-law  $Z-R$  relationship by Marshall and Palmer (1948), which is used by MeteoSwiss to derive the QPE, does not correspond with the  $Z-R$  relationships derived from the COSMO microphysical parameterizations. This explains part of the discrepancy between radar QPE and simulated precipitation intensities, but in general should

not impact the validity of the multifractal comparison. Indeed, if the  $Z - R$  relationship derived from the COSMO parameterizations can be approximated by a power-law, then the correction needed to account for discrepancies in  $Z - R$  relationships is itself a power-law:  $R_{\text{corr}} = aR^b$ , where  $R_{\text{corr}}$  is the precipitation intensity one would obtain by first converting COSMO precipitation intensities to reflectivities and then back to precipitation intensities using the radar QPE  $Z - R$  relationship. It can be shown (Tessier et al., 1993) that, in the context of universal multifractals, the corrected field will have the same value of  $\alpha$  and the same scaling properties as the original field, while  $C_1$  will be multiplied by  $b^\alpha$ . Moreover, for the one-moment scheme, it was observed that while the intercept parameter  $a$  changes significantly, the exponent parameter  $b$  is almost the same:  $R_{\text{corr}} = 0.68R^{0.98}$ . As the exponent 0.98 is close to unity, this implies an almost direct proportionality, and as such even  $C_1$  should barely be affected. Note that this power-law was derived by using the T-matrix method (Mishchenko et al., 1996) to compute radar cross-sections at C-band.

For the two-moment scheme, things are more complicated as no one-to-one relationship exists between rainrate and reflectivity. However, a rough estimation of the error on  $C_1$  was derived by considering a representative set of rainy time steps from all events. The estimated values of  $b$  for the two-moment scheme varied between 0.81 and 1.23, which would imply a maximum relative error on  $C_1$  of 51% on spatial fields and 23% on time series.

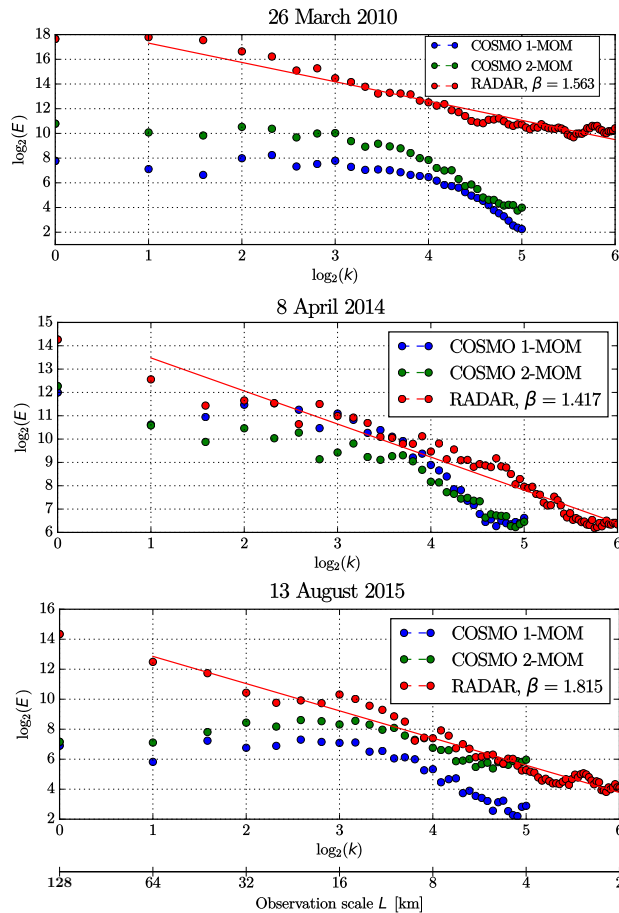

Overall, correcting precipitation fields for discrepancies in  $Z - R$  relation is a difficult task, especially in the solid phase and for the two-moment scheme, where deriving a  $Z - R$  relation from the model parameterization is difficult. However, in the multifractal context, only  $C_1$  should be affected and only with significant solid precipitation or when using the two-moment scheme. This should be kept in mind when interpreting  $C_1$  values.

## 5.1 Scaling analysis

A multifractal comparison of the precipitation fields simulated by COSMO in its one-moment and two-moment schemes with the QPE product from the Swiss radar composite was performed. As a first step, a spectral analysis was performed both in time (ensemble of one-dimensional time series of precipitation intensities), and in space (ensemble of two-dimensional maps of precipitation intensities).

Figure 7 shows the spectral analysis in space for all events and data. A best-fit line is shown for the radar QPE from which the value of  $\beta$  is computed.  $\beta$  is equal to  $-m$ , where  $m$  is the slope of the best-fit line.

For the 26 March 2010, we observe a single scaling regime for the radar QPE, with a good scaling both at large (16-64 km) and small scales (2-16 km), as the spread around the line is relatively small. For the model intensities, we observe strong discrepancies with the radar QPE in terms of spectral slope at smaller scales (2 - 8 km), which are not well represented. A possible explanation for this break in scaling properties of the model is the fact that large scales are dominated by the dynamics of the model (primitive equations of the atmosphere), whereas smaller scales are dominated by the parameterizations of sub-grid phenomena (turbulence, convection). However, even at larger scales (8-64 km), the agreement between radar QPE and model simulations is still quite poor in terms of

**Figure 7.** Spectral analysis in space of the QPE products during the three events. Bold lines are best-fit lines. The associated value of  $\beta$  is given in the legend. *Note that the maximal represented observation scale, which corresponds to the Nyquist frequency, is twice the maximal resolution.*

spectral slope. Obviously, for this rainfall event, COSMO is not able to recreate the spatial structure of precipitation observed by the radar.

For the 8 April 2014, the scaling is similar between radar and model precipitation intensities, possibly indicating that for this stratiform rain event, parameterizations and dynamics match better. Both radar and simulations show a **weak** scaling break at around **8 km**.

For the last event, we observe again a good scaling for the radar QPE and a much worse scaling for the model precipitation intensities. **However**, in contrast with the first event, the larger scales ( $> 16$  km) are not well represented. Indeed, inspection of the time series of precipitation shows that COSMO is not able to locate accurately the convective cells of precipitation and generally overestimates their extent. In terms of microphysical parameterizations, we observe that the spectral slopes of the one-moment scheme are generally closer to the ones obtained from the radar QPE.

This is especially visible for the last (convective) event, where the COSMO simulations show weak scaling ( $\beta$  close to zero). This implies that the simulated rainfall intensities are dominated by small-scale features, while large-scale features are underestimated. Note also that for large-scale features, the power density function of COSMO simulations corresponds to white noise, indicating that the COSMO model has a shorter decorrelation range than the radar data.

The spectral analysis in time (not displayed) generally shows similar results, but with larger values of  $\beta$  and overall better scaling (less spread).

Table 4 displays the non-conservation parameter  $H$  and the fractal dimension  $D_f$  evaluated for time series of precipitation intensities (analysis in time) and for spatial fields of precipitation intensities (analysis in space), for both the radar QPE (in regular font), the COSMO one-moment scheme (in bold), and the COSMO two-moments scheme (in italic) and for all events. A value of  $H$  larger than 0 indicates that the field is smoother than the observed field from a direct multifractal cascade process, and a value of  $H$  smaller than 0 indicates that the field is too discontinuous. The larger  $D_f$ , the more uniform the binary precipitation field is. In space  $D_f = 2$  implies that it rains everywhere, while in time  $D_f = 1$ , implies that it rains all the time. Taking the radar as a reference, one sees that the convective event is characterized by the largest values of  $H$ , followed by the snowfall event and the stratiform event. When comparing  $H$  between COSMO and the radar QPE, one observes that  $H$  in time is always larger with the one-moment scheme than on the radar QPE, indicating that the temporal structure of the simulated fields is likely to be too smooth. In space, the trend is not as obvious and the match between the radar QPE and the precipitation intensities simulated with the one-moment scheme seems better. In terms of fractal dimension, it can be seen that for all events, both in space and time, the radar QPE has the most discontinuous binary precipitation field due to its smaller values of  $D_f$ . COSMO simulations are characterized by larger values of  $D_f$ , indicating a wider coverage of precipitation and less convoluted precipitation fields and time series. It is interesting to notice that the two-moment scheme gives values of  $D_f$  that are closer to those of QPE, which indicates that it is better at simulating small-scale variations in the temporal and spatial occurrence of precipitation.

Overall, it is worth noticing that the two-moment scheme almost always has smaller  $H$  values than the one-moment scheme, which indicates that it is more discontinuous both in time and space.

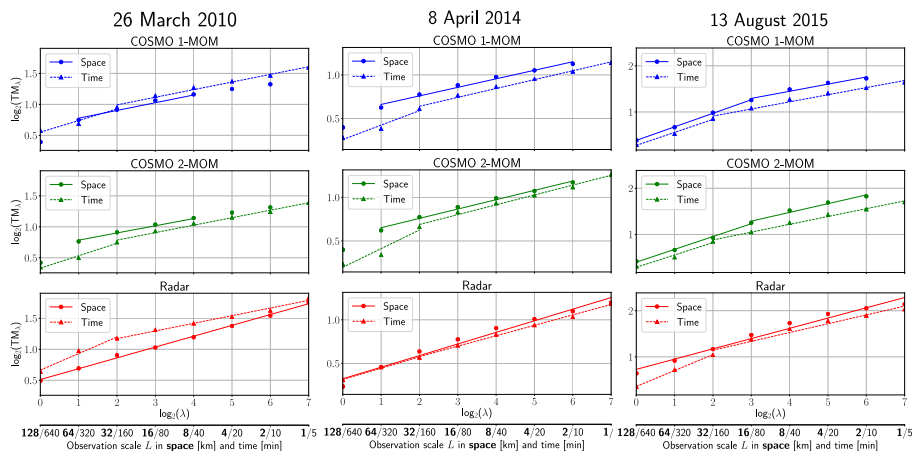

In order to account for the fact that the fields are mostly non-conservative ( $|H| > 0.5$ ), and to treat all fields in a consistent way, all further analysis were performed on fluctuations of the original fields (Equation 14). Note that while this does not result in perfectly conservative fields, it still makes them more conservative since all values of  $|H|$  are smaller than 0.5 after taking the fluctuations.

Figure 8 shows the trace-moment (TM) analysis in space and time for the three events and for a value of  $q = 1.5$ . The value of  $K(q = 1.5)$  is the slope of the best-fit lines. Repeating the TM analysis for various values of  $q$  allows to characterize  $K(q)$  and to estimate  $\alpha$  and  $C_1$ . For the two first events a scaling break can be observed at large scales for the COSMO precipitation intensities (64-128 km). These scales were excluded from the analysis due to the limited number of points in this scale range. For consistency with the observations of the spectral analysis, the

**Table 4.** Values of the non-conservation parameter  $H$  and the fractal dimension  $D_f$  in time and space for all events, for the radar QPE, the COSMO **one-moment scheme** and the COSMO *two-moment scheme*.

**Figure 8.** Scaling (TM) analysis of the QPE product during the three events obtained with  $q = 1.5$ . Bold lines are best-fit lines taking into account a possible scaling break.

scale range of 2-8 km was excluded from the analysis for the first event. This scale range does not scale well on COSMO simulations when compared with radar observation in this event. For the last event, two scaling regimes are observed for the COSMO intensities (2-16 and 16-128 km), which were studied separately. On the contrary, for the radar QPE no scaling break is observed in space. In time, a weak scaling break can be observed both for radar and COSMO intensities at a resolution of around 160 minutes. Hence, results are discussed only for the time scales between 5-160 min (smaller scales).

## 5.2 Spatio-temporal analysis

Values of  $\alpha$ ,  $C_1$  and  $\gamma_s$  obtained with an analysis in time and in space of the three events are given in Figure 9. For the first two events, all parameters are computed only on the smaller scales (up to 64 km in space and up to 160 minutes in time), in order to account for the observed scaling break. For the last event both scale ranges are considered.

**Figure 9.**  $\alpha$ ,  $C_1$  and  $\gamma_s$  parameter values obtained with an analysis in time and space on the fluctuations of the precipitation intensities for the three events. For the last event, both the parameters at large and small spatial scales are displayed. The numbers in blue are the space/time ratios for  $\alpha$  and  $C_1$ .

For the first event, both COSMO microphysical schemes give very similar multifractal parameters and the discrepancy with the radar QPE is quite important. In space, it can be observed that  $\alpha$  is slightly smaller in the COSMO simulations than on the radar QPE. It is clear as well that the simulated  $C_1$  is too small compared with the radar observations. This tends to indicate that COSMO is underestimating the spatial intermittency. Generally, the observed discrepancies in  $\alpha$  and  $C_1$  tend to indicate that the spatial structure of the simulated fields is too smooth and lacks the variability observed by the radars. In time, the agreement is better for  $C_1$ , but COSMO has clearly higher values of  $\alpha$  indicating a larger temporal variability than the radar QPE. For this event, there is a noticeable discrepancy between the maximum singularity  $\gamma_s$  in space obtained from the radar QPE (0.721) and the  $\gamma_s$  obtained from the model (around 0.6 for both schemes). This indicates that during this event COSMO had a tendency to under-estimate extreme values, which might be caused by its difficulty to accurately simulate snowfall events, since COSMO does not consider partially melted snow (Frick and Wernli, 2012). Note that QPE in snow is very difficult and it is likely that the radar QPE itself is already underestimating precipitation intensities (Speirs et al., 2016), which would make this difference in  $\gamma_s$  even more noteworthy.

For the stratiform rain event, the multifractal parameters of the COSMO simulations are in better agreement with the radar QPE. In time, the two-moment COSMO scheme gives values that are in relatively close agreement

with the radar QPE and, in this regard, outperforms the one-moment scheme. COSMO simulations show generally smaller values of  $\alpha$  and  $C_1$  than the radar QPE, which is a trend that is observed for all events.

For the last convective event, two scaling regimes are considered in space: larger scales (16-128 km) and smaller scales (2-16 km). As already observed in the spectral analysis, there is a better agreement between the radar observations and the simulations with the one-moment scheme at smaller spatial scales. In time, however, the temporal intermittency of COSMO is smaller than for the radar QPE, which can be explained by the fact that COSMO generally overestimates the extent of the convective systems. Compared with the one-moment scheme and the radar QPE, the two-moment scheme has a smaller  $\alpha$  in space but a larger  $\alpha$  in time, as well as a smaller intermittency in time and space.

In summary, the observations of the spatio-temporal analysis are consistent with the spectral and scaling analysis where (1) a strong discrepancy in scaling behaviour was observed between COSMO and the radar QPE at small scales for the first event, (2) a better scaling of the model precipitation intensities was observed for the second event, (3) a discrepancy in scaling at large scales was observed between COSMO (especially for the two-moment scheme) and the radar QPE for the third event.

Overall, it can be observed that except for the first event where both schemes give similar values, the two-moment scheme is usually characterized by a larger  $C_1$  than the one-moment scheme, both in time and space, whereas in terms of  $\alpha$  there is no recurring trend. However one must keep in mind that this difference in  $C_1$  is within the expected range of uncertainty for this parameter (see second paragraph of Section 5). For the multifractal parameters  $\alpha$  and  $C_1$ , there is generally a good agreement between radar observations and simulations on the range of scales where the model exhibits a good scaling behaviour. In terms of  $\alpha$  and  $C_1$ , none of the two microphysical schemes seems to perform significantly better than the other. The two-moment scheme is however generally characterized by a slightly larger maximum singularity  $\gamma_s$ , indicating a better capacity to simulate extreme values. This is especially visible in the last convective event. In terms of space/time ratios, the observed ratios differ significantly from the theoretical model: the  $\alpha$  space/time ratio is always larger and the  $C_1$  space/time ratio always smaller than the theoretical values (1 and 1.44 respectively).

Gires et al. (2011) found different scaling breaks for a Cevenol event (strong precipitation events occurring in Fall in the south of France): roughly 16 km in space and 1h in time, as well as a better agreement with a simple space time model, but only for large scales which are not the primary focus of this study. These differences could be associated with the fact that the topography of the area analysed in this paper is more pronounced than in Gires et al. (2011).

It should also be noted that, in our case, the values of UM parameters  $\alpha$  and  $C_1$  exhibit a better agreement between observations and model simulations on the relevant range of scales.

### 5.3 Time series of universal multifractal parameters

To compare time series of universal multifractal parameters  $\alpha$  and  $C_1$ , the focus is put on the third (convective) event which shows the largest temporal variability. It was observed that the conclusions drawn for the third event in terms of discrepancies between radar and model multifractal parameters can be generalized to all events.

Figure 10 shows the time series of  $\alpha$  and  $C_1$  throughout the third (convective) event for the COSMO and the radar QPE precipitation intensities, as well as some illustrative precipitation fields that will be discussed.

Figure 10.  $\alpha$  and  $C_1$  time series during event 3.

During the convective event, four different phases can be identified. In the first short phase (12:00-14:00), observations and simulations agree relatively well in  $\alpha$  and  $C_1$ . This period corresponds to the initial stages of the event when only a few isolated cells are present (panel (a) in Figure 10).

In the second phase (14:00 - 17:00), a large convective system is crossing the domain on the radar observations, which causes a strong increase in  $\alpha$  and a decrease in  $C_1$ . This convective system is however located more in the south on the simulation and enters the domain only at around 15:30 (panel (b) in Figure 10).

During the third phase (17:00-21:00), the large convective system is visible on the simulated field, whereas on the observed radar fields, the most intense convective cells are already out of the domain. This causes a larger  $\alpha$  on the simulations than on the observations (panel (c) in Figure 10). Finally, during the last phase (21:00-24:00), a new convective system is visible on the observed field but is more or less absent on the simulated fields. This causes a discrepancy, the simulated fields having a smaller  $\alpha$  and a larger  $C_1$  than the observations (panel (d) in Figure 10). For this event, the spatial and temporal shifts between the convective system simulated by COSMO and the real convective system observed by the radar network are the main causes of the bad scaling observed at larger scales.

Note that the succession of phases detailed before is also clearly visible in the time series of wet area fraction displayed in Figure 11.

**Figure 11.** Fraction of wet area during the event of the 13 August 2015.

For the two other events, the conclusions are similar: discrepancies in multifractal parameters between simulated and observed precipitation intensities, are caused primarily by temporal and spatial shifts in the simulated precipitation patterns. The effect of such shifts on the multifractal analysis hints at the possibility of a further analysis based not on a fixed study domain but on a study domain which follows the precipitation system, in a way similar to Nykanen and Harris (2003). Using a mobile window would make the discrepancies in multifractal parameters depend much more on the small-scale structures of simulated precipitation intensities, since it would strongly reduce the effect of misplacements of the simulated precipitation systems.

## 6 Conclusions

In this work a spatial and temporal analysis of precipitation intensities simulated by the COSMO NWP model was performed using the universal multifractal (UM) framework which allows for the representation of the variability across scales with a limited number of parameters.

5 The first part of this work focused on a multifractal analysis of the climatology of precipitation intensities simulated by COSMO in its operational analysis mode. Analysis of the correlations between multifractal parameters and external synoptical and topographical descriptors revealed that the fractal dimension ( $D_f$ ) and the mean intermittency ( $C_1$ ) are strongly correlated to the fraction of rainy simulations. Additionally, the fractal dimension tends to increase and the mean intermittency tends to decrease with the latitude, which indicates that rainfall fields are more  
10 homogeneous at higher latitudes. The effect of topography is visible in the values of  $C_1$  and the maximum singularity  $\gamma_s$  (related to extreme values) which tend to decrease with altitude, as well as in  $H$  and  $\beta$  which tend to increase with altitude. This indicates a smaller intermittency and less rainfall extremes in mountainous regions, as well as smoother rainfall intensity fields, which can be linked to the dominance of large-scale orographic effects. A hierarchical clustering was performed based on the synoptical and topographical descriptors. The resulting classification  
15 into three classes was shown to correspond well with the famous Köppen (1936) climate classification. Distributions of multifractal parameters within these three classes were found to be statistically significantly different, indicating that the multifractal signature of rain is indeed climate dependent. Finally, investigation of the spatial structure of multifractal fields confirmed the conclusions of the correlation analysis, namely that the values of  $\beta$  and  $H$  are mostly influenced by the altitude (simulated precipitation tends to be smoother at higher altitudes) and  $D_f$  and  $C_1$   
20 are mostly influenced by the latitude (the intermittency decreases with the latitude).

The second part of this work focused on three different events, one cold front associated with heavy snowfall, one stationary front associated with stratiform rain and a stable atmosphere, and one summer convection event with heavy rain. All events were simulated at a 2 km resolution with both the standard operational one-moment microphysical parameterization of COSMO and a more advanced two-moments microphysical scheme. A comparison  
25 of the precipitation intensities at the ground simulated by COSMO and the Swiss radar composite was performed in terms of their multifractal signature. Whereas the radar data shows one single scaling regime over the studied spatial scale ranges (1-128 km), the COSMO simulations display scaling breaks for the first and the last event. It can be observed that during the snowstorm event, COSMO is unable to properly reproduce radar observations at small scales, which might be caused by the intrinsic difficulty of simulating solid precipitation. During the last convective  
30 event, the opposite can be observed, and COSMO is struggling to reproduce the larger scales, due to its difficulty in locating accurately the convective system in time and space during this event. In the temporal scales, a scaling break is observed both for the radar data and the COSMO simulations at around 3 hours. Comparisons of the one-moment and two-moments COSMO microphysical parametrizations show that the fields simulated by the two-moments scheme tend to display a larger intermittency and variability than the one-moment scheme. This does not generally

translate into a better agreement of multifractal parameters  $\alpha$  and  $C_1$  with the radar composite, except during the stratiform event where the two-moment scheme performs slightly better. However, the two-moments scheme gives a consistently better agreement with the radar QPE in terms of spatial and temporal fractal dimensions, which measure how convoluted the precipitation occurrence signal is.

- 5 Ultimately, the multifractal framework can be used to identify the scale ranges in which the model is able to simulate realistic fields of water contents, and as such this technique can be used as a diagnostic tool for model evaluation.

*Acknowledgements.* The authors would like to thank MeteoSwiss for the access to the Swiss operational radar composite as well as the initial and boundary conditions used in the COSMO simulations.

- 10 The authors thank the Partenariat Hubert Curien – Germaine de Staël (Projet 32709UK) for financial support that made this collaboration possible.

The authors also thank Tim Raupach for proofreading the paper.

## Appendix A: Spatial representation of climatological descriptors

**Figure 12.** Spatial representation of the location of all areas used in the climatological study of multifractal parameters as well as the corresponding local descriptors. Note that the squares are mere indicators of the location of the center of all areas and their size is not in scale with their real sizes. The colors drawn below the squares correspond to the classification obtained in Section 4.2.

## Appendix B: Visual example of the effect of multifractals on the structure of a field

Figure B.1 illustrates the effect of varying  $\alpha$  and  $C_1$  on randomly generated isotropic conservative multifractal fields. One can see how increasing  $\alpha$ , increases the variability within non-zero intensity regions whereas increasing  $C_1$  decreases the intermittency and makes the field look more spatially homogeneous.

Figure B.2 illustrates the effect of  $H$  on isotropic multifractal fields, with constant  $\alpha$  and  $C_1$ .  $H$  can be considered as a kind of smoothness parameter, that denotes the order of integration ( $H < 0$ ) or differentiation ( $H > 0$ ) needed to obtain the observed field from a direct multifractal cascade process.

**Figure B.1.** Illustration of the effect of  $\alpha$  and  $C_1$  on randomly generated fields. Blue pixels correspond to zero intensity, whereas pixels with non-zero intensity are shown with a greyscale colormap. Taken from Lovejoy (2017)

**Figure B.2.** Illustration of the effect of  $H$  on randomly generated fields for  $\alpha = 1.2$  and  $C_1 = 0.05$ . Blue pixels correspond to zero intensity, whereas pixels with non-zero intensity are shown with a greyscale colormap. Taken from Lovejoy (2017)

### Appendix C: Comparison with the Köppen classification

Figure C.3 shows the aggregated Köppen classification of the 209 subsquares used in Section 4. Indeed, the classification is quite close to the one obtained in Section 4.2 with topographical and synoptical descriptors. The main differences are the fact that class 3 gets smaller and class 2 larger, especially in the south-west and that some areas in the North of Italy are in class 2. Note also that that sea regions are absent, since the Köppen classification does consider only land areas.

**Figure C.3.** Aggregated Köppen climate classification within all 209 subsquares used in Section 4.2. Class 1 corresponds to Köppen classes Dwa, Dwb and Dfc (Cold climates), class 2 to Köppen class Cfb (temperate with warm summer) and class 3 to Köppen classes Cfa and Csa (temperate with hot summer).

Distribution of MF parameters within aggregated Köppen classes (not displayed) show only minor deviations from those obtained with the synoptical classification (Figure 5). However, some differences are visible in space for the distributions of  $\alpha$  and  $C_1$ , which tend to be less distinguishable between classes 1 and 2 than on the original synoptical classification. As a consequence, in the Köppen classification, differences in the distributions of  $\alpha$  in space are not statistically significant according to the Kruskal-Wallis test. All other statistical tests, however, give the same outcomes as the original classification, but often with a larger but still significant  $p$ -value.
