Abstract

Secondary organic aerosol (SOA) formation from volatile organic compounds (VOCs) in the atmosphere can be thought of as a succession of oxidation steps. The production of later-generation SOA via continued oxidation of the first-generation products is defined as chemical aging. This study investigates aging in the α -pinene ozonolysis system with hydroxyl radicals (OH) through smog chamber experiments. The first-generation α -pinene ozonolysis products were allowed to react further with OH formed via HONO photolysis. After an equivalent of 2-4 days of typical atmospheric oxidation conditions, homogeneous OH oxidation of the α -pinene ozonolysis products resulted in a 20-40 % net increase of the SOA for the experimental conditions used in this work. A more oxygenated product distribution was observed after aging based on the increase in aerosol atomic oxygen to carbon ratio (O:C) by up to 0.04. Experiments performed at intermediate relative humidity (RH) of 50 % showed no significant difference in additional SOA formation during aging compared to those performed at low RH of less than 20 %.

1. Introduction

Anthropogenic activities such as fuel combustion as well as biogenic sources such as emissions from vegetation can introduce particles and particle precursors into the atmosphere. In most areas, about half of the submicron aerosol mass on average is composed of organic compounds (Zhang et al., 2007). Organic particles directly emitted to the atmosphere are traditionally defined as primary organic aerosol (POA), while those formed through atmospheric

29 reactions and condensation of species with corresponding volatility are secondary (SOA).
30 Atmospheric aerosols represent a significant risk to human health by causing respiratory problems
31 and heart attacks (Davidson et al., 2005; Pope et al., 2009). At the same time these particles
32 influence the climate of our planet (Intergovernmental Panel on Climate Change, 2007).

33 Oxygenated OA with a high oxygen to carbon ratio (O:C) is often the most important
34 component of ambient OA suggesting the importance of atmospheric chemistry in the formation
35 and processing of OA (Zhang et al., 2007). Early studies of SOA formation (Grosjean and Seinfeld,
36 1989; Izumi and Fukuyama, 1990; Odum et al., 1996) focused on the first stage of reactions
37 involving the target precursor reacting with the chosen oxidant. In the atmosphere, organic vapors
38 and particles interact with oxidants for days and therefore successive oxidation processes are
39 inevitable.

40 Chemical aging refers to the subsequent stages of SOA formation and evolution due to the
41 production of later-generation products via oxidation of first-generation products by oxidants such
42 as OH free radicals (Donahue et al., 2006; Henry et al., 2012). Previous studies have explored
43 various forms of aging, including heterogeneous reactions of oxidants and aerosols (George et al.,
44 2008), oligomerization (Kalberer et al., 2006), photolysis of either gas or condensed-phase
45 products (Henry and Donahue, 2012), and homogeneous gas-phase oxidation by OH (Donahue et
46 al., 2012). Homogeneous gas-phase oxidation reactions appear to be in general much faster than
47 heterogeneous reactions, due to diffusion limitations of the latter (Lambe et al., 2009). The first-
48 generation oxidation reactions of most SOA precursors convert much less than 50 % of the
49 precursor to SOA, leaving more than half of the carbon still in the gas-phase. Additional oxidation
50 of these vapors can potentially contribute additional and more oxygenated SOA components.
51 These later-generation reactions have been proposed to be a major missing step connecting
52 chamber studies to field measurements.

53 Zeroth order parameterizations have been developed to model the chemical aging of semi-
54 volatile POA emissions in chemical transport models (Robinson et al., 2007). CTMs using these
55 schemes show improved performance in urban areas such as Mexico City (Tsimpidi et al., 2011),
56 but tend to over-predict OA in areas such as the southeastern United States where biogenic VOCs
57 dominate if chemical aging is assumed to be a major source of additional SOA (Lane et al., 2008).
58 As a result, the importance of aging of biogenic SOA as a source of SOA mass concentration
59 remains an issue of debate.

60 The ozonolysis of α -pinene ($C_{10}H_{16}$) is considered one of the most important global SOA
61 sources (Griffin et al., 1999). The system has been well characterized through smog chamber
62 experiments where researchers quantified its SOA yields under different conditions, explored the
63 reaction pathways and mechanisms, and identified its product distributions. Recent studies suggest
64 that there is significant potential for additional SOA formation from homogeneous gas-phase aging
65 by OH of the first-generation α -pinene oxidation products (Donahue et al., 2012; Müller et al.,
66 2012; Chacon-Madrid et al., 2013). Major identified products existing in gas phase such as
67 pinonaldehyde and pinonic acid can serve as SOA precursors and further react with OH.
68 Pinonaldehyde reacts with OH, with SOA mass yields up to 5 % under low- NO_x conditions and
69 20 % under high- NO_x conditions (Chacon-Madrid et al., 2013). Müller et al. (2012) demonstrated
70 the formation of 1,2,3-butanetricarboxylic acid (MBTCA), an SOA product of low volatility
71 identified in α -pinene ozonolysis, through the gas-phase OH oxidation of pinonic acid. They
72 reported an experimental yield of 0.6 % for MBTCA from the gas-phase OH oxidation of pinonic
73 acid, accounting for about 10 % of the total SOA formed. The proposed formation mechanisms of
74 MBTCA is a classic example of semi-volatile precursors going through oxidation and forming
75 products of lower volatility.

76 The Multiple Chamber Aerosol Chemical Aging Study (MUCHACHAS) explored the gas-
77 phase OH aging effects of the α -pinene ozonolysis products via experiments performed in four
78 different smog chambers (Donahue et al., 2012). They were able to isolate the aging effect by
79 using different OH sources (HOOH photolysis, HONO photolysis, TME ozonolysis), light sources
80 (sunlight, quasi-solar lamps, 350 nm UV lamps), and chambers of different design in size and
81 material (Teflon and aluminum). Almost in all experiments, additional formation of SOA (up to
82 55 %) and a more oxidized product distribution (increasing O:C) were observed after aging.
83 However, in one of the chambers, strong UV photolysis led to decreasing SOA mass
84 concentrations in experiments with low to moderate OH levels, $[OH] \leq 2 \times 10^6$ molecules cm^{-3}
85 (Henry and Donahue, 2012). These authors concluded that chemical aging involves a complex set
86 of interacting processes with competing functionalization (conserved C number with products of
87 lower volatility and higher oxidation states) and fragmentation (cleavage of C-bond with products
88 over a wide volatility range and higher oxidation states) of the various organic compounds. A 2D-
89 volatility basis set (2D-VBS) simulation based on these two pathways and a branching ratio
90 between them showed that homogeneous OH aging can potentially more than double the α -pinene

91 SOA mass concentration, after about a day's equivalent of typical atmospheric oxidation
92 conditions. Uncertainties such as "ripening" during which SOA volatility evolves but its mass
93 remains constant, UV photolysis and heterogeneous OH uptake can further complicate the aging
94 process.

95 Qi et al. (2012) also explored aging of the α -pinene ozonolysis system through smog
96 chamber experiments using HOOH as an OH source and studied the UV photolysis effect. They
97 observed a 7.5 % increase in the SOA volume concentration and an increase of 0.03 in the O:C
98 after aging. Minimum photolysis effect was reported for these experiments.

99 One complication of chamber experiments is the interaction of particles with chamber
100 walls. The wall-loss rate of particles is a function of particle size, charge distribution, chamber
101 geometry, turbulence, and electric field within the chamber (Crump and Seinfeld, 1981). In order
102 to quantify SOA yields from chamber experiments, it is important to correct for particle wall loss.
103 Recent findings that organic vapors in the chamber can be directly lost to the Teflon walls as well
104 further complicate the wall-loss correction process (Matsunaga and Ziemann, 2010; Zhang et al.,
105 2014). Krechmer et al. (2016) measured the loss rate of vapors formed in the chamber and found
106 the corresponding timescale to be 7-13 min. Ye et al. (2016) determined the vapor wall-loss
107 timescale in the Carnegie Mellon chamber used in this work to be around 15 min for semi-volatile
108 organic compounds.

109 Despite the consensus from the aforementioned chamber studies that gas-phase OH aging
110 of α -pinene ozonolysis products can contribute to additional SOA formation, there lacks
111 consistency in the extent to which the additional mass can form for different OH exposures. Part
112 of the problem is that the estimated amount of additional SOA formed from these long-lasting
113 aging experiments can be extra sensitive to the particle and the vapor wall-loss correction methods
114 deployed. The uncertainties at the end of a 10-hour long aging experiment during which most
115 particles are lost to chamber walls and the measured suspended mass is low can be relatively high.
116 In this work, we aim to quantify the additional SOA formed during the aging step comparing
117 measurements from a suite of instrumentation. We adopt a size-dependent particle wall-loss
118 correction method and develop a procedure to better constrain the associated errors. We also
119 attempt to constrain the vapor loss using both theoretical calculations and measurements.

120
121

122 2. Experimental approach

123 We conducted experiments in a 12 m³ Teflon (Welch Fluorocarbons) smog chamber at
124 Carnegie Mellon University (CMU). The reactor was suspended in a temperature-controlled room
125 with walls covered with UV lights (GE 10526 and 10244). Prior to each experiment, we flushed
126 the chamber overnight with purified air under UV illumination to remove any residual particles
127 and gas-phase organics. We generated purified air by passing ambient air through a high-efficiency
128 particulate air (HEPA) filter to remove particles, an activated carbon filter to remove any organics,
129 a Purafil filter to remove NO_x, and finally a silica gel filter, keeping relative humidity (RH) below
130 5 % in the chamber before each experiment.

131 We pumped an ammonium sulfate solution (1 g L⁻¹) into the chamber at the beginning of
132 each experiment through an atomizer (TSI, model 3076) at a constant rate of 90 mL h⁻¹ to produce
133 droplets. The droplets passed through a diffusion dryer and a neutralizer to produce dry ammonium
134 sulfate seed particles. We injected seeds with a number mode size of 110 nm until they reached a
135 number concentration of 2×10⁴ cm⁻³, resulting in an initial seed mass concentration of around 40
136 μg m⁻³ and a surface area concentration of up to 1000 μm² cm⁻³. Typical organic vapors with a
137 molar weight of 250 g mol⁻¹ thus had an initial collision frequency with these seeds of 0.01 s⁻¹. We
138 injected α-pinene (Sigma-Aldrich, ≥ 99 %) into the chamber using a septum injector with purified
139 air as carrier flow. We generated ozone using a corona-discharge ozone generator (AZCO,
140 HTU500AC) to initiate the ozonolysis reaction. We prepared a fresh HONO solution in a bubbler
141 by adding a 4.9 g L⁻¹ sulfuric acid solution to a 6.9 g L⁻¹ sodium nitrite solution. We then turned
142 on the UV lights to start the photo-dissociation of HONO, producing OH.

143 At the end of each experiment, we injected additional ammonium-sulfate seeds into the
144 chamber using the same method with a more concentrated solution (5 g L⁻¹) in order to characterize
145 the particle wall-loss rates a second time.

146 We added butanol-d9 (Cambridge Isotope Laboratories, 98 %) into the chamber through
147 the septum injector as an OH tracer before the reaction started and used the method described in
148 Barmet et al. (2012) to calculate the OH produced by HONO photolysis. The OH concentration in
149 these experiments was around 2.4×10⁷ molecules cm⁻³ for the first hour, then dropped to around
150 5×10⁶ molecules cm⁻³ afterwards. The introduction and photolysis of HONO produces hundreds
151 of ppb of NO_x, and thus the aging reactions in this work occurred under high NO_x conditions; the
152 majority of the peroxy radicals reacted with NO during the aging phase of the experiments.

153 We performed experiments at both low RH of less than 20 % and intermediate RH of 50 %.
154 To add water vapor to the chamber, we used a stream of purified air to carry ultrapure water
155 (Millipore water purification system) in a bubbler into the chamber before the introduction of seeds.

156 We measured the particle size distribution using a TSI Scanning Mobility Particle Sizer,
157 SMPS (classifier model 3080; CPC model 3010 or 3772), with flows adjusted to measure particle
158 diameters in the 15-700 nm range. We measured the particle composition and mass spectrum of
159 the OA with an Aerodyne High Resolution Time-of-flight Aerosol Mass Spectrometer (HR-Tof-
160 AMS). We monitored the concentrations of α -pinene and butanol-d9 using a Proton Transfer
161 Reaction-Mass Spectrometer (PTR-MS, Ionicon), the ozone concentration using a Dasibi 1008
162 ozone monitor (ICE: Teledyne 400E), and NO_x (NO + NO₂) levels using a Teledyne API NO_x
163 Analyzer 200A (ICE: Teledyne T201). We held the chamber temperature constant at 22 °C
164 throughout all experiments. We list the initial conditions of the experiments performed for this
165 work in Table 1.

166

167 **3. Data analysis**

168 **3.1 SOA yields**

169 The SOA mass yield, Y , is a metric of the ability of a gaseous precursor to form SOA, and
170 is defined as $Y = C_{\text{SOA}}/\Delta\text{VOC}$, where C_{SOA} is the produced SOA mass concentration (in $\mu\text{g m}^{-3}$)
171 and ΔVOC the amount of the VOC precursor (α -pinene in this case) reacted (in $\mu\text{g m}^{-3}$). To
172 separate the effect of aging on SOA mass concentration, we define a first-generation SOA mass
173 yield, $Y_1 = C_{\text{SOA},1}/\Delta\text{VOC}$, and a second-generation SOA mass yield, $Y_2 = C_{\text{SOA},2}/\Delta\text{VOC}$. $C_{\text{SOA},1}$ and
174 $C_{\text{SOA},2}$ are the concentrations of SOA formed before, and after aging with hydroxyl radicals. All
175 α -pinene reacts away during the first stage and thus ΔVOC for the second stage is the same as the
176 initial α -pinene concentration in the chamber.

177

178 **3.2 Particle wall-loss correction**

179 In this work, we try to reduce the uncertainties in the estimated SOA mass concentration
180 associated with the particle wall-loss correction. This uncertainty can be significant due to two
181 aspects of these aging experiments: the evolution of the particle size distribution and the duration
182 of the experiments. In these aging experiments, where particles grow by condensation and
183 coagulation for several hours, the particle size distribution can potentially shift, covering a wide

184 size range over the course of an experiment. Particle wall losses are size dependent, and this shift
185 can introduce significant errors if a constant loss rate constant is assumed. To minimize these
186 problems, we adopted a size-dependent particle wall-loss correction method where we determined
187 the particle wall-loss rate constant, k , at each particle size, D_p .

188

189 **3.2.1 Determination of particle wall-loss rate constants**

190 The size-dependent particle wall-loss correction method (Keywood et al., 2004; Ng et al.,
191 2007; Loza et al., 2012; Nah et al., 2016) adopted in this work is based on the SMPS-measured
192 particle size distribution. At each particle size bin i , the first-order particle wall-loss rate constant
193 k , can be determined as the slope of the following equation:

194

$$195 \ln[N_i(t)] = -k_i t + Q \quad (1)$$

196

197 where $N_i(t)$ is the SMPS-measured aerosol number concentration at size bin i and Q is an arbitrary
198 constant. Applying Eqn. 1 across the entire SMPS-measured particle size range, we obtain the
199 particle wall-loss rate constant function, $k(D_p)$.

200 To determine the $k(D_p)$ profile, we utilized the initial four-hour ammonium sulfate seed
201 wall-loss period for each experiment. Since k may also vary with time (McMurry and Rader, 1985),
202 we determined a second $k(D_p)$ profile for each experiment using the ammonium sulfate seed wall-
203 loss period at the end. It is important to ensure that the k 's, especially at sizes where the majority
204 of SOA mass is distributed, remain the same over the course of each experiment.

205 The $k(D_p)$ values calculated (with an $R^2 > 0.5$) based on SMPS measurements of the seed
206 distribution from this work usually only cover particle size range of 30-300 nm due to the lack of
207 particles at either end of the particle size distribution. To determine the $k(D_p)$ for $D_p < 30$ nm, we
208 use a simple log-linear fit of k 's from 30-50 nm and back extrapolate it to 10 nm. To determine
209 $k(D_p)$ for $D_p > 300$ nm, we assume that the constant is practically the same in the 300-700 nm
210 range. We confirmed this with additional seed-only experiments where there were enough particles
211 at that size range (Wang et al., 2017). Significant increases of the rate loss constant are observed
212 for particles larger than 1 μm , while in our experiments the particles remained small than 600 nm
213 or so. A measure of the uncertainty of these corrections is the variability of the corrected mass
214 concentration during the seed wall-loss periods as discussed in the next section. Details regarding

215 the wall-loss profiles in the CMU chamber and the execution of the size-dependent particle wall-
 216 loss correction for this work can be found in Wang et al. (2017).

217

218 3.2.2 Correction of SMPS measurements

219 The corrected particle number concentration at each size bin i , $N_i(t)$, can be calculated
 220 numerically,

221

$$222 N_i(t) = N_i^m(t) + k_i \int_0^t N_i^m(t) dt, \quad (2)$$

223

224 from the measured values $N_i^m(t)$ and the $k(D_p)$ corresponding to the size bin i , k_i .

225 For closed systems in which coagulation is slow, the particle wall-loss corrected number
 226 concentration should be constant. In order to evaluate how well the correction works, we define
 227 the parameter: $\varepsilon_N = 2\sigma_{N_s}/\overline{N_s}$, where σ_{N_s} is the standard deviation of the particle wall-loss
 228 corrected number concentration for the seed wall-loss periods and $\overline{N_s}$ the average. Similarly, we
 229 define $\varepsilon_V = 2\sigma_{N_s}/\overline{V_s}$ based on the particle wall-loss corrected volume concentration for the two
 230 seed wall-loss periods. Only when all four values, ε_N and ε_V for both the initial and the final seed
 231 periods, are less than 5 % do we deem the particle wall-loss correction valid for that individual
 232 experiment. Experiments in which these criteria were not met were not included in the analysis.

233 To calculate the mass concentration of the formed SOA, C_{SOA} , during the course of an
 234 experiment, we treated the particle wall-loss corrected aerosol volume concentration $V(t)$
 235 differently before and after its maximum, V_{max} . For

236

$$237 t < t_{V_{max}}, C_{SOA}(t) = (V(t) - V_s)\rho_{SOA},$$

$$238 t \geq t_{V_{max}}, C_{SOA}(t) = [V(t) - V_s \frac{V(t)}{V_{max}}]\rho_{SOA}, \quad (3)$$

239

240 where $t_{V_{max}}$ is the corresponding time at the maximum particle wall-loss corrected total aerosol
 241 volume concentration. V_s is the average particle wall-loss corrected seed volume concentration
 242 before the beginning of each experiment. ρ_{SOA} is the SOA density, assumed to be equal to $1.4 \mu\text{g}$
 243 m^{-3} (Kostenidou et al., 2007). Ideally, $V(t)$ should equal to V_{max} after the reactions are completed
 244 and particle wall loss is the only process after $t_{V_{max}}$. However, deviations of $V(t)$ from V_{max} are

245 caused by the uncertainty associated in applying the size-dependent wall-loss corrections. By
246 scaling V_s with $V(t)/V_{\max}$, we are distributing the impact of any potential fluctuations in $V(t)$ evenly
247 to both the seeds and the organics, and thus obtain a more stable C_{SOA} after aging.

248

249 **3.3 Analysis of AMS measurements**

250 The HR-AMS was operated in V mode during the experiments in this work. Squirrel v1.56D was
251 used to analyze the data. The atomic oxygen to carbon ratio, O:C, was determined based on the
252 unit-resolution correlation described in Caragaratna et al. (2015). Nitrate signals were attributed
253 to organics since the only sources of them in these experiments are organonitrates.

254 In an attempt to explore the functionalities/products that may have changed during aging,
255 we used the AMS high-resolution (HR)family analysis. We used Pika 1.15D to analyze the HR
256 data. Each fitted ion is grouped into a “family” based on their chemical formula, and the families
257 used are: CH, CHO, CHO₂, C_x, HO, and NO. These are the main components of the organics
258 formed, with family HO calculated by subtracting the concentrations of the other families from the
259 total organic signal. This is necessary because the fragmentation of sulfates can interfere with the
260 family HO. Family NO can be used to represent the organonitrates formed during the aging phase
261 of the experiments.

262

263 **4. Results and discussion**

264 The particle wall-loss corrected aerosol number concentration evolution during a typical
265 experiment (Exp. 1) together with the SMPS raw measurements are shown in Fig. 1. Prior to the
266 ozonolysis, 18,000 cm⁻³ ammonium sulfate particles were added to the chamber as seeds. After a
267 4.5 h wall-loss period, 8,000 cm⁻³ particles remained suspended, serving as pre-existing surface
268 for condensation. At $t=0$, ozone was added into the chamber, reacting with α -pinene to form
269 condensable first-generation products. The ozonolysis of α -pinene has been found to produce OH
270 with a molar yield of approximately 0.7 (Paulson et al., 1998), which in our experiments resulted
271 in approximately one third of the precursor reacting with OH. An additional 100 cm⁻³ particles
272 were formed due to nucleation at this time. Two doses of HONO were added into the chamber in
273 this experiment at $t=0.4$ h and $t=1.3$ h, respectively. HONO was allowed to mix in the chamber
274 and then the UV lights were turned on at $t=0.8$ h and $t=1.8$ h to produce OH. At $t=3.5$ h, another

275 10,000 cm⁻³ ammonium sulfate particles were added into the chamber for a second 4 h long
276 determination of the $k(D_p)$ profile for this experiment.

277 The two $k(D_p)$ profiles determined from the initial seed wall-loss period and the one at the
278 end of the experiment are shown in Fig. 2. They agree relatively well with small discrepancies at
279 $D_p < 50$ nm. The complete $k(D_p)$ profile used for the size-dependent particle wall-loss correction
280 is also shown.

281 As indicated in Fig. 1, the particle wall-loss corrected aerosol number concentration
282 remains relative level at $t < 0$ h and $t > 3.5$ h, with $\varepsilon_{N,1} = 3.3$ % and $\varepsilon_{N,2} = 0.5$ %, respectively. The
283 particle wall-loss corrected aerosol volume concentration (Fig. 3) at the initial seed wall-loss
284 period and that at the end had variabilities equal to $\varepsilon_{V,initial} = 4.2$ % and $\varepsilon_{V,end} = 3.8$ %, respectively.
285 All parameters were less than 5 % and therefore the accuracy of the wall-loss
286 correction was acceptable.

287 The particle wall-loss corrected aerosol volume concentration evolution for Exp. 1 together
288 with the corresponding SMPS raw measurements are shown in Fig. 3. Particles grew from $t=0$ to
289 0.7 h and $t=0.8$ to 1 h due to vapor condensation. The total aerosol volume peaked at $t=0.7$ h during
290 the first-generation oxidation, and reached its maximum at $t=1.1$ h due to aging during the second-
291 generation oxidation. The change in volume during the second addition of OH at 1.7 h was
292 negligible.

293 The SOA mass concentration evolution for Exp. 1 calculated using Eqn. 3 is shown in Fig.
294 4. The error bars are calculated using the highest ε (in this case $\varepsilon_{V,1} = 4.2$ %). For this experiment,
295 37.7 ± 1.6 $\mu\text{g m}^{-3}$ of SOA was formed during ozonolysis. An additional 11.1 ± 2.6 $\mu\text{g m}^{-3}$ SOA was
296 formed during the first aging period. The SOA reached 48.8 ± 2 $\mu\text{g m}^{-3}$ after aging and remained
297 approximately constant until the end of the experiment. The total SOA produced and the calculated
298 SOA yields for all experiments are listed in Table 2.

299 The AMS-derived atomic oxygen to carbon ratio (O:C) evolution for Exp. 1 is shown
300 together with the AMS-measured aerosol composition (assuming CE=1) in Fig. 5. The increase in
301 the sulfate signals at $t=0$ is caused by a change in the instrument collection efficiency. Due to the
302 uncertainty caused by CE changes over the course of an experiment, we did not use the absolute
303 AMS-measured organic mass concentration for any quantitative analysis. Using the algorithm
304 derived by Kostenidou et al. (2007), we calculated the CE to be ~ 0.25 for the initial seed period
305 and ~ 0.4 after the seeds were coated with organics. A quick check comparing the two stepwise

306 increase in the CE-corrected organic mass concentration to those derived from SMPS revealed that
307 the results from both instrument agreed reasonably well. The algorithm also estimated that the
308 SOA density was $1.3 \pm 0.15 \text{ g cm}^{-3}$ in good agreement with the Kuwata et al. (2012)
309 parameterization based on the measured O:C and H:C which also predicted 1.3 g cm^{-3} .

310 The O:C is a collective measure for the ongoing chemistry during these aging experiments.
311 In Exp. 1, the O:C kept decreasing due to the freshly-formed semi-volatile SOA condensing onto
312 particles from $t=0$ to 0.5 h. Later during the dark period ($t=0.5$ h to 0.8 h), the O:C ratio kept
313 decreasing to 0.42 while the organic mass concentration stayed almost constant. This is consistent
314 with the “ripening” phenomenon, first observed during the MUCHACHAS campaign, where the
315 composition of the formed SOA keeps evolving after α -pinene has reacted while the change in
316 SOA mass is minimal (Tritscher et al., 2011). The nature of this process is not well-understood,
317 but it probably involves heterogeneous reactions. After OH radicals were generated in the chamber
318 at $t=0.8$ h, the semi-volatile vapors got oxidized to form second-generation products of lower
319 volatility, resulting in an increase of 0.02 in O:C in about 10 min. After $t=1$ h, the O:C remained
320 relatively constant but it started to decrease at $t=1.25$ h when the UV lights were turned off. Since
321 aging is a complex process that involves functionalization, fragmentation and heterogeneous
322 reactions, the trends in O:C are indicative of the competition among these processes. The decrease
323 we observed here was associated with turning the UV lights off, and thus it is likely that some
324 chemistry was perturbed and thus the processes resulting in decreasing O:C took over. The
325 decrease in O:C associated with turning off the UV lights was not consistent across the five
326 experiments. This further proves that this phenomenon is the result of several competing process
327 and needs further investigation on a molecular level. An inflection point at $t=1.7$ h was observed
328 after a second dose of OH being introduced in the chamber. Instead of the stepwise increase like
329 the one observed after the first dose of OH, the O:C increased slowly but steadily this time until
330 the end of the experiment to 0.45 with no significant increase in organic mass. This is also quite
331 consistent with what was observed in MUCHACHAS.

332 We used the organic to sulfate ratio (Org/Sulf) derived from AMS measurements to look
333 at the SOA formation in these experiments due to its insensitivity to changes in collection
334 efficiency. The Org/Sulf time series for Exp. 1 is shown in Fig. 6. The ratio increased to 1.25 at
335 $t=0.7$ h as the result of the first-generation vapors condensing onto pre-existing particles. After we
336 first turned on the UV lights, a stepwise increase in the ratio was observed and reached the

337 maximum value of 1.60 at $t=1.1$ h as a result of the second-generation oxidation chemistry. After
 338 that, the ratio kept decreasing. A small bump was observed after the second introduction of OH
 339 and then the ratio kept decreasing. One possible explanation for this continuous decrease is the
 340 effect of the size-dependent particle wall-loss process. The faster removal of smaller particles
 341 (which contain more SOA than sulfate) than that of the bigger ones (which have a lower SOA to
 342 sulfate ratio) can lead to a decrease of the overall organic to sulfate ratio. Fig. 7 shows the size
 343 dependence of the Org/Sulf, together with the mass distribution of both organic and sulfate for
 344 Exp. 1. The Org/Sulf decreased dramatically from 10 to 1 over the particle vacuum aerodynamic
 345 diameter (D_{va}) range of 200 – 500 nm, indicating strong composition dependence on particle size.
 346 Since the majority of the mass is distributed in this range, the size-dependent particle wall-loss rate
 347 can contribute significantly to the decrease observed in Fig. 6 after the Org/Sulf reached its
 348 maximum.

349

350 4.1 Effect of size-dependent losses on the organic to sulfate ratio

351 To quantify the effect of the size-dependence of the particle wall-loss process on the
 352 organic to sulfate ratio, we discretized the AMS-measured mass distribution $M(D_p)$ into 10 bins
 353 in the particle diameter space and defined a mass-weighted particle wall-loss rate constant for each
 354 species j , \bar{k}_j , as

355

$$356 \quad \bar{k}_j = \frac{\sum_{i=1}^{10} M_{ij} k_i}{\sum_{i=1}^{10} M_{ij}} \quad (4)$$

357

358 where M_{ij} is the aerosol mass concentration of species j for size bin i and k_i is the averaged $k(D_p)$
 359 across size bin i . Note that the particle diameter used in this section refers to the SMPS-measured
 360 mobility equivalent diameter D_p . The particle vacuum aerodynamic diameters derived from the
 361 AMS measurements have been converted to D_p using an SOA density of $1.4 \mu\text{g m}^{-3}$.

362 From Eqn. 4 we are able to determine a mass-weighted particle wall-loss rate constant for
 363 sulfate, \bar{k}_{SO_4} , and for organics, \bar{k}_{Org} . For the period after completion of the reactions and if there
 364 are only particle losses to the walls the Org/Sulf ratio should satisfy:

365

$$366 \quad (\text{Org/Sulf})(t) = (\text{Org/Sulf})_m(t) \exp(\bar{k}_{SO_4} - \bar{k}_{Org})t \quad (5)$$

367

368 where $(\text{Org/Sulf})_m(t)$ is the AMS-measured and $(\text{Org/Sulf})(t)$ the loss-corrected organic to
369 sulfate ratio.

370 We can test if indeed the particle wall losses are responsible for the decreasing ratio in Exp.
371 1 focusing on the period from $t_1 = 1.2$ h to $t_2 = 1.7$ h (Fig. 6). In this example t_1 corresponds to
372 the maximum Org/Sulf and t_2 is the second time in which the UV lights were turned on. Applying
373 Eqn. 4, we found the mass-weighted particle wall-loss rate constant for organics, $\bar{k}_{Org} = 0.06$ h⁻¹,
374 and for sulfate, $\bar{k}_{SO_4} = 0.05$ h⁻¹. The black line in the inset graph of Fig. 6 indicates the particle
375 wall-loss corrected Org/Sulf for the chosen time period using Eqn. 5. The loss-corrected ratio
376 remained relatively constant indicating that the size-dependent particle wall-loss process coupled
377 with the different size distributions of the sulfate and organics were causing the decrease in the
378 ratio. This exercise was repeated for the other experiments arriving in the same conclusion.

379

380 **4.2 Effect of chemical aging on additional SOA formation**

381 To quantify aging effects based on the SMPS measurements, we define the fractional
382 change in the particle wall-loss corrected SOA mass concentration after aging, $\Delta[\text{OA}]$, as:

383

$$384 \Delta[\text{OA}] = (C_{\text{SOA},2} - C_{\text{SOA,UV}}) / C_{\text{SOA},1}, \quad (6)$$

385

386 where $C_{\text{SOA,UV}}$ is the particle wall-loss corrected aerosol mass concentration at the time when we
387 first turned on the UV lights. $C_{\text{SOA,UV}}$ can be equal to $C_{\text{SOA},1}$ depending on how level the first-
388 generation SOA mass concentration remains after wall-loss correction. Fig. 8 summarizes the
389 $\Delta[\text{OA}]$ for all five experiments with the values and corresponding errors listed in Table 2. The OH
390 exposure resulted in an average increase of 24 ± 6 % in SOA mass concentration after aging, ranging
391 from 20 to 29 %. Our HONO injection method creates OH levels of about 2.4×10^7 molecules
392 cm⁻³ for the first hour and then the concentration dropped to around 5×10^6 molecules cm⁻³. The
393 OH exposure is equivalent to 2-4 days of typical atmospheric oxidation conditions, assuming an
394 OH concentration of 2×10^6 molecules cm⁻³. The uncertainties displayed in Fig. 8 were propagated
395 from uncertainties in the SOA mass concentration.

396 To quantify aging effects based on the AMS data, we define the fractional change in the
397 organic to sulfate ratio:

398

$$\Delta[\text{Org/Sulf}] = ([\text{Org/Sulf}]_2 - [\text{Org/Sulf}]_{\text{UV}}) / [\text{Org/Sulf}]_1, \quad (7)$$

399
400

401 where $[\text{Org/Sulf}]_{\text{UV}}$ refers to the organic to sulfate ratio at the time when we first turned on the UV
402 lights, $[\text{Org/Sulf}]_1$ the maximum before we first turned on the UV lights and $[\text{Org/Sulf}]_2$ the
403 maximum after the OH exposure. Fig. 8 summarizes the $\Delta[\text{Org/Sulf}]$ calculated for all five
404 experiments with the values and corresponding errors listed in Table 2. The uncertainties are based
405 on the deviation between the measured and the corrected Org/Sulf (Fig. 6 inset) over the chosen
406 time period. An associated error is calculated respectively for $[\text{Org/Sulf}]_{\text{UV}}$, $[\text{Org/Sulf}]_1$ and
407 $[\text{Org/Sulf}]_2$. The reported error for $\Delta[\text{Org/Sulf}]$ in Table 2 is the propagated results of the three.
408 For experiments in this work, the percent increase in organic to sulfate ratios ranged from 18 to
409 27 % with an average increase of 21 ± 4 %. The values are fairly consistent with the SMPS-derived
410 $\Delta[\text{OA}]$.

411

412 **4.2.1 Role of RH**

413 Exp. 5, performed at the intermediate RH of 50 %, resulted in a comparable change in SOA
414 formation after aging as experiments at lower RH (Fig. 8). In this experiment, the increase in
415 Org/Sulf after aging was 21.2 %, 1.5 % higher than the average $\Delta[\text{Org/Sulf}]$ of experiments 2-4.
416 $\Delta[\text{OA}]$ for Exp. 5 was 20.5 %, about 2 % lower than the average $\Delta[\text{OA}]$ of experiments 2-4. The
417 effect of RH on the SOA formation during chemical aging, at least for these conditions, appears
418 to be small.

419

420 **4.2.2 Role of organic vapor loss to the Teflon walls**

421 For chamber SOA experiments with preexisting particles, the particles act as competing
422 surface against the chamber walls. We calculated the condensation sink (CS) of particles using the
423 method described in Trump et al. (2014) with a unit accommodation coefficient, consistent with
424 recent findings (Julin et al., 2014; Palm et al., 2016). The calculated condensation sink in the form
425 of time scale for vapors condensing onto particles ($1/\text{CS}$) for Exp. 1 is shown in Fig. 9. During the
426 entire experiment, the timescale for vapors to condense onto particles remained less than a minute.
427 Compared to the organic vapor wall-loss timescale of 15 min in the CMU chamber (Ye et al.,
428 2016), the vapors condense onto the particles 15 times faster than that onto the walls. This

429 corresponds to a 6.3 % loss of the semi-volatile vapors to the walls. Assuming the yields for the
430 experiments conducted in this work also increase by 6.3 %, the absolute yields should be increased
431 by 1-3 % after accounting for the vapor wall-loss effect. This approach is a conservative estimation
432 of vapor wall loss, and yet the results are consistent with what we observed from the measurements.
433 As indicated in Fig. 6, the organic to sulfate ratio stayed practically constant after its first peak at
434 $t=0.7$ h until the introduction of OH. This is consistent with the fact that the semi-volatiles formed
435 in our system only accounted for a small fraction of the products. Ye et al. (2016) studied the
436 SVOCs formed in the α -pinene ozonolysis system and found 20 % SVOCs in the products formed
437 from experiments with moderate precursor concentration (α -pinene=75 ppb). They also observed
438 that the SVOC fraction increased with increased amounts of reacted α -pinene. Since the reacted
439 α -pinene in our experiments was less than 35 ppb, our observation of small amount of SVOCs
440 forming is also consistent with their results.

441 The situation is a little more complex for the second-generation oxidation because material
442 with higher volatilities that could have become SOA were lost during the time after the end of the
443 first phase and before the beginning of the second. To address this issue, OH radicals were
444 introduced about an hour earlier in Exp. 1 as compared to the rest of the experiments. A shorter
445 timescale ensures the first-generation vapor products react efficiently with OH instead of
446 interacting with the chamber walls as in the case of longer timescales. There was an increase of
447 27 % in Org/Sulf in this experiment after aging, 7 % more than the average of the other four
448 experiments. $\Delta[\text{OA}]$ for Exp. 1 was 29.4 %, about 7.5 % higher than the average of the rest four
449 experiments. If we attribute this 7 % difference purely to the vapor wall-loss effect, then we
450 estimate that vapor losses can increase the additional SOA formation by roughly another 10 % for
451 the experiments conducted in this work.

452

453 **4.3 Effect of chemical aging on aerosol composition**

454 Fig. 10 summarizes the absolute increase in O:C after the two doses of OH, respectively,
455 with the corresponding exposure required to achieve the increase. As we discussed above using
456 Exp. 1 as an example, the O:C in all experiments showed a stepwise increase after the first OH
457 introduction while it grew continuously after the second OH introduction until the end of the
458 experiment. For these five experiments, it took 10 - 30 min for the O:C to increase by 0.02-0.04.
459 The stepwise increase in O:C is caused by the rapid reactions between the first generation vapor

460 products and the OH. One of the major products identified in the gas phase from the α -pinene
461 ozonolysis system, pinonaldehyde, reacts with OH at a rate of $3.5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Davis
462 et al., 2007). During the first hour of OH introduction, the OH concentration remains on average
463 at a steady state of $2.4 \times 10^7 \text{ molecule cm}^{-3}$. A quick estimation of $1/k_{OH}[OH]$ gives a timescale
464 of approximately 16 min, which is consistent with what we observed in these experiments.

465 The second exposure corresponds to the period until the end of each experiment. The
466 increase in O:C of 0.01 to 0.04 during this stage clearly indicates change in SOA composition,
467 however paired with minimum change in SOA mass. Although gas-phase reactions can contribute
468 to these observed changes in O:C, the corresponding condensation of the products should also
469 result in a detectable increase in SOA concentration during the same period. Given that changes
470 in SOA concentration could not be detected the contribution of gas-phase oxidation was probably
471 small. In addition, we observed small amounts of SVOCs forming in our system as discussed above.
472 The significant change in O:C without corresponding increase in SOA mass concentration was
473 likely caused by heterogeneous reactions.

474 Based on the HR family analysis results, the less oxidized ion family CH decreased around
475 10 percent during the aging process (i.e., from 41.9 to 38.1 percent of the OA in Exp. 1 and from
476 40.5 to 35.3 percent in Exp. 2) while the more oxidized CHO_2 increased 4 percent in Exp. 1 (from
477 12.8 to 13.3 percent) and 16 percent in Exp. 2 (from 14.9 to 17.3 percent). The changes in the
478 family CHO were +4 percent in Exp. 1 and -6 percent in Exp. 2, suggesting that there was both
479 production and destruction of the corresponding family members. The concentration of
480 organonitrates was, as expected, close to zero initially in these experiments. At the end of the aging
481 process, the NO family represented 3-3.5 % of the OA.

482 CO_2^+ (m/z 44) from family CHO_2 and $\text{C}_2\text{H}_3\text{O}^+$ (m/z 43) from family CHO are usually
483 identified in aged and relatively fresh aerosols, respectively. Their fractions of the total organics,
484 f_{44} and f_{43} , have been used as chemical indicators in chamber experiments (Donahue et al., 2012).
485 During the dark ozonolysis period of Exp. 1 (Fig. S2), the f_{43} increased initially and stayed
486 practically constant after $t=0.2$ h, while f_{44} decreased. After the first introduction of OH, both f_{43}
487 and f_{44} showed a stepwise increase. After the second introduction of OH, f_{43} decreased while f_{44}
488 increased over time until the end of the experiment, indicating that the SOA was getting
489 progressively more oxidized during aging. During Exp. 2 (Fig. S4), f_{43} increased sharply initially
490 and then slowly decreased during the dark ozonolysis period. This is consistent with the “ripening”

491 effect observed during the MUCHACHAS campaign (Donahue et al., 2012). Overall, f_{43}
492 decreased while f_{44} increased over the course of Exp. 2, indicating that the initially formed SOA
493 was getting more oxidized during aging.

494

495 **4.4 Comparison with other studies**

496 Overall, the results from our chamber experiments in this work are consistent to those from
497 the MUCHACHAS chambers. After adopting a size-dependent particle wall-loss correction
498 method, we observed 20-30 % additional SOA formation after aging. Vapor wall-loss effect can
499 account for an additional 10 %, increasing the range to 20-40 %. The O:C presented a stepwise
500 increase of 0.02-0.04 after the first introduction of OH, and then increased gradually overtime after
501 the second introduction of OH.

502 During the MUCHACHAS campaign, mixtures of SOA and gas-phase products formed in
503 the Paul Scherrer Institute (PSI) 27 m³ Teflon chamber from low (10 ppb) and high (40 ppb) initial
504 α -pinene concentration were exposed to OH by TME ozonolysis and HONO photolysis at an RH
505 of approximately 50 % (Tritscher et al. 2011). An OH concentration of 2×10^6 to 10×10^6 molecules
506 cm⁻³ was maintained up to four hours. The authors reported an additional 50 % SOA mass forming
507 after aging using the first-order, size-independent particle wall-loss correction for the suspended
508 organic mass concentration measured by AMS. An increase of 0.04 in the oxygen to carbon ratio
509 was also observed during aging.

510 In the 84.5 m³ Aerosol Interaction and Dynamics in the Atmosphere (AIDA) aluminum
511 chamber at Karlsruhe Institute of Technology, an OH concentration of 2×10^6 to 10×10^6 molecules
512 cm⁻³ was used by a constant flow of TME (dark aging). The authors observed an increase of 17-
513 55 % in the SMPS-derived SOA mass concentration (density corrected) after aging during four
514 experiments with initial α -pinene concentration ranging from 14 to 56 ppb (Salo et al., 2011). In
515 the 270 m³ Simulation of Atmospheric Photochemistry in a large Reaction (SAPHIR) Teflon
516 chamber at Forschungszentrum Jülich, SOA and vapors generated from the ozonolysis of 40 ppb α -
517 pinene was aged for three consecutive days with OH produced by ambient light chemistry. An OH
518 concentration of $2-5 \times 10^6$ molecules cm⁻³ was maintained and 9 %, 4 % and 1 % additional SOA
519 was formed respectively after aging each day. These values were corrected for particle wall loss
520 using different wall-loss rate constants determined during different periods of the experiment.

521 Our result of 20-40 % additional SOA formation due to aging is well within the range of
522 that from the above chambers. The difference in the results from each chamber could potentially
523 be attributed to different OH exposure (e.g. a constant flow of HONO or TME was provided in the
524 PSI chamber). Other plausible explanations include whether the reported values were particle wall-
525 loss corrected and whether the same method was adopted for the correction.

526 For the HONO aging experiment performed in the CMU chamber during the
527 MUCHACHAS campaign, Henry and Donahue (2012) suggested a potentially strong photolysis
528 effect based on decreasing organic to sulfate ratio derived from the AMS measurements. In our
529 experiments, the organic to sulfate ratio was affected by the size-dependent wall-loss process. Both
530 the AMS-measured organic to sulfate ratio and the SMPS-measured OA remained relatively
531 constant after correcting for the size dependence of the particle-wall process in these experiments.
532 We thus conclude that minimum photolysis was observed for our experiments.

533

534 **5. Conclusions**

535 With an OH exposure equivalent to 2-4 days of typical atmospheric oxidation conditions,
536 the OH aging of the α -pinene ozonolysis products formed 20-40 % additional SOA mass for the
537 experimental conditions used in this work. Elevated RH up to 50 % has minimum effect on SOA
538 production due to aging. We have constrained the aging effects on additional SOA formation
539 quantitatively using both SMPS and AMS measurements.

540 A more oxygenated product distribution was observed after aging. A stepwise increase of
541 0.02-0.04 in O:C was observed within half an hour after the first introduction of OH. After the
542 second-generation products were exposed to additional OH, the O:C grew continuously until the
543 end of the experiments with an absolute increase of up to 0.04. During this period, minimum SOA
544 production was observed. We attribute this phenomenon to condensed-phase reactions. Further
545 investigation on a molecular scale is needed.

546 This work explored the additional SOA formation potential of the α -pinene ozonolysis
547 products under high NO_x conditions. The aging time scale of this study of a few days corresponds
548 to the atmospheric lifetime of the corresponding aerosol. The additional formation of SOA
549 observed here is clearly non-negligible, but is also much less than the doubling or tripling of the
550 SOA that has been assumed in few modeling studies (Lane et al., 2008) which resulted in

551 overprediction of the biogenic SOA. The present results can be used for the improvements of the
552 currently used parameterizations for the aging of α -pinene SOA products in CTMs.

Table 1: Initial conditions of the α -pinene ozonolysis aging experiments.

Experiment	α-pinene (ppb)	O₃ (ppb)	Initial seed surface area ($\mu\text{m}^2 \text{cm}^{-3}$)	RH (%)	OH^a ($\times 10^7$ molecules cm^{-3})	OH introduction time (h after α- pinene consumption)
1	33	450	850	<20	2.4	0.3
2	14	600	760	<20	2.7	0.8
3	35	450	720	<20	2.0	1.1
4	16	500	950	<20	2.4 ^b	1.1
5	20	400	710	~50	2.7	0.8

711

712 ^aThe OH concentration was calculated using the decay of butanol-d9 (monitored by PTRMS)
713 (Barnet et al., 2012).

714 ^bEstimated OH concentration for Exp. 4 based on the other experiments. The PTRMS data was
715 not available during that time for Exp. 4.

745 **Figure 1:** SMPS-measured (black symbols) and the size-dependent particle wall-loss corrected
 746 (red symbols) aerosol number concentration evolution during a typical experiment (Exp. 1). Ozone
 747 was added into the chamber at time zero to initiate α -pinene ozonolysis. The shaded areas indicate
 748 that the chamber was dark. The dashed lines mark the beginning and the end of the two times
 749 HONO were added, respectively. The increase in number concentration at $t=3.5$ h is due to the
 750 injection of 5 g L^{-1} ammonium sulfate particles. An additional 100 cm^{-3} particles were formed
 751 to nucleation both at the ozonolysis step and the aging step. Data were not recorded from $t=-2$ h to
 752 -1.4 h.

753

754

755

756
 757 **Figure 2:** The size-dependent particle wall-loss rate constant profile, $k(D_p)$, for Exp. 1. The black
 758 symbols are the rate constants calculated based on the wall-loss process of the initial ammonium
 759 sulfate seed particles from $t=-4.5$ h to $t=0$ h, while the red open symbols those of the additional
 760 ammonium sulfate particles at the end from $t=4.5$ h to $t=8.5$ h. The blue line is the fit determined.
 761
 762
 763
 764

765

766 **Figure 3:** SMPS-measured (black symbols) and the size-dependent particle wall-loss corrected
 767 (red symbols) aerosol (seed and organic) volume concentration evolution during a typical
 768 experiment (Exp. 1). Ozone was added into the chamber at time zero to initiate α -pinene ozonolysis.
 769 The shaded areas indicate that the chamber was dark. The dashed lines mark the beginning and the
 770 end of the two times HONO were added, respectively. 5 g L^{-1} ammonium sulfate particles were
 771 injected into the chamber at $t=3.5 \text{ h}$. Data were not recorded from $t=-2 \text{ h}$ to -1.4 h .

772

773

774
 775
 776 **Figure 4:** The particle wall-loss corrected SOA mass concentration ($\rho=1.4 \text{ g cm}^{-3}$) evolution for
 777 Exp. 1 derived from SMPS measurements. The corresponding error shown is due to the particle
 778 wall-loss correction. Ozone was added into the chamber at time zero to initiate α -pinene ozonolysis.
 779 The shaded areas indicate that the chamber was dark. The dashed lines mark the beginning and the
 780 end of the two times HONO were added, respectively.

786
 787 **Figure 5:** The AMS-measured aerosol composition (CE=1) (left axis) and the atomic oxygen to
 788 carbon ratio (right axis) evolving with time for Exp. 4. The increase in the sulfate signal at $t=0$ is
 789 the result of a change in the collection efficiency (CE). Ozone was added into the chamber at time
 790 zero to initiate α -pinene ozonolysis. The shaded areas indicate that the chamber was dark. The
 791 dashed lines mark the beginning and the end of the two times HONO were added, respectively.

792
 793 **Figure 6:** The AMS-derived organic to sulfate ratio time series for Exp. 1. The inset is a blow-up
 794 of the Org/Sulf ratio from its maximum until the second time when the UV lights were turned on.
 795 The black symbols are the particle wall-loss corrected Org/Sulf during that half hour. Ozone was
 796 added into the chamber at time zero to initiate α -pinene ozonolysis. The shaded areas indicate that
 797 the chamber was dark. The dashed lines mark the beginning and the end of the two times HONO
 798 were added, respectively.

799

800 **Figure 7:** The dependence of the AMS-derived organic to sulfate ratio on particle vacuum
 801 aerodynamic diameter for Exp. 1 (left axis). Also shown are the AMS-measured organic (green)
 802 and sulfate (red) mass distribution (right axis). The results are based on PToF data averaged over
 803 ~2.5 hours ($t=1.1$ h to 3.5 h).
