33 34

35 Abstract. The implementation of European emission abatement strategies has led to 36 significant reduction in the emissions of ozone precursors during the last decade. 37 Ground level ozone is also influenced by meteorological factors such as temperature, 38 which exhibit interannual variability, and are expected to change in the future. The 39 impacts of climate change on air quality are usually investigated through air quality 40 models that simulate interactions between emissions, meteorology and chemistry. 41 Within a multi-model assessment, this study aims to better understand how air quality 42 models represent the relationship between meteorological variables and surface ozone 43 concentrations over Europe. A multiple linear regression (MLR) approach is applied to 44 observed and modelled time series across ten European regions in springtime and 45 summertime for the period of 2000-2010 for both models and observations. Overall, the 46 air quality models are in better agreement with observations in summertime than in 47 springtime, and particularly in certain regions, such as France, Mid-Europe or East-48 Europe, where local meteorological variables show a strong influence on surface ozone concentrations. Larger discrepancies are found for the southern regions, such as the 49

50 Balkans, the Iberian Peninsula and the Mediterranean basin, especially in springtime. 51 We show that the air quality models do not properly reproduce the sensitivity of surface 52 ozone to some of the main meteorological drivers, such as maximum temperature, 53 relative humidity and surface solar radiation. Specifically, all air quality models show 54 more limitations to capture the strength of the ozone-relative humidity relationship 55 detected in the observed time series in most of the regions, in both seasons. Here, we 56 speculate that dry deposition schemes in the air quality models might play an essential 57 role to capture this relationship. We further quantify the relationship between ozone and 58 maximum temperature ($m_{0.3-T}$, climate penalty) in observations and air quality models. 59 In summertime, most of the air quality models are able to reproduce reasonably well the observed climate penalty in certain regions such as France, Mid-Europe and North Italy. 60 61 However, larger discrepancies are found in springtime, where air quality models tend to 62 overestimate the magnitude of observed climate penalty.

74

73 **1. Introduction**

75 Tropospheric ozone is recognised as a threat to human health and ecosystem productivity (Mills et al. 2007). It is produced by photochemical oxidation of carbon 76 77 monoxide and volatile organic compounds (VOCs) in the presence of nitrogen oxides 78 (NOx=NO+NO₂) (Jacob and Winner, 2009). While it is an important pollutant on a 79 regional scale, due to the long-range transport effect it may also influence air quality on 80 a hemispheric scale (Hedegaard et al, 2013, Monks et al., 2015). Previous studies have 81 shown that the reduction of emissions of ozone precursors, lead to a decrease in 82 tropospheric ozone concentrations in Europe (Solberg et al. 2005, Jonson et al. 2006). 83 However, there is also a large year-to-year variability due to weather conditions 84 (Andersson et al. 2007).

85

86 Ozone variability is strongly related to meteorological conditions. Significant 87 correlations between ozone and temperature have been associated with the temperature-88 dependent lifetime of peroxyacetyl nitrate (PAN), and also due to the temperature 89 dependence of biogenic emission of isoprene (Sillman and Samson, 1995). Substantial 90 increases in surface ozone have been associated with high temperatures and stable 91 anticyclonic, sunny conditions that promote ozone formation (Solberg et al. 2008). 92 Moreover, its strong relationship with temperature represents a major concern, since 93 under a changing climate the efforts on new air pollution mitigation strategies might be 94 insufficient. This effect, referred to as the climate penalty (Wu et al., 2008), is expected 95 to play an important role in future air quality (Hendriks et al. 2016). Similarly, 96 increasing solar radiation leads to high levels of ozone, though with a weak correlation 97 (Dawson et al. 2007) and it has been suggested that it could reflect in part the 98 association of clear sky with high temperatures (Ordónez et al., 2005). Humidity 99 influences photochemistry through reactions between water vapor and atomic oxygen

100 (Vautard et al. 2012). High levels of humidity are normally related to enhanced cloud 101 cover and thus reduced photochemistry (Dueñas et al. 2002, Camalier et al. 2007). The 102 relationship between ozone and relative humidity can be also explained by dry 103 deposition through stomatal uptake: under low levels of humidity plants close their 104 stomata, which reduce the biogenic uptake (Hodnebrog et al. 2012, Kavassalis and 105 Murphy, 2017). High wind speed is usually correlated with low ozone concentrations 106 due to enhanced advection and deposition, although the processes involved are complex 107 and studies from different regions reported weak or insignificant correlations (Dawson 108 et al., 2007, Jacob and Winner, 2009).

109

110 Chemistry transport models (CTMs) are one of the most common tools to investigate the impacts of climate change on air quality (Jacob and Winner, 2009, Colette et al. 111 112 2015). Due to assumptions, parametrizations and simplifications of processes, the 113 models themselves are subject to large uncertainties (Manders et al. 2012), which have 114 been reflected in some regional differences in the magnitude of surface ozone response 115 to projected climate change (Andersson and Engardt, 2010). Thus, model biases when 116 compared to observations still remain a concern, especially in terms of the response of 117 air quality under future climate (Fiore et al. 2009, Rasmussen et al. 2012). Comparisons 118 between model outputs and measurements of available observational dataset are 119 essential to evaluate the models ability to reproduce observations. Discrepancies in the 120 outputs of CTMs can be due chemical and physical processes, fluxes (emissions, deposition and boundary fluxes) and meteorological processes (Vautard et al. 2012, 121 122 Bessagnet et al. 2016). In particular, quantification and isolation of the effects of meteorology on ozone is a challenge, due to the complex interrelation between ozone, 123 124 meteorology, emissions and chemistry (Solberg et al. 2015). Thus, evaluating air quality 125 models with respect the meteorological inputs is important given that meteorology drives numerous chemical processes (Vautard et al. 2012). A number of studies have 126 127 evaluated the performance of the meteorological models that drive CTMs by comparing 128 them with observations of weather parameters relevant for air quality (Smyth et al., 129 2006, Vautard et al. 2012, Brunner et al. 2014, Makar et al. 2015, Bessagnet et al. 130 2016).

131

132 Capturing observed sensitivities of ozone to meteorological factors is required to assess 133 the confidence in the models and their ability to reproduce the observed relationships 134 between pollutants and meteorology and better understand potential impacts under 135 climate change. However, only a few studies have used model simulations to analyse 136 ozone sensitivities to meteorological parameters. Davis et al. (2011) evaluated the 137 performance of the Community Multiscale Air Quality (CMAQ) model to reproduce the 138 ozone sensitivities to meteorology across Eastern US. Their results showed that the 139 model underestimated the observed ozone sensitivities to temperature and relative 140 humidity. Recently, Fix et al. (2017) examined the capability of the NRCM-Chem 141 model to capture the meteorological sensitivities of high/extreme ozone. Overall, they found substantial differences between the modelled and the observed sensitivities of 142 143 high levels of ozone to meteorological drivers that were not consistent between the three 144 regions of study. Due to the complex interactions and processes, estimating the ozone 145 sensitivities to key meteorological variables remains a challenge. Thus, we aim to examine the capabilities of a set of CTMs to reproduce the observed ozone responses to 146 meteorological variables. To our knowledge, this is the first multi-model evaluation that 147 148 compares observed and modelled meteorological sensitivities of ozone over Europe 149 using a set of regional air quality models.

150 151 The EURODELTA-Trends (EDT) exercise has been designed to better understand the 152 evolution of air pollution and assess the efficiency of mitigation strategies for 153 improving air quality. The EDT exercise allows the evaluation of the skill of regional 154 air quality models and quantification of the role of the different key driving factors of 155 surface ozone, such as emissions changes, long-range transport and meteorological 156 variability (more details on the EDT exercise can be found in Colette et al. 2017a). 157 Earlier phases of EURODELTA and other relevant modelling exercises, such as 158 AQMEII (Air Quality Model Evaluation International Initiative, Rao et al. 2009) 159 covered a short period of time of one year, while only a few studies assessed long-term 160 air quality but limited to one model (Vautard et al., 2006, Jonson et al. 2006, Wilson et 161 al. 2012), or utilised climate data rather than reanalysed meteorology (e.g. Simpson et 162 al., 2014; Colette et al., 2015). The EDT exercise presents a multi-model hindcast of air 163 quality over 2 decades (1990-2010), and thus offers a good opportunity to evaluate the 164 role of driving meteorological factors on ozone variability.

165

166 The present study provides a novel and simple method to evaluate the performance of 167 air quality models in terms of meteorological sensitivities of ozone. Specifically, our analysis focuses on the European ozone season (April to September) over the years 168 169 2000-2010. The choice of this period is mainly motivated by the availability of the observational dataset from Schnell et al. (2014, 2015) (see section 2.1). Within the EDT 170 171 framework, a recent report has presented the main findings on the long-term evolution 172 of air quality (Colette et al. 2017b). Part of these results was obtained from the analysis 173 of the 1990s (1990-2000) and 2000s (2000-2010) separately. We focus on the second 174 decade (2000-2010), for which the interpolated dataset of observed maximum daily 8-175 hourly mean ozone (MDA8 O₃) used in this study was available. Similarly to Otero et 176 al. (2016), we apply a multiple linear regression approach to examine the 177 meteorological influence on MDA8 O₃. Statistical models are developed separately for 178 observational datasets and air quality models, with the primary focus on examining both 179 observed and simulated relationships between MDA8 O₃ and meteorological drivers .

180

181 The present paper is structured as follows. Section 2 describes the observational data as 182 well as the air quality models studied here. The methodology and the design of the 183 statistical models are introduced in section 3. Section 4 discusses the results and the 184 summary and conclusions are discussed in section 5.

186 2. Data

2.1. Observations

188 189

187

190 This study uses gridded MDA8 O₃ concentrations created with an objective-mapping 191 algorithm developed by Schnell et al. (2014). They applied a new interpolation 192 technique over hourly observations of stations from the European Monitoring and 193 Evaluation Programme (EMEP) and the European Environment Agency's air quality 194 database (AirBase) to calculate surface ozone averaged over 1° by 1° grid cells (see 195 Schnell et al., 2014, 2015). Otero et al. (2016) used this dataset for examining the 196 influence of synoptic and local meteorological conditions over Europe. This 197 interpolated product offers a possibility to establish a direct comparison between 198 observations and CTMs. However, it must be acknowledged that for some areas with a 199 low number of stations (i.e. the southeastern or northeastern European regions) the 200 values interpolated into the 1°x1° degree grid cells may not be representative of such 201 large scales. Recently, Ordóñez et al. (2017) and Carro-Calvo et al. (2017) have used 202 this product to assess the impact of high-latitude and subtropical anticyclonic systems 203 on surface ozone and the synoptic drivers of summer ozone respectively. They reported 204 inhomogeneities during some years for specific grid-cells (e.g. in the Balkans and 205 Sweden), which were excluded from their analysis. However, we did not observe a clear 206 shift when analysing the spatial averages of the time series of the MDA8 O₃ for those 207 particular regions (e.g. Balkans and Scandinavia) (Figs. S1, S2), Therefore our analysis 208 includes the whole dataset.

209

210 This study investigates the influence of observed meteorological variables on MDA8 211 O₃, based on the ERA-Interim reanalysis product provided by the European Centre for Medium-Range Weather Forecasts (ECMWF) at 1°x1° resolution (Dee et al. 2011). 212 213 Meteorological reanalyses products are essentially model simulations constrained by 214 observations and they have been widely validated against independent observations. 215 Daily mean values are calculated as the mean of the four available time steps at 00, 06, 216 12, and 18UTC for 10m wind speed components (u and v) and 2m relative humidity. 217 Maximum temperature is approximated by the daily maximum of those time steps, 218 while daily mean surface solar radiation is obtained from the 3-hourly values provided 219 for the forecast fields.

220 221

222

2.2. Chemistry Transport Models (CTMs)

223 A set of state-of-the-art air quality models participating in the EDT exercise is used 224 here: LOTOS-EUROS (Schaap et al., 2008, Manders et al. 2017), EMEP/MSC-W (Simpson et al., 2012), CHIMERE (Mailer et al., 2017), MATCH (Robertson et al., 225 226 1999) and MINNI (Mircea et al., 2016). The domain of the CTMs extends from 17°W 227 to 39.8°E and from 32°N to 70°N and it follows a regular latitude-longitude projection 228 of 0.25x0.4 respectively. The main features of the CTM setup are largely constrained by 229 the EDT experimental protocol (e.g. meteorology, boundary conditions, emissions, 230 resolution, see Colette et al. 2017a for further details). For instance, the boundary 231 conditions were defined from a climatology of observational data for most of the 232 experiments of the EDT exercise (including the data used here). However, the 233 representation of physical and chemical processes and the vertical distribution differ in 234 the CTMs, as well as the vertical distribution of model layers (including altitude of the 235 top layer and derivation of surface concentration at 3m height in the case of EMEP, 236 LOTOS-EUROS and MATCH). Moreover, there were no specific constrains imposed 237 on biogenic emissions (including soil NO emissions), which are represented by most of 238 the models using an online module (Colette et al. 2017a). Since we aim here to 239 compare the modelled relationship between meteorology and surface ozone, prescribing 240 common features in the CTMs is particularly an advantage to identify potential sources 241 of discrepancies.

242

The CTMs were forced by regional numerical weather model simulations using boundary conditions from the ERA-Interim global reanalysis (Dee et al., 2011). Most of the CTMs used the same meteorological input data, with a few exceptions. Three of them (EMEP, CHIMERE and MINNI) used input meteorology from the Weather Research and Forecast Model (WRF) (Skamarock et al. 2008). LOTOS-EUROS and MATCH used the input meteorology produced by RACMO2 (van Meijgaard, 2012) and HIRLAM (Dahlgren et al. 2016), respectively. Unlike the rest of the regional weather 250 models, RACMO2 used in the EDT exercise excluded nudging towards ERA-Interim, 251 which might have some impact in the meteorological fields generated by RACMO2. A 252 summary of the CTMs and the corresponding sources of meteorological input data with 253 some of the main characteristics are given in Table 1. As with the observations, CTMs 254 and their meteorological counterpart were interpolated to a common grid with 1° x 1° 255 horizontal resolution. The use of a coarser resolution could have an impact in some regions with a complex orography where airflow is usually controlled by mesoscale 256 257 phenomena (e.g. see-breeze and mountain-valley winds) or in regions characterized by 258 high emission densities (Schaap et al., 2015, Gan et al. 2016). In such cases the use of a 259 finer grid could be beneficial to capture the variability of local processes.

260

A set of meteorological parameters was selected from the meteorological input data for the regression analyses. Similarly to the procedure with ERA-Interim, daily means are obtained from the available time steps every 3 hours in the case of WRF and RACMO2, and every 6 hours for HIRLAM for the following variables: 10m wind speed components, 2m relative humidity and surface solar radiation. Maximum temperature is also approximated by the daily maximum of those time steps.

268 3. Multiple linear regression model269

Summertime usually brings favourable conditions for high near-surface ozone concentrations, such as air stagnation due to high-pressure systems, warmer temperatures, higher UV radiation, and lower cloud cover (Dawson et al. 2007). This study attempts to better understand how CTMs represent the meteorological sensitivities of ozone. To this aim, we use a multiple linear regression approach that can provide useful information of sensitivities in the distribution of ozone concentration as a whole (Porter et al., 2015).

277

278 A total of five meteorological predictors (Table 2) are selected based on the existing 279 literature that has shown their strong influence on ozone pollution (e.g. Bloomfield et al. 280 1996, Barrero et al. 2005, Camalier et al. 2007, Dawson et al. 2007, Andersson and Engardt, 2010, Rasmussen et al. 2012, Davis et al. 2011, Doherty et al., 2013, Otero et 281 282 al. 2016). Moreover, it has been shown that the occurrence of air pollution episodes 283 might increase when the pollution levels of the previous day are higher than normal (Ziomas et al. 1995). Then, apart from the meteorological predictors, we add the effect 284 285 of the lag of ozone (MDA8 from the previous day) in order to examine the role of ozone 286 persistence. Additionally, we include harmonic functions that capture the effect of 287 seasonality as in Rust et al. al (2009) and Otero et al. (2016), which is referred as "day" 288 in the MLRs (see Table 2).

289

290 For this study, we divide the European domain into 10 regions: England (EN), Inflow 291 (IN), Iberian Peninsula (IP), France (FR), Mid-Europe (ME), Scandinavia (SC), North 292 Italy (NI), Mediterranean (MD), Balkans (BA) and Eastern Europe (EA). These regions 293 are based on those defined in the recent ETC/ACM Technical Paper (Colette et al. 294 2017b). For our study, we further subdivide the original Mediterranean region (MD) 295 into a region covering the Balkans (BA), due to the strong influence of the ozone 296 persistence on MDA8 O₃over this particular region as noted previously in Otero et al. 297 (2016). Figure 1 shows the spatial coverage of each region and Table 3 lists their 298 coordinates. As shown in Otero et al. (2016), the relative importance of predictors in the 299 MLRs shows distinct seasonal patterns. Here, multiple linear regression models (MLR, 300 hereafter) are developed for each region for two seasons: springtime (April-May-June, 301 AMJ) and summertime (July-August-September, JAS). These seasons differ from the 302 meteorological definition, but cover the period when surface ozone typically reaches its 303 highest concentrations (i.e. April-September). Additionally, we analysed the impact of 304 the seasons' definition by performing sensitivity tests using the meteorological seasons 305 (i.e. March-May-April, MAM and June-July-August, JJA). As shown in Figs. S3 and S4 306 (see Supplement), we found a stronger impact of some relevant key driving factors of 307 ozone (e.g. temperature and relative humidity) when using the seasons defined above 308 (AMJ and JAS) than when using the meteorological seasons. Therefore, we consider 309 that our choice of 3-month periods that cover the whole ozone season is particularly useful for examining the impact of individual meteorological parameters when ozone 310 311 levels are highest. Since the domains covered by observations and CTMs do not 312 coincide exactly, we applied an observational-mask to use the same number of grid-313 cells for CTMs and observations. Data used to estimate parameters of the MLR were 314 spatially averaged over each region. Thus, we compare MLRs developed separately for 315 CTMs and observations for each region and season. The observational dataset contains the gridded MDA8 O₃ and the meteorology input from ERA-Interim, while the dataset 316 317 for the CTMs contains the MDA8 O₃ from each one of them along with the 318 corresponding meteorological input (LOTOS and RACMO2, CHIMERE and WRF, 319 MATCH and HIRLAM) (see Table 1).

320

A MLR is built to describe the relationship between MDA8 O_3 (predictand) and a set of covariates (or predictors) describing seasonality, ozone persistence and the influence of meteorological fields (Table 2). A data series y_t , t= 1,...N (e.g. observations or CTM simulations) for a given region and season is conceived as a Gaussian random variable Y_t with varying mean μ_t and homogeneous variance σ^2 . The mean μ_t is described as a linear function of the covariates, i.e.

- 327
- 328 $Y_t \sim \mathcal{N}(\mu_t, \sigma^2)$

329
$$\mu_t = \beta_0 + \beta_{sin} sin\left(\frac{2\pi}{365.25}d_t\right) + \beta_{cos} cos\left(\frac{2\pi}{365.25}d_t\right) + \beta_{lag} y_{t-1} + \sum_{K=1}^{K} \beta_k x_{t,k}$$
 (1)
330

331 with t indexing daily values and d_t referring to the day in the year associated with the 332 index t. β_0 is a constant offset, β_{sin} and β_{cos} are the first order coefficient of a Fourier series (e.g. Rust et al. 2009, 2013, Fischer et al. 2017), β_{lag} describes the persistence 333 with respect to the previous day concentration y_{t-1} ; if t is the first day in the late summer season (JAS, July 1st), y_{t-1} is the concentration of June 30th. Further regression 334 335 coefficients β_k describe the linear relation to potential meteorological drivers (see table 336 337 2). For covariates standardized to unit variance, the regression coefficients (β) are 338 standardised coefficients giving the change in the predictand with the covariate in units 339 of covariate standard deviation.

340

Following the same strategy as used in Otero et al. (2016), the MLRs are developed through several common steps: 1) starting with the full set of potentially useful components in the predictor, a stepwise backward regression using the Akaike Information Criterion (AIC) as a selection criterion removes successively those components in the predictor, which contribute least to the model performance; and 2) a multi-collinearity index known as variance inflation factor (VIF, Maindonald and Braun 2006) is used to detect multi-collinearity problems in the predictor (i.e. high correlations between two or more components in the predictor). Components with a VIF above 10are left out of the predictor (Kutner et al 2004).

350

351 The statistical performance of each MLR (built separately from observations and CTMs) is assessed through the adjusted coefficient (R^2) and the root mean square error 352 (RMSE). The R² estimates the fraction of total variability described by the MLR and the 353 354 RMSE gives the average deviation between model and observation obtained in the 355 MLR. We also examine the relative importance of the individual components in the 356 predictor. According to the method proposed by Lindeman et al (1980), the relative importance of each predictor is estimated by its contribution to the R^2 coefficient 357 (Grömping 2007). We assess the sensitivities of ozone to the predictors through the 358 359 standardised coefficients obtained from the regression. These coefficients indicate the 360 changes in the ozone response to the changes in the predictors, in terms of standard 361 deviation. Thus, for every standard deviation unit increase (decrease) of a specific 362 predictor, the predictand (MDA8 O₃) will increase (decrease) the amount indicated by 363 its coefficient in standard deviation units,. The use of standardised coefficients allows 364 us to establish a direct comparison in the influence of individual predictors. The effect 365 of seasonality introduced by the harmonic functions (namely, "day", table 2) is kept in 366 the MLRs (Eq. 1) for its usefulness in improving the power of the regression analysis, 367 however further explanation about the effect of the predictors focuses on the rest of the 368 variables.

369

372

373

370 371

4. Results and discussion

4.1. CTM performance by region

We compare the seasonal cycle of observations and CTM results through the time series of daily averaged values of MDA8 O₃ from observations and CTMs for the whole period (i.e. April-September, 2000-2010) spatially averaged over each region. Furthermore, correlation coefficients between both CTMs and observations at each region and season are used to quantify the CTM performance.

379 380

381

4.1.1. Seasonal cycle of MDA8 O₃

382 We examine the ozone seasonal cycle represented by both the observational and 383 modelled dataset. Figure 2 depicts daily averages during 2000-2010 of MDA8 O₃ at 384 each region for the CTMs and observations. In general, all CTMs are biased high 385 compared with observations. CTM results are visually closer to observations in the 386 northwestern regions (i.e. IN, EN and FR), while the spread becomes larger over the 387 southern and southeastern regions (i.e. BA, NI, MD). The IN, EN and SC regions show 388 the highest observed concentrations in the starting months (AMJ), which is not 389 generally well captured by most of the CTMs, which show a more flat timeline (e.g. 390 LOTOS, MATCH, CHIMERE). For example, in the SC region, some of the CTMs 391 underestimate the ozone concentrations in AMJ (i.e. CHIMERE and MINNI). The rest 392 of the regions show the highest observed concentrations in JAS, which is generally 393 overestimated by the CTMs. Models show discrepancies in the ozone seasonal cycle 394 when compared to each other and when compared against observations. For example, 395 we observed substantial differences in the southern regions, such as IP, MD and BA, 396 where the models show a considerable spread. In those regions, the CTMs exhibit a 397 different behaviour when compared to each other. For instance, the EMEP model shows 398 ozone peak concentrations in April, while CHIMERE and MINNI show a peak in July.
399 Overall LOTOS shows a relatively constant positive bias in all regions, more evident in
400 the MD and NI regions.

401

402 403

404

4.1.2. Correlation coefficients between modelled and observed time series

405 The correlation coefficients between the observed and modelled values of MDA8 O3 at 406 each region and in each season are shown in Fig. 3. Overall, MDA8 O₃ from the CTMs 407 is better correlated with observations in JAS than in AMJ in the regions ME, NI, EA 408 and EN. As expected from inspection of the average time series (Fig. 2), the lowest 409 correlations between models and observations are found in BA, especially in AMJ for 410 all models. In particular, EMEP is negatively correlated with observations over this 411 region. As mentioned above, the larger discrepancies between CTMs and observations 412 found over BA might be attributed to a low density of observation sites from which the 413 interpolated dataset is derived, resulting in a lower quality or higher uncertainties of 414 such products (Schnell et al. 2014). The highest correlations in AMJ are obtained at the 415 following regions: ME; FR; NI; and EN for most of the models, except for EMEP for 416 which the highest correlation with observations was found in IN and SC. In general, the 417 models that are most closely correlated with observations are MATCH, MINNI and 418 CHIMERE, while LOTOS shows the lowest correlations, which could be partially due 419 to the use of a different set-up of the RACMO2 model, without nudging towards ERA-420 Interim (section 2.2). These correlations reflect the patterns represented by the seasonal 421 cycle described above.

422

4.2. MLR performance

423 424

Figures 4 and 5 depict the statistical performance of each MLR in terms of R^2 and 425 RMSE (respectively) at the different regions for both seasons, AMJ and JAS. The R^2 426 427 values indicate that all MLRs models (based on both observations and CTMs) are able to explain more than 60% of the MDA8 O₃ variance in all regions. Overall, the MLRs 428 429 show a stronger fit in JAS than in AMJ in most of the regions (Fig. 4). The MLRs 430 appear to perform better in regions such as NI, ME, FR or EA, while the poorest 431 statistical performance is found in IN and EN. The results obtained from the CTM-432 based MLRs show a similar performance to the observation-based MLRs in most of the 433 regions. The lowest RMSE values for most of the MLR are found in SC ranging 434 between 1 and 3 ppb, while EN shows the largest RMSE values. The MLRs from 435 MATCH and CHIMERE show the lowest RMSE values (1-3ppb) suggesting the best 436 statistical fit from a predictive point of view.

437

Both R^2 and RMSE metrics indicate that the statistical performance of MLRs for 438 observations and CTMs show distinct variations between seasons and regions. Overall, 439 better performances are found in JAS and in some regions (i.e. ME, NI, or FR) where 440 441 MLRs are able to describe more than the 80% of the variance in CTMs and 442 observations. This could be attributed to the major role of meteorology in summer 443 influencing local photochemistry processes of ozone production, while in spring long 444 range transport plays a stronger role (Monks, 2000, Tarasova et al. 2007). As it includes 445 the bias, the RMSE reveals more differences among the MLRs when compared to each 446 other (e.g. larger errors for LOTOS when compared to MATCH or CHIMERE). 447 However, it is interesting that in general all MLRs show a similar tendency when 448 evaluating the statistical performance, which indicate that observations-based and 449 CTMs-based MLRs present a similar statistical performance for modelling MDA8 O₃. 450 The ability of the CTMs to reproduce the influence of meteorological drivers on MDA8 451 O₃ is discussed in more detail below.

452

4.3. Effects of drivers on ozone concentrations

453 454

455 The analysis of the influence of the predictors in the MLRs reveals distinctive regional 456 patterns in both observation-based and CTM-based MLRs. In agreement with Otero et 457 al. (2016), here we also find that the regions geographically located towards the interior 458 (including central, western and eastern regions) appear to be more sensitive to the meteorological predictors, especially in JAS. On the contrary, less meteorological 459 460 contribution is found in the regions over the northernmost and southernmost part of the 461 domain, implying that non-local processes (e.g. long-range transport) play a stronger 462 role here. Considering such similarities, in the following, the regions: EN, FR, ME, NI 463 and EA are referred as the internal regions, while the rest of the regions: IN, SC, IP, MD 464 and BA, are referred as the external regions (see Fig. 1).

- 466 4.3.1 Relative importance
- 467

465

468 Figure 6 depicts the relative importance of the predictors for the observation-based and 469 CTM-based MLRs in the internal regions (Fig. 1). Here, a larger meteorological 470 influence (i.e., the predictors other than LO3 and day) can be seen in JAS compared to 471 AMJ in all of these regions. In general, the dominant meteorological drivers from the 472 observation-based MLRs in these internal regions are RH and Tx. The contribution of 473 RH is evident in AMJ (e.g. ME, or EA), while Tx is clearly dominant in JAS. SSRD is 474 also a key driver of MDA8 O₃ and generally, the wind factors (W10m and Wdir) appear 475 to have a minor contribution.

476

477 Despite the CTM-based MLRs being able to capture the meteorological predictors, we 478 observe discrepancies among the internal regions when compared to the observation-479 based MLR. The inter-model differences in terms of the relative importance of 480 predictors are greater in AMJ than in JAS. For instance, the contribution of the LO3 is 481 overestimated by most of CTMs. Substantial differences are found in the influence of 482 RH when comparing the observation-based and the CTMs-based models. The CTMs do 483 not capture the relative importance of the RH well, especially in AMJ. In general, the 484 CTMs driven by WRF meteorology show a slightly larger contribution of RH in most of 485 the cases, although we notice that there are also some differences among the models that 486 share the same meteorology. CTMs do capture the relative importance of Tx in all 487 regions, but overall they overestimate it, as they also show for SSRD. Here, we find 488 discrepancies when comparing the contribution of predictors in the statistical models 489 from CTMs driven by the same meteorology (e.g. EMEP when compared to CHIMERE 490 and MINNI). Such differences among the models using the same meteorology point out 491 that the model setup (e.g. number of vertical levels, depth of first layer) and model 492 parameterizations (e.g chemistry/physical processes) have a larger influence in the 493 model performance than the meteorological processes.

494

495 Figure 7 presents the relative importance of individual predictors in the MLRs 496 developed at the external regions (Fig. 1) for both seasons. The observation-based 497 MLRs show that the main driving factor is LO3 in AMJ, while the effect of meteorological drivers becomes stronger in JAS. RH presents a larger contribution in
some regions (e.g. IN, IP or SC) in AMJ and Tx in JAS (e.g. IN, IP, SC and BA). The
contribution of wind components, Wdir and W10m, is mainly reflected in both seasons
in the western regions (i.e. IN and IP) and in MD, respectively.

502

503 Overall, all CTMs show this tendency, although there are substantial differences when 504 comparing the individual drivers' contribution in the observation-based and CTM-based MLRs, particularly in AMJ (Fig. 7). CTMs do not capture the contribution of LO3 505 506 reflected by the observation-based MLRs. As in the previous analysis (section 4.1) the 507 largest discrepancies are found in BA. In this region, the observation-based MLR shows 508 that most of the variability of ozone would be explained by LO3, while the CTM-based MLRs underestimate the contribution of LO3 and overestimate the meteorological 509 510 contribution of Tx, SSRD and RH (e.g. LOTOS, CHIMERE and MINNI). The 511 contribution of RH is, again, underestimated by the CTMs in most of the regions, 512 (except in BA). On the contrary, the relative importance of SSRD is overestimated in 513 some regions (e.g. IP, IN or MD) and Tx (IN, SC), in particular for the CTMs driven by 514 WRF. Overall, CTMs show the observed contribution of W10m and Wdir in both 515 seasons, although with some inconsistences among the regions and CTMs.

516

517 Our results indicate that the relative importance of meteorological factors is stronger in 518 the internal regions (Fig.6) than in the external regions (Fig.7), which could be partially 519 attributed to a larger variability of most of the meteorological fields in internal regions 520 (Fig. S5). The external regions are also more likely to be influenced by the lateral boundary conditions applied by each CTM. In addition, in some external regions (e.g. 521 522 IP or MD), as mentioned in section 2, the use of a coarser grid in some regions might be 523 insufficient to capture mesoscale processes, such as land-sea breezes, which also control 524 MDA8 O₃ concentrations (Millán et al. 2002). Moreover, we observe that meteorology 525 becomes more important in summer, when local photochemistry processes are 526 dominant. In general, CTMs show this tendency, but limitations to reproduce the effect of some meteorological drivers are found. Specifically, while CTMs tend to 527 528 overestimate the contribution of Tx, and SSRD, they underestimate the relative 529 importance of RH, which is also reflected in the correlations coefficients between 530 predictand the predictors (Figs. S6, S7).

- 531
- 532 4.3.2 Sensitivity of ozone to the drivers533

534 We assess the sensitivities of MDA8 O_3 to the drivers through their standardised 535 coefficients obtained in the MLR (Section 3). These coefficients provide further 536 information about the changes of MDA8 O3 due to the effect of each driver. Figures 8 537 and 9 depict the values of the main driving factors obtained in the MLR for the internal 538 and the external regions (respectively): LO3, Tx and RH. Similarly to those patterns 539 described by the relative importance of drivers, we observe that the ozone response to 540 LO3 is stronger in AMJ than in JAS: the corresponding standardised coefficients are 541 always positive and generally higher in AMJ. The observed sensitivities to LO3 are smaller in the internal regions (Fig. 8), being particularly dominant in the external 542 543 regions (Fig. 9). Overall, most of the CTMs reflect a similar tendency. However, there 544 are evident differences between observations and CTMs when comparing the values of 545 the standardised coefficients, specifically in some regions such as BA or MD. When 546 comparing the ozone responses of the CTMs to LO3, we observe that in most of the

regions MATCH and MINNI show values closest to observations, which is consistentwith the results described at the beginning of this section (4.1.2).

549

550 Correlations between MDA8 O_3 and Tx are strong, especially in the internal regions in 551 JAS (Fig. S6). Overall, we show that the CTMs appear to capture the observed effect of 552 Tx better in JAS than in AMJ in most of the regions. The highest sensitivities to Tx are 553 found in internal regions such as ME, NI, FR and EN, which is also shown in the CTMs 554 (Fig. 8). However, we see that most of the CTMs tend to overestimate the effect of Tx 555 and distinct sensitivities to Tx are also found for those models that share the same meteorology (i.e. CHIMERE, EMEP and MINNI). In particular, the MINNI and 556 557 CHIMERE models show higher Tx sensitivities when compared to the rest of the 558 CTMs. While the MINNI model presents the highest sensitivities to Tx in spring, 559 especially in EN and FR, EMEP shows smaller values and it underestimates the 560 correlations between Tx and MDA8 O₃ (Figs. S6, S7).

561

562 The slope of the ozone-temperature relationship (m_{O3-T}) has been used in several studies 563 to assess the ozone climate penalty (eg. Bloomer et al., 2009, Steiner et al., 2010, 564 Rasmussen et al., 2012, Brown-Steiner et al. 2015) in the context of future air quality. 565 Thus, we additionally analyse the ozone-temperature relationship in order to provide 566 insight into the ability of CTMs to reproduce the observed m_{O3-T} . Similarly to previous work (Brown-Steiner et al. 2015), the slopes are obtained from a simple linear 567 568 regression using only Tx (without the influence from other predictors) and they are used 569 to quantify such relationship in both seasons, AMJ and JAS.

570

571 Figures 10 and 11 illustrate the m_{O3-T} for the internal and the external regions 572 respectively. The observed m_{O3-T} is larger in JAS than in AMJ. In AMJ, it ranges between -0.45 and 1.15 ppbK⁻¹ with the largest values found in ME, NI and MD. In 573 574 JAS, the observed climate penalty is of the order of 1-2.7 ppbK⁻¹ with the largest values 575 in EN, FR, ME, NI, and MD. CTMs show a better agreement with observations in JAS 576 than in AMJ. CTMs tend to overestimate the climate penalty in AMJ in most of the 577 regions, with some exceptions, such as EMEP and MATCH that systematically 578 underestimate the slopes. Also, CTMs are generally better in simulating the observed 579 m_{O3-T} in the internal regions compared to the m_{O3-T} in the external regions, where in 580 general CTMs appear to overestimate the climate penalty in both seasons. Using this 581 metric, we identify some regions particularly sensitive to temperature, with larger 582 values of m_{O3-T} (e.g. EN, ME, FR, NI or MD). Through a multi-model assessment, 583 Colette et al. (2015) showed a significant summertime climate penalty in southern, 584 western and central European regions (e.g. EA, IP, FR, ME or MD) in the majority of 585 the future climate scenarios used. Our study shows that most of the CTMs confirm the 586 observed climate penalty in JAS in such regions in the near present, although we found 587 that most of the CTMs overestimate the climate penalty in AMJ, especially in the 588 external regions.

589

We see a stronger effect of RH in AMJ than in JAS in the observations with the greatest impact in the internal regions (e.g. EA, ME, NI, FR and EN), which is not well represented by the CTMs (Figs. 8 and 9). As mentioned, CTMs underestimate the strength of the correlations between ozone and relative humidity (Figs. S6, S7). This general lack of sensitivity to RH could also partially explain the tendency for all CTMs to show a high bias in simulated ozone compared with observations (Fig. 2). Among the possible reasons for this inconsistency, we hypothesize that it can be related to the 597 fact that ozone removal processes can be associated with higher relative humidity levels 598 during thunderstorm activity on hot moist days, which might not be well captured by 599 CTMs. As previous studies pointed out (e.g. Andersson and Engardt, 2010), the impacts 600 of ozone dry deposition suggest that it may also play a role in explaining the problems 601 that CTMs show to reproduce the observed ozone-relative humidity relationship. With a 602 simple modelling approach, Kavassalis and Murphy (2017) found that the relationship 603 between ozone and relative humidity was better captured by the inclusion of the vapour pressure deficit-dependent dry deposition, pointing out the relevance of detailed dry 604 605 deposition schemes in the CTMs.

606

607 High SSRD levels favour photochemical ozone formation and it is usually positively 608 correlated to ozone. In this case, CTMs also present some limitations to capture this effect and they overestimated the sensitivities of ozone to SSRD (Figs. S8, S9). For 609 610 example, the observations show a lower and surprisingly negative effect of SSRD. 611 Although the correlations between SSRD and ozone are positive (see Figs. S6, S7), the 612 presence of other predictors in the regression may reverse the sign of the estimated coefficient. The CTMs show a stronger sensitivity of ozone to SSRD and they 613 614 overestimate its influence on surface ozone. Similarly, the sensitivities to Wdir and 615 W10m are also overestimated by the CTMs, especially in AMJ (Figs. S8, S9).

616

617 Our analysis suggests that CTMs present more limitations to reproduce the influence of 618 meteorological drivers to MDA8 O_3 concentrations in the external regions than in the 619 internal regions, particularly in AMJ. Moreover, we find the largest discrepancies in 620 BA, where models show the poorest seasonal performance and correlation coefficients 621 (Figs. 2 and 3, respectively), probably due a low quality of the observational dataset.

622

623 Furthermore, LO3 is the main driver over most of the external regions and explains a 624 large proportion to the total variability of MDA8 O₃, while meteorological factors play 625 a smaller influence. Lemaire et al. (2016) found a very low performance (based on \mathbb{R}^2) 626 over the British Isles, Scandinavia and the Mediterranean using a different statistical 627 approach that only included two meteorological drivers. They attributed this low skill to the large influence over those regions of long-range transport of air pollution (Lemaire 628 629 et al. 2016). Our results confirm the small influence of the meteorological drivers over those regions and the strong influence of the ozone persistence. Moreover, in the case of 630 631 the external regions of northern Europe, it could also be explained due to the dominance 632 of transport processes such as the stratospheric-tropospheric exchange or long-range 633 transport from the European continent, rather than local meteorology, particularly in 634 AMJ (Monks, 2000, Tang et al. 2009, Andersson et al. 2009).

635

636 Previous work suggested that local sources of NOx and biogenic VOC (ozone precursors) are important factors of summertime ozone pollution in the Mediterranean 637 638 basin (Richards et al. 2013). Moreover, some studies suggested that the local vertical 639 recirculation and accumulation of pollutants play an important role in ozone pollution 640 episodes in this region: during the nighttime the air masses are held offshore by land-sea 641 breeze, creating reservoirs of pollutants that are brought back the following day (Millán 642 et al. 20002, Jiménez et al. 2006, Querol et al. 2017). All of these factors (e.g. local 643 emissions as well as local and large-scale processes) control the ozone variability, 644 which might explain the smaller influence of local meteorological factors shown in this 645 study over the Mediterranean basin when compared to meteorological influence in the 646 internal regions. Thus, we may hypothesize that the strong impact of LO3 observed in

647 the external regions over southern Europe (i.e. IP, MD, BA) could be partially due to 648 the role of vertical accumulation and recirculation of air masses along the 649 Mediterranean coasts as a result of the mesoscale phenomena, which is enhanced by the 650 complex terrains that surround the Basin. Other important factor for the strong impact 651 of LO3 observed is the slow dry deposition of ozone on water that would favour the 652 ozone persistence in southern Europe.

653

654 Overall we conclude that CTMs capture the effect of meteorological drivers better in the internal regions (EN, FR, ME, NI and EA), where the influence of local meteorological 655 656 conditions is stronger. The major effect of meteorological parameters found in the internal European regions might be also attributed to the fact that overall the variability 657 of meteorological conditions is larger in those regions (Fig. S5). We also find 658 659 differences among the CTMs driven by the same meteorology. As mentioned in the 660 introduction, Bessagnet el al. (2016) suggested that the spread in the model results 661 could be partly explained by the differences in the vertical turbulent mixing in the 662 planetary boundary layer, differently diagnosed in each of the CTMs. Our results also 663 indicate that even though models share the same meteorology (considering the 664 prescribed requirements defined by the EDT exercise) they show discrepancies when 665 compared to each other, which could be attributed to other sources of uncertainties 666 (such as physical and chemical internal processes in the CTMs). The NMVOC and NO_x emissions from the biosphere are critical in the ozone formation. Since biogenic 667 emissions were not specifically prescribed, which have a strong dependence on 668 669 temperature and solar radiation, discrepancies in the CTMs performances, (e.g. different sensitivities to Tx) might be expected. Furthermore, we notice that the CTMs do not 670 671 reproduce consistently the regional ozone-temperature relationship, which is a key 672 factor when assessing the impacts of climate change on future air quality.

673 674

675

5. Summary and conclusions

676 The present study evaluates the capabilities of a set of Chemical Transport Models 677 (CTMs) to capture the observed meteorological sensitivities of daily maximum 8-hour 678 average ozone (MDA8 O₃) over Europe. Our study reveals systematic differences 679 between the CTMs in reproducing the seasonal cycle when compared to observations. 680 In general, CTMs tend to overestimate the MDA8 O_3 in most of the regions. In the 681 western and northern regions (i.e. Inflow, England and Scandinavia), some models did not capture the high ozone levels in spring (e.g. CHIMERE and MINNI), while in some 682 southern regions (e.g. Iberian Peninsula, Mediterranean and Balkans) 683 they overestimated the ozone levels in summer (e.g. LOTOS, CHIMERE). Of the CTMs, 684 685 MATCH and MINNI were the most successful in capturing the observed seasonal cycle 686 of ozone in most regions. All CTMs revealed limitations to reproduce the variability of 687 ozone over the Balkans region, with a general overestimation of the ozone 688 concentrations, considerably larger during the warmer months (July, August). As reflected in the results, a limitation of the interpolated observational product used here 689 690 is that in some regions (e.g. southern Europe) it has a lower quality due to a reduced 691 number of stations (section 2.1).

692

693 The MLRs performed similarly for most of the CTMs and observations, describing 694 more than 60 % of the total variance of MDA8 O_3 . Overall, the MLRs perform better in 695 JAS than in AMJ, and the highest percentages of described variance were found in Mid 696 Europe and North Italy. This could be attributed to local photochemical processes being 697 more important in JAS, and is consistent with a relatively stronger influence of long-698 range transport in AMJ.

699

700 The effects of predictors revealed spatial and seasonal patterns, in terms of their relative 701 importance in the MLRs. Particularly, we noticed a larger local meteorological 702 influence in the regions located towards the interior of Europe, here termed as the 703 internal regions (i.e. England, France, Mid-Europe, North Italy and East-Europe). A 704 minor local meteorological contribution was found in the remaining regions, referred as 705 the external regions (i.e. Inflow, Iberian Peninsula, Scandinavia, Mediterranean and 706 Balkans). The CTMs are in better agreement with the observations in the internal 707 regions than in the external regions, where they were not as successful in reproducing 708 the effects of the ozone drivers. Overall, the different behaviour in the MLRs developed 709 in the external regions could be attributed to (i) a larger influence of dynamical 710 processes rather than local meteorological processes (e.g. long range transport in the 711 northern regions) (ii) a stronger impact of the boundary conditions (iii) the use of a 712 coarser grid that might be insufficient to capture mesoscale processes that also influence 713 MDA8 O₃ (e.g. sea-land breezes in the southern regions).

714

715 We found substantial differences in the sensitivities of MDA8 O₃ to the different 716 meteorological factors among the CTMs, even when they used the same meteorology. As Bessagnet et al. (2016) point out, the differences amongst CTMs could be partly 717 718 attributed to some other diagnosed model variables (e.g. vertical turbulent mixing and 719 boundary layer height, as well as vertical model resolution). To assess the effect of such 720 potential sources of uncertainties, further investigations would be required. Moreover, 721 variations in the sensitivity of ozone to meteorological parameters could depend on 722 differences in the chemical and photolysis mechanisms and the implementation of 723 various physics schemes, all of which differ between the CTMs (see Colette et al. 724 2017a). Specifically, the discrepancies found in the sensitivities of MDA8 O₃to 725 maximum temperature might be also attributed to biogenic emissions not prescribed in 726 the models. This was particularly reflected in the analysis of the slopes ozone-727 temperature (m_{O3-T}) to assess the climate penalty, which differed between CTMs and 728 regions when compared to the observations in both seasons. Most of the CTMs confirm 729 the observed climate penalty in JAS, but with larger discrepancies in the external 730 regions than in the internal regions. Furthermore, CTMs tend to overestimate the 731 climate penalty in AMJ (particularly in the external regions).

732

733 Our results have shown discrepancies in the observed and simulated ozone sensitivities 734 to relevant meteorological parameters for ozone formation and removal processes. In 735 particular, we found that CTMs tend to overestimate the influence of maximum 736 temperature and surface solar radiation in most of the regions, both strongly associated 737 with ozone production. None of the CTMs captured the strength of the observed 738 relationship between ozone and relative humidity appropriately, underestimating the 739 effect of relative humidity, a key factor in the ozone removal processes. We speculate 740 that ozone dry deposition schemes used by the CTMs in this study may not adequately 741 represent the relationship between humidity and stomatal conductance, thus 742 underestimating the ozone sink due to stomatal uptake. Further sensitivity analyses 743 would be recommended for testing the impact of the current dry deposition schemes in 744 the CTMs.
