18 **Abstract**

19 Multi-wavelength *in situ* aerosol extinction, absorption and scattering measurements made at two
20 ground sites during the 2010 Carbonaceous Aerosols and Radiative Effects Study (CARES) are analyzed
21 using a spectral deconvolution method that allows extraction of particle size-related information,
22 including the fraction of extinction produced by the fine mode particles and the effective radius of the
23 fine mode. The spectral deconvolution method is typically applied to analysis of remote sensing
24 measurements. Here, its application to *in situ* measurements allows for comparison with more direct
25 measurement methods and validation of the retrieval approach. Overall, the retrieved fine mode
26 fraction and effective radius compare well with other *in situ* measurements, including size distribution
27 measurements and scattering and absorption measurements made separately for PM₁ and PM₁₀,
28 although there were some periods during which the different methods yielded different results. One key
29 contributor to differences between the results obtained is the alternative, spectrally based definition of
30 “fine” and “coarse” mode from the optical methods, relative to instruments that use a physically
31 defined cut-point. These results indicate that for campaigns where size, composition, and multi-
32 wavelength optical property measurements are made, comparison of the results can result in closure or
33 can identify unusual circumstances. The comparison here also demonstrates that *in situ* multi-

34 wavelength optical property measurements can be used to determine information about particle size
35 distributions in situations where direct size distribution measurements are not available.

36

37 Introduction

38 Aerosols remain a substantial source of uncertainty in climate models, despite considerable progress in
39 scientific understanding of their chemical, physical and optical properties in the last few decades (IPCC,
40 2013). As greater understanding has developed in each of these areas, new complexity is also uncovered
41 and the interconnectedness of the various properties becomes even more evident. Light scattering by
42 atmospheric particles has a net cooling effect on climate that is one major offset to greenhouse gas
43 induced climate warming (Charlson et al., 2005; Bond et al., 2011). The efficiency with which the
44 atmospheric aerosol interacts with electromagnetic radiation (e.g. sunlight) is dependent upon the size,
45 composition, shape and morphology of the particles. These properties are not static in time, instead
46 evolving as particles are transported through the atmosphere as a result of chemical processing,
47 scavenging and changes in the environmental conditions (e.g. relative humidity and temperature)
48 (Doran et al., 2007; George and Abbatt, 2010; Lack and Cappa, 2010).

49 Characterization of the spatial distribution of aerosol particle concentrations and properties is important
50 to assessing their impact on the atmospheric radiation budget through direct aerosol-radiation and
51 indirect aerosol-cloud interactions. Aerosol optical properties can be measured directly in the laboratory
52 and in the field using both in situ methods (Andrews et al., 2004; Moosmuller et al., 2009; Coen et al.,
53 2013) and remote sensing instruments/platforms, such as sunphotometers and satellites (Holben et al.,
54 1998; Anderson et al., 2005). Alternatively, aerosol optical properties can be inferred from
55 measurements of particle composition, abundance and size distributions (Atkinson et al., 2015). One
56 particular advantage of the remote sensing instruments is that they allow for characterization of
57 column-average atmospheric particle burdens and properties over a large spatial scale and are free from
58 sampling biases as the particles are characterized as they exist in the atmosphere. However, they can
59 only reliably retrieve aerosol properties under cloud-free conditions, and determination of properties
60 beyond the aerosol optical depth (such as the single scatter albedo or the aerosol size distribution)
61 typically requires a data 'inversion' process that relies on an assessment of the wavelength-dependent
62 light attenuation and scattering (Dubovik and King, 2000). *In situ* methods can allow for more detailed
63 characterization of aerosols, including the relationships between size, composition and optical
64 properties, but typically at the expense of reduced spatial coverage and with long-term measurements
65 typically restricted to the surface (Andrews et al., 2004). Given the wide-spread use of aerosol remote
66 sensing and the extensive availability of the data (in particular from ground-based sunphotometer
67 networks such as AERONET and AEROCAN (Holben et al., 1998; Bokoye et al., 2001)), continued

68 assessment and validation of the inversion methods by comparison with measurements by *in situ*
69 methods is important.

70 Multi-wavelength optical measurements can yield information about the aerosol size distribution, a
71 principle that dates back to Ångström's observation that the wavelength-dependence of light
72 attenuation by particles was weaker for larger particles (diameters of hundreds of nanometers to
73 micrometers) than for smaller particles (Ångström, 1929). One of the simplest ways of characterizing the
74 wavelength-dependence of optical measurements (whether extinction, scattering or absorption) is
75 through the Angstrom exponent. For a pair of optical measurements at different wavelengths, α
76 $= -\log(b_{x,\lambda_1}/b_{x,\lambda_2})/\log(\lambda_1/\lambda_2)$, where $b_{x,\lambda}$ is the optical coefficient at one of the wavelengths λ ; for
77 scattering and extinction α typically increases as particle size decreases. The dependence of b_x on
78 wavelength can alternatively be obtained from a $\log(b_{x,\lambda})$ vs. $\log(\lambda)$ plot using two or more wavelengths;
79 if the dependence is linear, a regression would obtain the same value as the pair-wise treatment, but
80 non-linearity can be accommodated by using the continuous derivative $\alpha = -d\ln(b_{x,\lambda}) / d\ln(\lambda)$ at a
81 specified wavelength. A list of the symbols and acronyms used in this work is provided in Appendix A.

82 The two-wavelength version will be referred to here as the Ångström exponent and the multi-
83 wavelength variant as the spectral derivative. Particle size classification schemes have been proposed
84 (Clarke and Kapustin, 2010) and supported/validated (Eck et al., 2008; Massoli et al., 2009; Cappa et al.,
85 2016) based on the Ångström exponent of extinction or scattering. When observations are made at
86 more than two wavelengths (ideally, widely spaced), further information regarding the nature of the
87 particle size distribution can be extracted. For example, an additional level of refinement of wavelength-
88 dependent measurements of aerosol optical depth (path integrated extinction) was introduced by
89 O'Neill et al. (2005) to aid in the interpretation of the data obtained by the ground-based
90 sunphotometer networks AERONET and AEROCAN. Specifically, O'Neill et al. (2003; 2005) showed that
91 the fine mode fraction (FMF) of extinction and the fine mode effective radius, $R_{eff,f}$ could be extracted
92 directly from the multi-wavelength optical depth or extinction measurements available from remote
93 sensing. The FMF provides for an approximate discrimination between what are typically naturally
94 produced coarse mode particles (dust or sea spray) and what are often anthropogenically associated
95 fine mode particles. Thus, parameters such as the FMF can provide a nominal indication of the relative
96 contributions of natural versus anthropogenic particles to the atmospheric AOD. Variations in $R_{eff,f}$
97 provide information on the sources of the fine mode particles - as different sources yield fine mode

98 particles with different size distributions - or the extent to which particles have undergone atmospheric
99 processing, which can change the size distribution (and chemical composition) in systematic ways.

100 In the spectral curvature approach of O'Neill et al. (2003), the fine mode spectral derivatives (α_f = first
101 derivative and α_f' = second) and the FMF are first extracted from multi-wavelength extinction data using
102 a process described as Spectral Deconvolution. The fine mode spectral derivatives can then be used to
103 obtain the fine mode effective radius from a fine mode spectral curvature algorithm. Alternatively, the
104 fine mode effective radius can be calculated from direct measurements of size distribution (e.g. from
105 scanning mobility particle sizer) using equation 1 (Hansen and Travis, 1974):

$$106 \quad R_{eff,f} = \frac{\int_0^{\infty} R\pi R^2 \frac{dN}{d\ln R} d\ln R}{\int_0^{\infty} \pi R^2 \frac{dN}{d\ln R} d\ln R} \quad (1)$$

107 where R is the particle geometrical radius and $dN/d\ln R$ is a number weighted size distribution for which
108 $R_{eff,f}$ is the first moment (average radius) of the surface-area weighted size distribution. $R_{eff,f}$ is an
109 effective radius that characterizes, approximately, the average size of particles in the fine mode that
110 scatter solar radiation. In this work, we compare the optically obtained $R_{eff,f}$ retrievals to those
111 calculated by numerically evaluating the integrals of Equation 1 using the observed size distributions
112 produced by scanning mobility particle sizers. A single log-translatable particle size distribution (i.e., a
113 PSD that can be translated along the log-transformed particle size axis without changing the form of the
114 distribution function) is, in many cases, a reasonable representation of the size distribution of observed
115 aerosol fine modes (O'Neill et al., 2005). In these cases, the fine mode can be characterized by the single
116 parameter $R_{eff,f}$ facilitating comparisons and examination of trends in sources and/or atmospheric
117 processing.

118 Numerical methods such as those developed by O'Neill et al. (2003) were originally applied to remote
119 sensing measurements, but can also be applied to *in situ* extinction measurements. Beyond adding to
120 the utility of the *in situ* optical measurements, this provides an opportunity to test the methods against
121 other, complementary measures of particle size and size-dependent scattering and extinction. For
122 example, Atkinson et al. (2010) used the approach of O'Neill et al. (2003) to analyze *in situ*, three-
123 wavelength aerosol extinction measurements made during the 2006 TexAQS II campaign near Houston,
124 TX. More recently, Kaku et al. (2014) showed, for a range of marine atmospheres, that the application of
125 this spectral approach to obtain FMF from three-wavelength scattering coefficient measurements was
126 largely coherent with the sub-micron fraction of scattering (SMF), obtained from scattering coefficient
127 measurements of the fine and coarse mode components using impactor-based separation of the

128 aerosol. These studies, and others, provide a useful basis for understanding the accuracy and
129 applicability of the parameters retrieved from remote sensing data. However, further assessment in a
130 wide range of environments is necessary given that networks employing such spectral remote sensing
131 algorithms (AERONET and some surface based sites) represent locations impacted by particles from
132 diverse sources.

133 In this work, measurements of aerosol optical properties (extinction, scattering and absorption
134 coefficients) made at multiple wavelengths during the 2010 Carbonaceous Aerosols and Radiative
135 Effects Study (Fast et al., 2012; Zaveri et al., 2012) are reported and analyzed using the O'Neill et al.
136 (2003) and the O'Neill et al. (2008b) methods. The measurements were made at two locations near
137 Sacramento: a more urban site in Granite Bay, CA (T0) and a more rural site in Cool, CA (T1) that were
138 often linked by direct atmospheric transport. The multi-wavelength measurements were made using
139 three types of optical instruments (specifically seven separate instruments at the two locations). The
140 multi-wavelength measurements of the extinction coefficients (either measured directly or produced
141 from the sum of scattering and absorption coefficients) are used to retrieve the fine mode fraction of
142 extinction and fine mode effective radius. These results from the retrieval, described in more detail in
143 the next section, are compared to other, complementary *in situ* measurements. Scattering and
144 absorption coefficients were measured after aerodynamic separation into the PM₁ and PM₁₀ fractions,
145 which allowed the sub-micron fraction (SMF) of extinction to be directly determined. The *in situ* SMF can
146 be compared with the FMF from the spectral retrieval method. In this work, sub-micron particles are
147 those with nominal aerodynamic diameters ($d_{p,a}$) smaller than 1 μm , likely resulting in geometric
148 diameters below 800 nm. Also, size distribution measurements allowed for determination of the fine-
149 mode effective radii (via Eqn. 1), which are compared with those obtained from the spectral retrieval.

150 **Theoretical Approach**

151 ***The Spectral Deconvolution Algorithm with Fine Mode Curvature (SDA-FMC) Approach***

152 This section provides a qualitative description of the fine and coarse mode AOD (or extinction) retrieval
153 algorithm (SDA, or spectral deconvolution algorithm) and fine mode optical sizing (FMC or fine mode
154 curvature) method developed by O'Neill. The details of the derivation and application of the SDA are
155 provided in previous publications (O'Neill et al., 2003; Atkinson et al., 2010; Kaku et al., 2014). The
156 MATLAB code that implements the approach is available from O'Neill upon request. Application of both
157 approaches requires a robust set of measurements of aerosol optical extinction or scattering (or optical

158 depth) at a minimum of three wavelengths that should be widely spread across the optical region of the
159 spectrum (near UV through the visible to the near IR; see, for example, O'Neill et al. (2008a)).

160 The fundamental assumption of the SDA approach is that most ambient aerosol size distributions are
161 composed of two optically-relevant modes: a fine mode having an effective radius (and to a lesser
162 extent, geometric standard deviation) that is a function of atmospheric processing, and a separate
163 coarse mode, largely in the supermicron ($d_{p,a} > 1 \mu\text{m}$) size range. A common assumption is that the fine
164 mode is more closely associated with anthropogenic activities and the coarse mode with natural
165 sources, although this can be somewhat confounded by smoke from biomass burning (Hamill et al.,
166 2016). In particular, it can be difficult to distinguish biomass burning particles from particles derived
167 from urban sources, as both primarily fall within the fine mode and are somewhat absorbing. The FMC
168 (Fine Mode Curvature) algorithm employs the fine mode optical parameters retrieved using the SDA to
169 estimate both a fundamental indicator of optical particle size (the fine mode van de Hulst parameter)
170 and from this, an indicator of microphysical particle size (the fine mode effective radius); these are both
171 defined below.

172 ***Spectral deconvolution of the fine and coarse mode extinction and derivation of the fine mode*** 173 ***spectral derivatives (SDA)***

174 The spectral deconvolution algorithm begins by isolating the fraction of total extinction due to particles
175 in the fine mode, based on the stronger dependence of the extinction (scattering)¹ on wavelength for
176 smaller particles. Current applications of the method start by fitting $\ln(b_{\text{ext}})$ (or $\ln(b_{\text{scat}})$ or $\ln(\text{AOD})$)
177 versus $\ln(\lambda)$ to a second order polynomial, where b_{ext} is the measured wavelength-dependent extinction
178 coefficient (see Atkinson et al. (2010) and Kaku et al. (2014) for scattering and extinction coefficient
179 applications, Saha et al. (2010) for a sunphotometry AOD application and Baibakov et al. (2015) for a
180 starphotometry AOD application). The extinction and its first and second derivatives are determined
181 from the fit at a reference wavelength of 500 nm, a common reference wavelength along with 550 nm
182 in optical studies. The first derivative (i.e. slope) is denoted α in analogy to the Ångström exponent, but
183 in this non-linear, second order approach it is a function of wavelength. The second derivative α' (i.e.
184 spectral curvature) may, in principle, be wavelength dependent over the observed range, but using a
185 second order polynomial fit yields a constant value. Values of α and α' associated with the fine mode

¹ We will stop inserting "(scattering)" at this point although all references below should be understood to apply to both scattering and extinction.

186 and the coarse mode are indicated using subscript f or c, respectively. In this work, only a second order
187 fit is possible because only three measurements are used to define the wavelength dependence. In the
188 SDA-FMC approach, the observed spectral derivative (α) is used along with the SDA-derived fine mode
189 spectral derivative (α_f) to produce the fine mode fraction of extinction (FMF), given as:

190

$$191 \quad FMF = \frac{\alpha - \alpha_c}{\alpha_f + \alpha_c} \quad (2)$$

192

193 Ultimately, the fine mode slope and curvature are both used in the FMC algorithm to determine the fine
194 mode effective radius (discussed in the next section).

195 The algorithm proscribes constant values of the spectral slope and curvature for all coarse mode
196 aerosols (α_c and α'_c) at the reference wavelength of 500 nm. Specifically, $\alpha_c = -0.15 \pm 0.15$ and $\alpha'_c =$
197 0.0 ± 0.15 , with the uncertainties as per O'Neill et al. (2003). O'Neill et al. (2001) showed that an
198 assumption of an aerosol size distribution with two distinct modes yields a series of three equations that
199 express the relationships between the observed parameters (AOD or extinction coefficient, α , α') and
200 their fine and coarse mode analogues. Specifically, the equations can be inverted to yield the fine mode
201 spectral derivative, the fine mode curvature (α'_f) and the fine and coarse mode AOD or b_{ext} values. It
202 should be noted that the fitting of a 2nd order polynomial to input AOD or b_{ext} spectra is only an
203 approximation relative to a higher order polynomial. The use of a 2nd order polynomial represents a
204 compromise between higher order spectral polynomials being better representations of theoretical Mie
205 spectra and the beneficial damping effects of lower order polynomials in the presence of noisy spectra
206 (O'Neill et al., 2001). The observationally determined total and fine mode spectral derivative and
207 proscribed coarse mode spectral derivative are then used to calculate the fine mode fraction of
208 extinction at the reference wavelength (here 500 nm) using Eqn. 2.

209

210 ***Estimation of the Fine Mode Effective Radius – the Fine Mode Curvature (FMC) approach***

211 Using the SDA-derived, fine mode spectral derivatives (α'_f and α_f), an estimate of the fine mode effective
212 radius is obtained. The basis for this approach is a fundamental parameterization involving the effective
213 van de Hulst phase shift parameter for fine mode aerosols and its representation in α'_f versus α_f space.

214 Full details are provided in O'Neill et al. (2005) and O'Neill et al. (2008b), and only a summary of the
215 parameterization is provided here. The van de Hulst parameter for the fine mode, $\rho_{eff,f}$, is given by:

$$216 \quad \rho_{eff,f} = 2 * \frac{2 \pi R_{eff,f}}{\lambda} |m - 1| \quad (3)$$

217
218 where λ is the reference wavelength and m is the complex refractive index at that wavelength (O'Neill et
219 al., 2005). An estimate of this purely optical parameter is based on a 3rd order polynomial derived from
220 numerical Mie simulations that relate $\rho_{eff,f}$ and the polar angle (ψ) coordinate of any point in α_f' vs. α_f
221 space (O'Neill et al., 2005). The value of ψ for any given retrieval is simply the arctangent of α_f' divided
222 by α_f (minus small prescribed offsets of $\alpha_{f,0}'$ over $\alpha_{f,0}$ respectively). Individual simulated contour curves
223 of α_f' versus α_f correspond to particle size distributions of differing $R_{eff,f}$ for constant values of refractive
224 index and were illustrated in Figure 1 of O'Neill et al. (2005). The three different "lines of constant $\rho_{eff,f}$ "
225 in that figure correspond to three different values of ψ (where both $\rho_{eff,f}$ and ψ increase in the
226 counterclockwise direction from the horizontal). The $R_{eff,f}$ value are then computed from the retrieved
227 value of $\rho_{eff,f}$, by inverting equation (3), if the refractive index of the particles is known. Since the
228 refractive index is generally unknown for the situations we consider here, the information provided by
229 this approach is actually a combination of size and composition. In many cases, an average, constant
230 value for the real portion of the refractive index can be assumed and the imaginary part neglected to
231 provide an estimate of the effective radius; this is, in part, because the imaginary component is typically
232 much smaller than the real component of the refractive index, and thus the $R_{eff,f}$ value is relatively
233 insensitive to variations in the imaginary component. This treatment is questionable if strong changes in
234 the average composition that lead to changes in m are suspected. For example if the composition
235 shifted from pure sulfate aerosol ($m = 1.53 + 0i$) to a brown carbon organic ($m = 1.4 + 0.03i$) this would
236 introduce a 33% shift in the derived radius with no change in actual size; the majority of this shift in the
237 derived radius results from the change in the real component of the refractive index.

238 The FMC method represented by the inversion of equation (3) has been less rigorously validated than
239 the SDA portion and is expected to be more susceptible to problems related to measurement errors and
240 a decreasing sensitivity with decreasing fine mode fraction of extinction. The FMC validation is largely
241 confined to comparisons with the more comprehensive AERONET inversions of Dubovik and King (2000),
242 referred to henceforth as the D&K inversions. These inversions, which require the combination of AOD
243 and sky radiance data, are of a significantly lower frequency than simple AOD measurements. The sky
244 radiance data are collected nominally once per hour while AOD measurements are made once every 3

245 minutes. Comparisons between the FMC method and the D&K inversions show averaged FMC versus
246 AERONET differences of $10\% \pm 30\%$ (mean \pm standard deviation of $(\rho_{\text{eff},f,\text{FMC}} - \rho_{\text{eff},f,\text{D\&K}}) / \rho_{\text{eff},f,\text{D\&K}}$) for large
247 FMF values > 0.5 , at least for the limited data set of O'Neill et al. (2005) and confirmed by more recently
248 unpublished AERONET-wide comparisons between the FMC and D&K methods.

249 **Application of the SDA-FMC method to in situ extinction measurements**

250 This paper seeks to address the following two key questions pertaining to the use of the SDA-FMC
251 algorithm with extinction measurements, especially those produced by the cavity ring-down
252 instruments, to extract information about aerosol size, both the partitioning of the extinction between
253 the fine and coarse modes and the extraction of a single parameter size characterization of the fine
254 mode.

255 1.) Can the approach be used reliably to extract the fine and coarse mode fractions of the
256 extinction in situations where only a single optical instrument is used?

257 and,

258 2.) In situations where complementary measurements (mobility-based sizers, parallel or switching
259 nephelometers, etc.) are available, what information can be determined from the comparison of
260 the products of the SDA-FMC approach to comparable information obtained in other ways?

261 It has been suggested that a single multi-wavelength optical measurement of the fine mode fraction
262 could be less expensive than derivation of the sub-micron fraction of scattering using parallel
263 nephelometers (Kaku et al., 2014). The use of two size-selected inlets (e.g., 1 and 10 μm cyclones) and
264 parallel nephelometers is not prohibitively expensive, but the typical concerns regarding calibration
265 maintenance and careful and consistent application of correction factors for truncation angle and non-
266 Lambertian illumination can be magnified when measurements are combined (either as differences or
267 ratios) since systematic errors may not undergo partial cancellation like random errors.

268 In principle, the use of two parallel CRD extinction measurements could mitigate some of the possible
269 errors with parallel nephelometers. Cavity ring-down measurements directly quantify total extinction
270 within the cavity, which is contributed from both gases and particles (Smith and Atkinson, 2001; Brown,
271 2003). To determine extinction by aerosols only, the entering air stream is periodically directed through
272 a filter such that a gas-only reference is determined. Extinction by aerosol particles is determined
273 relative to this gas zero. The aerosol extinction is further corrected to account for the practical aspect

274 that the complete mirror-to-mirror distance of the optical cavity is typically not filled with aerosols (to
275 keep the mirrors clean) (Langridge et al., 2011). The former (zeroing) limits instrument precision and
276 sometimes accuracy while the latter (path length) limits instrument accuracy. In general these
277 procedures are identical for the two parallel instruments and are very stable in time, so they would only
278 be expected to produce a small and consistent bias. To our knowledge, currently no single-package,
279 multi-wavelength direct extinction (cavity-enhanced) instruments are commercially available. Multiple
280 single-wavelength instruments operating at different wavelengths could be deployed, but might be
281 prohibitively expensive.

282 For detailed knowledge of the fine mode size distribution, the use of scanning mobility analyzer-based
283 sizing instruments is preferable since the full mobility size distribution is obtained, as opposed to only
284 the effective radius provided by the FMC procedure. However, scanning mobility sizer instruments
285 typically have maximum diameters of only 700 to 800 nm, and both scanning and multi-channel variants
286 are of comparable expense and complexity as CRD instruments. In order to obtain additional
287 information about the coarse mode size distribution and contribution to the optical effects, an aerosol
288 particle spectrometer (APS) is generally added to the measurement suite.

289 The purely spectrally-based mode separation inherent in the SDA obviates the need for a physical cut
290 point selection, such as that required to measure the PM₁ scattering product used in this work. This can
291 be advantageous, since selection and maintenance of a size cut-point is a possible source of differences
292 between some measurements (and variability of all measurements using physical separation) of the sub-
293 micron fraction (SMF) of scattering, absorption or extinction. The SMF is fundamentally different from
294 the FMF, although both provide an indication of the fractional optical contribution of smaller particles.
295 In fact, there are fundamental differences between many of the SMF or FMF data products that are
296 currently available. For example, the Dubovik and King (2000) SMF data product tries to locate the
297 separation radius (called the inflection point) at a minimum of the particle size distribution obtained
298 from the inversion procedure. This results in a variable cut point that can be interpreted as assigning a
299 portion of the coarse mode to the fine mode (O'Neill et al., 2003). The aerodynamic diameter selected
300 for the physical separation used in the SMF presented in this work might result in some mis-assignment
301 of fine mode extinction to the coarse mode, since (i) the aerodynamic separation results in a cut point
302 that is less than 1 μm geometric diameter and (ii) the cut point might not correspond to a local
303 minimum of the size distribution. These definitional differences should be kept in mind when comparing
304 fine mode apportionments (SMF or FMF) from different measurements/data treatments. And all of

305 these data products will usually differ significantly from the optical properties of the PM_{2.5} fraction used
 306 to define the fine mode for air quality regulations and to exclude larger particles in the CRD instruments
 307 at T0. The latter allowed a significant fraction, but not all of the optically coarse particles into the
 308 instruments, as shown in the Results section. For the comparisons presented in this work, in cases
 309 where there is significant penetration of one of the modes into the size regime defined by the physical
 310 cut-point as the other mode (or significant overlap of two or more size modes) there are noticeable
 311 differences between the physically-defined SMF and the FMF produced by the SDA.

312 **Experimental**

313 The instrument suites used, sampling conditions and methodology and goals of the CARES study have
 314 been summarized by Zaveri et al. (2012). A summary of the instrumentation used to make the light
 315 extinction, scattering and absorption measurements is provided in Table 1. Extinction was measured
 316 either directly (using cavity ringdown spectroscopy) or as the sum of scattering and absorption. A brief
 317 description of the key instruments used in the current analyses is given below.

318

319 **Table 1: Summary of optical instruments used at the T0 and T1 sites**

Property	Instrument	Wavelength	Size Cut*
<i>T0</i>			
Extinction	UCD CRD	405, 532 nm	2.5 μm
	PSU CRD	532, 1064 nm	2.5 μm
Scattering	PNNL Nephelometer	450, 550, 700 nm	1 μm, 10 μm
Absorption	PNNL PSAP	470, 522, 660 nm	1 μm, 10 μm
<i>T1</i>			
Extinction	PSU CRD	355, 532, 1064 nm	None applied
Scattering	PNNL Nephelometer	450, 550, 700 nm	1 μm, 10 μm
Absorption	PNNL PSAP	470, 522, 660 nm	1 μm, 10 μm

*For the entries with two size cuts listed, the sampling system switched between the two on a 6 minute cycle

320

321 ***Instruments used at the T0 site (American River College, Granite Bay, CA USA)***

322 Cavity Ring-down Extinction: The b_{ext} measurements at 405 nm and 532 nm were made using the UC
 323 Davis two-wavelength Cavity Ring Down-Photoacoustic Spectrometer (CRD-PAS) instrument (Langridge
 324 et al., 2011; Lack et al., 2012). Full details of these measurements are available in Cappa et al. (2016) and
 325 Atkinson et al. (2015). These measurements were only made for a subset of the CARES campaign, from
 326 20:00 PDT on 16 June through 09:00 PDT on 29 June. At 532 nm, b_{ext} was measured at low (~25%), mid

327 (~75%) and high (~85%) relative humidity. At 405 nm only low RH measurements were made, and so
328 only the low RH 532 nm measurements are used in this study. The CRD-PAS sampled behind a PM_{2.5}
329 (aerodynamic diameter <2.5 μm) URG Teflon-coated aluminum cyclone. A separate CRD instrument
330 deployed by the PSU group at T0 used a single optical cavity to measure the sub-2.5 μm (sampled
331 through a similar URG cyclone) aerosol extinction coefficient at 532 and 1064 nm simultaneously
332 (Radney et al., 2009). This instrument did not incorporate intentional RH control, but efforts were made
333 to maintain nearly ambient conditions, resulting in low RH (25 - 40 %) throughout most of the campaign,
334 as measured by an integrated RH/T sensor (Vaisala HMP70). Daytime ambient RH was similar to the low
335 RH value during the CARES campaign (Fast et al., 2012).

336 To obtain three-wavelength b_{ext} measurements for use in the SDA-FMC analysis, we combined the
337 measurements from the two CRD instruments (the 1064 nm measurements from the PSU instrument
338 were used with the 532 nm and 405 nm UCD data after all had been averaged to one-hour). To assess
339 whether this was a reasonable approach, the 532 nm time series data from the two instruments were
340 overlaid and examined for differences. There is a high degree of temporal correspondence between the
341 measurements from the two instruments, although there was a clear difference in precision, with the
342 UCD CRD having approximately 3 times better precision than the PSU instrument at comparable
343 integration times. This difference in precision results from differences in instrumental design and (likely)
344 mirror quality. A scatterplot (Figure S1) of $b_{ext,PSU}$ versus $b_{ext,UCD}$ also showed good correlation, with a best
345 fit line from an orthogonal distance regression fit having a slope = 0.96 and an intercept that was
346 statistically indistinguishable from zero. This is within the uncertainties of the instruments. The good
347 agreement at 532 nm between the PSU and UCD instruments suggests that combining the 1064 nm
348 measurements from PSU with the 405 nm and 532 nm measurements from UCD is reasonable. If the
349 very slight low bias in the 532 nm b_{ext} from PSU relative to the UCD measurements applies to the 1064
350 nm measurements then the derived FMF values might be slightly overestimated.

351
352 Size-selected absorption and scattering (nephelometer and PSAP): The low RH scattering and absorption
353 coefficients were alternately measured for PM₁₀ and PM₁ aerodynamic size selected aerosol using the
354 PNNL Aerosol Monitoring System, a clone of NOAA/CMDL's Aerosol Monitoring System (detailed
355 description at <http://www.esrl.noaa.gov/gmd/aero/instrumentation/instrum.html> and in Zaveri et al.
356 (2012)). The relevant measurements are: light absorption coefficients at three-wavelengths (Radiance
357 Research Particle Soot Absorption Photometer [PSAP]) and total scattering coefficients (three-
358 wavelength nephelometer, TSI 3563). The scattering coefficients were corrected for truncation error

359 (Anderson and Ogren, 1998) and the absorption coefficients for filter effects (Ogren, 2010). The
360 absorption coefficients were interpolated to the nephelometer wavelengths assuming the inverse
361 wavelength dependence characteristic of uncoated black carbon, as appropriate for this region (Cappa
362 et al., 2016). The absorption and scattering coefficients for PM₁ or PM₁₀ are then summed after
363 averaging to one-hour intervals and using the mean of the 450 and 550 nm values to obtain $b_{ext}(500$
364 nm). The extinction fraction of the PM₁ (herein, the SMF) at the visible wavelength (500 nm) is then
365 calculated from their ratio

$$366 \quad SMF_{ext} = \frac{b_{ext,PM1}}{b_{ext,PM10}} \quad (4)$$

367 Particle size control was effected by 2 impactors (1 μm and 10 μm) upstream of the PSAP and
368 nephelometer. The 10- μm impactor was always present in the sampling line, and the flow was switched
369 to run through the 1- μm impactor on 6-min intervals, yielding alternating 6-min measurements of
370 submicron and coarse (< 10 μm) particle modes.

371 Fine particle size distribution: The submicron dry particle mobility diameter ($d_{p,m}$) size distribution (12
372 nm to 737 nm) was measured using a scanning mobility particle sizer (SMPS) comprised of a charge
373 neutralizer, differential mobility analyzer and condensation particle counter (TSI 3081 DMA column and
374 model 3775 CPC). The SMPS data were corrected for multiply-charged particles and diffusional losses.
375 These size distribution measurements are used to calculate $R_{eff,f}$ values from Eqn. 1, which will be
376 referred to as $R_{eff,f,size}$. It should be noted that a mobility diameter of 737 nm corresponds to an
377 aerodynamic diameter of 919 nm (assuming a density of 1.5 g cm⁻³, a reasonable value for the campaign
378 based on the observed particle composition (Atkinson et al., 2015)).

379

380 ***Instruments used at the T1 site (Evergreen School, Cool, CA USA)***

381 Cavity Ring-down Extinction: The PSU group deployed a custom CRD instrument that used separate
382 optical cavities to measure b_{ext} at 355 nm, 532 nm, and 1064 nm simultaneously in each of four separate
383 flow systems that were intended to measure total and submicron aerosol and submicron aerosol that
384 had been conditioned to have elevated and suppressed RH. Only the total aerosol flow results are used
385 here as this prototype system suffered from signal to noise problems and RH/temperature control
386 issues. As with the T0 PSU instrument, the total aerosol system attempts to measure particle extinction
387 at nearly ambient conditions, resulting in low RH (25 – 40 %) throughout most of the campaign, as

388 measured by an integrated RH/T sensor (Vaisala HMP70). No intentional size cut was applied to these
389 measurements, although the system was not optimized for transmission of coarse mode particles.

390 Size-selected absorption and scattering (Nephelometer and PSAP): An identical instrument suite to that
391 used at T0 was deployed and the same data analysis was conducted.

392 Fine particle size distribution: The SMPS used at T1 is a similar design described in (Setyan et al., 2012)
393 and it measured low RH particle sizes from 10 nm to 858 nm. The SMPS data were corrected to take into
394 account the DMA transfer function, the bipolar charge distribution, the CPC efficiency and the internal
395 diffusion losses (Setyan et al., 2014).

396 ***Uncertainties in the derived and measured values***

397 The uncertainty in the SMF has been estimated from standard error propagation of the uncertainties in
398 the PM₁ and PM₁₀ extinction measurements. The assumed uncertainties in $b_{\text{ext,PM1}}$ and $b_{\text{ext,PM10}}$ are ± 1
399 Mm⁻¹. This uncertainty estimate accounts only for random errors, not systematic errors.

400 Uncertainties in the FMF have been estimated based on the uncertainties in the inputs to the SDA-FMC
401 procedure, namely the b_{ext} values. The assumed uncertainties in the input b_{ext} were instrument specific:
402 < 1 Mm⁻¹ for the UCD CRD, 1 Mm⁻¹ for the nephelometer plus PSAP and PSU CRD at T0, and 3 Mm⁻¹ for
403 the PSU CRD at T1. The input uncertainties are propagated through the various mathematical
404 relationships using standard methods. The FMF error estimate includes some of the factors that
405 contribute systematic uncertainty in the method. As noted in the Theoretical Approach section, FMF
406 values from the SDA-FMC procedure have been shown to agree well with those determined from the
407 more comprehensive inversion method of Dubovik and King (2000).

408 Uncertainties in the derived $R_{\text{eff},f}$ are also estimated from the uncertainties in the input values. The size-
409 distribution derived $R_{\text{eff},f}$ values depend on the SMPS measurements. The SMPS instruments were
410 calibrated (using 200 nm polystyrene latex spheres) prior to the campaign and a drier was used to keep
411 the aerosol RH $< 30\%$ throughout the entire campaign. Periodic checks throughout the campaign
412 indicate consistent sizing performance to within 5%. The size distribution data used here were corrected
413 for DMA transfer function, the bipolar charge distribution, the CPC efficiency and internal diffusion
414 losses. Under these conditions the estimated uncertainties for D_p are around 10% for the size range
415 between 20 and 200 nm (Wiedensohler et al., 2012). Although larger uncertainties could exist for
416 smaller and larger particle sizes, the derived $R_{\text{eff},f}$ values fell primarily in this range. The estimated SMPS
417 uncertainty (Wiedensohler et al., 2012) was estimated based on intercomparisons between different

418 SMPS instruments and thus probably represents both determinate and indeterminate errors. The
419 relative uncertainty in the $R_{eff,f}$ from the size distribution measurement is thus estimated to be 10%.
420 This estimate mainly reflects uncertainties in the absolute size, since there is expected to be significant
421 cancellation in the errors produced by the particle counter (the same data are used in the numerator
422 and denominator of Eq. 1).

423 Estimating the uncertainty in the $R_{eff,f}$ from the SDA-FMC is more challenging because the uncertainties
424 cannot be simply propagated through the equations. Therefore, an approach was taken wherein a large
425 number of $R_{eff,f}$ values were calculated from input b_{ext} that were independently, randomly varied within
426 one standard deviation of the measured value, assuming a normal distribution of errors. Potential
427 uncertainty or variability in the real refractive index was accounted for based on the compositional
428 variation (Atkinson et al., 2015) and assuming volume mixing applies. The standard deviation (1s) was
429 0.015. This is likely a lower estimate of the uncertainty in the RI, as it does not account for absolute
430 uncertainty in the estimate. The standard deviation of the derived $R_{eff,f}$ is taken as the uncertainty. This
431 Monte Carlo-style approach does not incorporate systematic error sources. The relative uncertainty in
432 the derived $R_{eff,f}$ is found to range from a few percent up to 40%, depending on the particular instrument
433 suite considered and measurement period. In general, the uncertainties were larger for the PSAP and
434 nephelometer, presumably because the wavelengths used are more closely spaced.

435

436 **Results and Discussion**

437 *Fine mode fraction of extinction*

438 The CRD-based extinction measurements were used to derive the FMF_{ext} using the SDA. This will be
439 referred to as the $FMF_{ext,CRD}$. For the T0 site, the $FMF_{ext,CRD}$ is for $PM_{2.5}$ while at T1 no physical cut point
440 was introduced, so PM_{10} is a reasonable expectation. The time series of the CRD-based b_{ext} values and of
441 the derived $FMF_{ext,CRD}$ at the T0 site are shown in Figure 1 (all times in PDT – local time during the study).
442 The $FMF_{ext,CRD}$ varies from 0.54 to 0.97, with a mean of 0.79 ± 0.1 (1 σ) as summarized in Table 2.

443

444

445

446 **Figure 1** – Time series of CRD extinction coefficient observations (left axis) and the derived $FMF_{ext,CRD}$
 447 (right axis) at T0 during the time period analyzed in this work. The blue, green and red traces are the
 448 405 nm, 532 nm and 1064 nm b_{ext} (respectively) and the black points show the 1 h average $FMF_{ext,CRD}$
 449 from the SDA analysis. A $PM_{2.5}$ size cut was applied during the sampling.

450

451 The fine mode fraction of extinction at T0 was alternatively determined from the PM_{10} b_{ext}
 452 measurements from the nephelometer and PSAP, referred to as $FMF_{ext,sum}$. The SDA-derived $FMF_{ext,CRD}$
 453 and $FMF_{ext,sum}$ values are compared with the sub-micron fraction of extinction determined from the
 454 combined PM_1 and PM_{10} nephelometer and PSAP measurements (from the latter part of the campaign)
 455 at T0 (Fig. 2). The $FMF_{ext,CRD}$, $FMF_{ext,sum}$ and $SMF_{ext,sum}$ all exhibit the same general temporal dependence.
 456 In general, the $FMF_{ext,CRD} > FMF_{ext,sum} \sim SMF_{ext,sum}$ although the specific relationships vary with time. For
 457 example, there are periods when the $FMF_{ext,sum}$ and $SMF_{ext,sum}$ are nearly identical (e.g. 20 June – 23
 458 June) and periods when the $SMF_{ext,sum}$ is somewhat lower than the $FMF_{ext,sum}$ (e.g. 24 June – 25 June).

459

460 **Figure 2** – Time series of the fine mode fractions and sub-micron fraction of extinction at T0. The
 461 red trace is the $SMF_{ext,sum}$ determined from the $b_{ext}(PM_1) / b_{ext}(PM_{10})$ ratio. The black and blue
 462 traces are the FMF_{ext} from the SDA analysis of the CRD extinction (black) and nephelometer +
 463 PSAP extinction (blue). The $FMF_{ext,CRD}$ values are the same as those of Fig. 1 for the latter half of
 464 the campaign. Uncertainty ranges are shown as light colored bands. The uncertainty of SMF is
 465 only slightly wider than the heavy line that was chosen to represent it.

466

467 The $FMF_{ext,CRD}$ was determined for $PM_{2.5}$ while the $FMF_{ext,sum}$ was determined for PM_{10} . If a substantial
 468 fraction of the scattering was contributed by particles with diameters $>2.5 \mu m$, then the $FMF_{ext,CRD}$

469 should be larger than the $FMF_{ext,sum}$, as was observed. Kassianov et al. (2012) used measured particle size
470 distributions from CARES to show that supermicron particles contributed significantly to the total
471 scattering, consistent with the observation that $FMF_{ext,CRD} > FMF_{ext,sum}$. Variability in the difference
472 between the $FMF_{ext,CRD}$ and $FMF_{ext,sum}$ likely reflects variability in the contribution of these larger particles
473 to the total scattering.

474 The $FMF_{ext,CRD}$, $FMF_{ext,sum}$ and $SMF_{ext,sum}$ were similarly determined from the measurements at the T1 site
475 (Figure 3). For T1, the CRD measurements were made for particles without any intentional size cut
476 applied, as opposed to the $PM_{2.5}$ size cut used for the T0 measurements. At this downwind site the
477 $SMF_{ext,sum}$, $FMF_{ext,CRD}$ and $FMF_{ext,sum}$ were all very similar, both in terms of the absolute magnitude and
478 the temporal variability. The $FMF_{ext,CRD}$ ranged from 0.22 to 0.89, with a mean of 0.58 ± 0.16 . That the
479 $FMF_{ext,CRD}$ and $FMF_{ext,sum}$ are very similar in absolute magnitude for T1 but differ at T0 (while still
480 exhibiting similar temporal variability) is likely related to the application of an intentional size cut for the
481 CRD measurements at T0 but not at T1. The observations suggest that the T1 CRD without the size cut
482 samples coarse-mode particles with a similar efficiency as the nephelometer and PSAP having the PM_{10}
483 size cut.

484 Overall, these results indicate that the use of the spectral deconvolution algorithm on optical data can
485 robustly provide information on the fine mode fraction of extinction. Moreover, since the FMF_{ext} results
486 at T1 are similar for the two types of extinction measurements, it seems that the narrower wavelength
487 range of the nephelometer (450, 550, 700 nm) and PSAP (470, 522, 660 nm) compared to the CRD
488 instruments used here is still adequate to define the spectral dependence of extinction for extraction of
489 the slope and curvature parameters. However, the results demonstrate that the optical method does
490 not allow for a precise definition of “fine” and “coarse” in terms of a specific, effective size cut that
491 distinguishes between the two regimes. While the SMF has an explicitly defined size cut (PM_1), the
492 effective size cut for the FMF can vary. The effective size cut is dependent on the shapes (i.e. widths,
493 positions and number of actual modes) of the size distributions in the “fine” and “coarse” size regimes
494 and the extent of overlap between them, which is dependent on the size range of particles sampled (e.g.
495 $PM_{2.5}$ versus PM_{10}). For remote sensing measurements, the particular size that distinguishes between
496 the fine and coarse mode therefore likely varies between locations and seasons. Nonetheless, since the
497 major sources of fine and coarse mode particles are likely to be reasonably distinct in many
498 environments, the $FMF_{ext,CRD}$ provides a reasonable characterization of the variability in the

499 contributions of such sources to the total extinction and, in environments where the extinction is
500 dominated by scattering (i.e. when the SSA is large), to the total scattering as well.

501

502

503 **Figure 3** – the fine mode fraction of extinction (SMF and FMF_{ext}) for the latter half of the
504 campaign at T1. Here, the $FMF_{ext,CRD}$ is determined for particles sampled without a size cut
505 applied. Uncertainty ranges are shown as light colored bands.

506

507 ***Effective fine mode radius product of SDA-FMC***

508 The SDA-FMC analysis also allows for derivation of the fine mode effective radius, $R_{eff,f}$, via Eq. 3.
509 Determination of $R_{eff,f}$ requires knowledge of the real and imaginary parts of the refractive index. Here,
510 an average value of $m_r = 1.5$ is used, based on Atkinson et al. (2015), and absorption is assumed to be
511 negligible. The latter is a reasonable assumption given the relatively high single scatter albedo values at
512 the two sites (Cappa et al., 2016), and because assuming the particles to be slightly absorbing has
513 minimal influence on the results. Temporal variability in m_r due to variability in particle composition will
514 contribute to uncertainty in the retrieved $R_{eff,f}$. As discussed above, a change in m_r of 0.13 corresponds
515 approximately to a shift in $R_{eff,f}$ by 30%. The actual variability in m_r is not known for the particles here,
516 but we expect a shift of 0.13 in m_r to be a reasonable upper limit on physical grounds.

517 Values of $R_{eff,f}$ are determined using both the CRD-measured b_{ext} and the PM_{10} b_{ext} from the
518 nephelometer + PSAP measurements for both T0 and T1 (Figure 4). $R_{eff,f}$ values are also determined from
519 the PM_1 nephelometer + PSAP measurements at both sites. Comparison of the $R_{eff,f}$ values between the
520 PM_{10} and PM_1 measurements provides a test of the robustness of the overall retrieval method. The $R_{eff,f}$
521 from the CRD measurements will be referred to as $R_{eff,f,CRD}$ and from the nephelometer + PSAP as $R_{eff,f,sum}$.
522 Comparator values of $R_{eff,f}$ were also calculated from the observed mobility size distributions using Eqn.
523 1, and are referred to as $R_{eff,f,size}$.

524

525

526 **Figure 4** – Time series of the effective fine mode radii, $R_{eff,f}$, produced by the SDA-FMC analysis of the
 527 CRD data (black) and the nephelometer + PSAP data (blue) from T0 (top) and T1 (bottom). For the
 528 nephelometer + PSAP observations, separate results are shown using either the PM₁₀ (dark blue) or
 529 PM₁ (light blue) observations. The $R_{eff,f}$ values determined from the size distribution measurements (i.e.
 530 from Eqn. 1) are shown in red. Uncertainty ranges are shown as light colored bands for each method;
 531 for the SDA-FMC the uncertainty range is only shown for PM₁₀ to avoid clutter, but the uncertainty
 532 range is similar for PM₁.

533

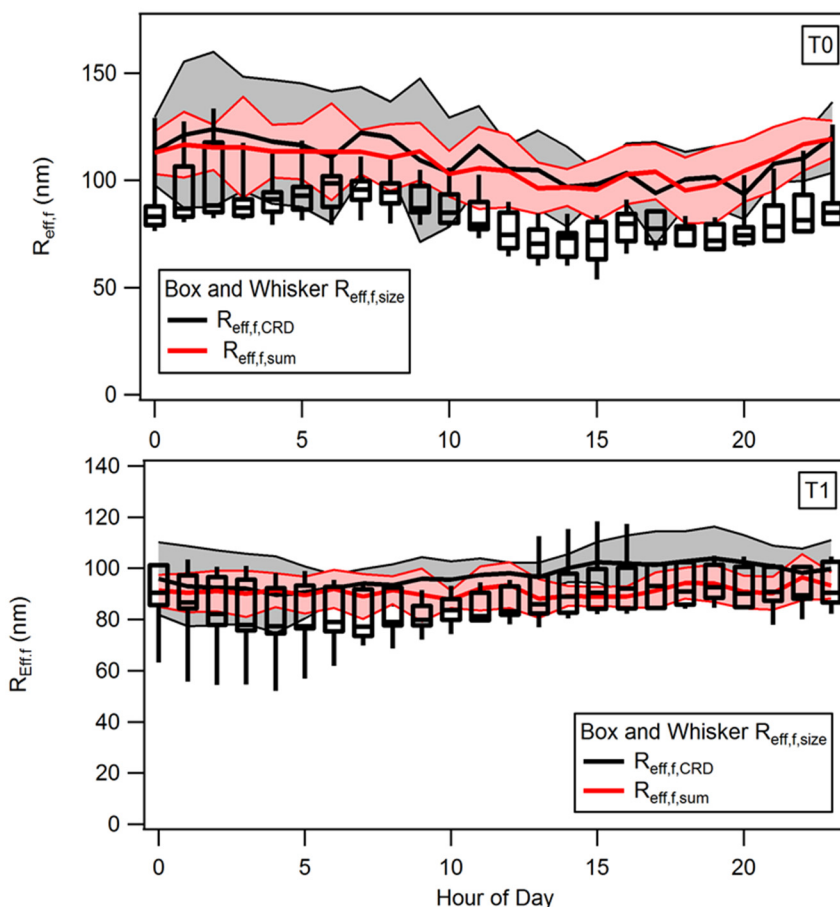

534 The SDA-FMC-derived $R_{eff,f}$ values from the CRD and from the nephelometer + PSAP exhibit reasonably
 535 good agreement in terms of the absolute values and the temporal variability at both the T0 and T1 sites
 536 (Table 2, Fig. 4). Notably, there is good agreement between the $R_{eff,f,sum}$ values obtained from the PM₁₀
 537 and PM₁ measurements. This provides an important validation of the SDA-FMC procedure, since the
 538 coarse mode contribution to the PM₁₀ extinction is substantial and highly variable (Figure 2 and Figure
 539 3).

540 At T0, the derived $R_{eff,f}$ values range from approximately 70 nm to 140 nm (Table 2), with a few short-
 541 duration periods when $R_{eff,f}$ is outside this range, reflecting short-duration variability in the particle
 542 sources. At T1 the derived $R_{eff,f}$ are generally less variable, ranging from approximately 65 nm to 110 nm,
 543 with fewer particularly low or high periods. The mean $R_{eff,f}$ values between the two sites are similar
 544 (Table 2). At T0, there is a fair degree of temporal coherence of the SDA-FMC results and those obtained
 545 from integration of the size distributions. The generally good temporal agreement between the
 546 optically- and size-derived $R_{eff,f}$ values are even observed during periods where the changes in radius
 547 happened rapidly, for example near midnight between June 21-22. On that night there is some evidence

548 that paving operations near the T0 site produced a strong local source of asphalt particles in the coarse
549 mode with a long tail into the sub-micron regime (Zaveri et al., 2012; Cappa et al., 2016). This short-
550 duration source of large particles pushed the $R_{\text{eff},f}$ temporarily towards larger values. (The $R_{\text{eff},f}$ changes
551 from the nephelometer + PSAP at this time were smaller than from the CRD or size distribution
552 observations. Most likely this reflects the alternating 6-min sampling of the nephelometer and the very
553 short duration of the event leading to discrepancies in the 1 h average.)

554 Despite the generally good correspondence between $R_{\text{eff},f,\text{size}}$ and the optically derived values, the $R_{\text{eff},f,\text{size}}$
555 values were often (but not always) smaller (Table 2). This is most clearly seen when comparing the
556 average diurnal profiles of the $R_{\text{eff},f}$ values from the different methods, as shown in Figure 5. All three
557 $R_{\text{eff},f}$ estimates exhibit similar diurnal behavior at T0, even though the $R_{\text{eff},f}$ from the SDA-FMC method
558 are larger than $R_{\text{eff},f,\text{size}}$. The diurnal variability in the $R_{\text{eff},f}$ is more pronounced at T0 than at T1. The
559 diurnal trend in the effective radius of the fine mode at T0 from all methods exhibits a minimum at
560 around mid-day and then an increase to a maximum right near daybreak. Particle number and sizes at
561 both sites were influenced by frequent regional new particle formation and growth events during CARES
562 (see Figure S2). The events tended to start in the morning with a sharp increase of 10 - 20 nm particles
563 followed by growth of these particles to 50 – 100 nm in the afternoon as discussed in Setyan et al.
564 (2014). The next day the cycle repeats (on average) with the introduction of the new small particles
565 which has the effect of decreasing the average particle radius (Setyan et al., 2014). Although observed at
566 both sites, the new particle formation events had a greater impact on the size distributions at T0,
567 especially in terms of surface area-weighted size distributions (Figure S3) that determine $R_{\text{eff},f}$. In part,
568 this is likely because of continued growth of the new particle mode as it transits from T0 to T1. In
569 addition, for T0 there is a notable mode in the surface-area weighted distribution at ~1 micron that is
570 most evident in the early morning (Figure S3). This mode has little influence on the $R_{\text{eff},f}$ values
571 determined from the size distributions, but contributes to the higher optically determined $R_{\text{eff},f}$ values in
572 the early morning for T0. This mode is much less prevalent at the T1 site, and thus there is better
573 correspondence between the size-distribution and optical methods.

574

575
 576 **Figure 5** – The diurnal dependence of $R_{\text{eff},f}$ for the period shown in Fig. 4 for the (top) T0 and
 577 (bottom) T1 sites. The box and whisker plot (bottom and top of box are 5% and 95% of data
 578 range, bar is mean, and whiskers extend to full range) shows the results from the direct size
 579 distribution measurement ($R_{\text{eff},f,\text{size}}$). The thick lines show the mean diurnal dependence of the
 580 optically derived $R_{\text{eff},f}$, using the CRD (black) and nephelometer + PSAP (red) measurements. The
 581 light colored bands show the $\pm 1\sigma$ standard deviation based on the measurement variability over
 582 the averaging period.

583

584 One possible explanation for the differences between the optically and size-derived $R_{\text{eff},f}$, in particular at
 585 T0, may be inaccurate specification of the refractive index. Temporal variations in or an overall offset of
 586 the real refractive index used here from the true value would lead to errors in the optically derived $R_{\text{eff},f}$.
 587 The refractive index is used to convert the derived van de Hulst parameter to $R_{\text{eff},f}$ (Eqn. 3). Given the
 588 form of the relationship, an absolute error in the real RI of 0.1—likely an upper limit—corresponds to an
 589 error in the derived $R_{\text{eff},f}$ of 20%, with larger values of the real RI leading to smaller derived $R_{\text{eff},f}$. The
 590 imaginary component was assumed zero. The effective imaginary RI is likely ≤ 0.01 , given the range of
 591 single scatter albedo values observed (Cappa et al., 2016). Thus, the assumption of zero for the

592 imaginary RI introduces negligible error. The actual real RI depends on the particle composition since
 593 different chemical components (e.g. sulfate, organics, dust) have different RI values. Here, the RI values
 594 used were determined based only on measurements of the non-refractory PM composition and only an
 595 average value was used (Atkinson et al., 2015). To the extent that refractory components, in particular
 596 dust or sea salt, contributed to the fine mode scattering, their influence on the real RI would not be
 597 accounted for. However, dust and sea salt contributions are most likely confined primarily to the coarse
 598 mode. Thus, the fine mode real refractive index is unlikely to be strongly affected by their presence and
 599 the real RI can probably be constrained to a fairly narrow range around 1.5. The relative uncertainty of
 600 the $R_{\text{eff},f}$ derived from the SDA-FMC method has been estimated as ranging from 40% to 70%. This range
 601 of values was computed from a quadrature combination of the estimated errors (20-50%) in the SDA-
 602 FMC retrieval (O'Neill et al., 2003), the CRD measurements (< 5% for the UCD and T0 PSU instrument
 603 and 20% for the T1 PSU instrument) and the refractive index term above (estimated maximum of 20%).
 604 In this context, the agreement shown in Fig. 4 is acceptable and may suggest that the above error
 605 estimates are overly conservative.

606 **Table 2:** Summary statistics for $R_{\text{eff},f}$ values (nm) and FMF (unitless fraction)

Site	Method	Maximum		Minimum		Mean		Standard Deviation	
		$R_{\text{eff},f}$ (nm)	FMF	$R_{\text{eff},f}$ (nm)	FMF	$R_{\text{eff},f}$ (nm)	FMF	$R_{\text{eff},f}$ (nm)	FMF
T0	SDA-FMC + CRD (PM _{2.5})	208	0.97	39	0.54	110	0.79	21	0.09
T0	SDA-FMC + Neph. & PSAP (PM ₁₀)	153	0.85	68	0.35	107	0.62	14	0.12
T0	Size Distribution Integration	133	0.87	54	0.34	85	0.58	14	0.12
T1	SDA-FMC + CRD (no size cut)	176	0.89	46	0.22	102	0.58	18	0.16
T1	SDA-FMC + Neph. & PSAP (PM ₁₀)	111	0.9	76	0.24	91	0.58	6	0.16
T1	Size Distribution Integration	118	0.87	52	0.24	88	0.61	11	0.15

607

608 Conclusions

609 This work demonstrates that the use of a non-size-selected, three wavelength CRD measurement in
 610 continuous field monitoring, coupled with the SDA-FMC analysis, can provide information about the
 611 relative contribution of the fine mode to the observed total particle extinction. The retrieved value of
 612 the fine mode fraction of extinction is dependent upon the size range of particles sampled and the
 613 overall nature of the particle size distribution. The relationship between the FMF_{ext} and the SMF_{ext} ,

614 determined from near-coincident measurement of extinction by PM_1 and PM_{10} , provides insights into
615 the effective FMF_{ext} split size. For one of the sites considered here the split point size is around $1 \mu m$
616 while for the other it is somewhat larger than $1 \mu m$ and perhaps more variable. In many environments,
617 variability in aerosol properties on short (<10 min) timescales is relatively minimal. In such cases, a single
618 instrument can be used to sequentially sample PM_1 and PM_{10} , allowing for *in situ* measurement of both
619 the FMF_{ext} and SMF_{ext} . However, remote sensing measurements characterize only the FMF_{ext} , (or at best,
620 an optically influenced size cut as is done in the AERONET retrievals of Dubovik & King, 2000). Thus,
621 further consideration of *in situ* measurement results, such as those investigated in this study, can
622 provide insights into the interpretation of the FMF_{ext} determined from remote sensing in different
623 environments.

624 The SDA-FMC approach also allows for determination of the effective fine mode radius. The $R_{eff,f}$
625 characterizes the surface-area weighted size of the particles within the fine mode distribution. The
626 similarity of the results in Figure 4 for application of the SDA-FMC to both size-selected and non-size-
627 selected aerosol as well as the comparison with results derived from the PSD measurements verify that
628 “whole air” measurements (i.e., no imposed size-selection) can provide reliable fine mode radii at least
629 for large FMF values.

638 **Appendix A – Glossary of Symbols and Acronyms used**

639	Å	Ångström exponent (from wavelength pair)
640	α	Spectral derivative of optical property
641	α'	Curvature (second derivative of optical property in log-log space)
642	α_f or α'_f	Fine mode version of properties (also coarse mode properties α_c)
643	AOD	Aerosol optical depth
644	b_{ext} , b_{scat} , b_{abs}	Optical coefficient for extinction, scattering, absorption (inverse length units)
645	CRD	Cavity ring down
646	$R_{eff,s}$	Effective radius for fine mode
647	FMF (aka η)	Fine mode fraction of an optical property, usually extinction
648	SMF	Sub-micron fraction (particle mode with radius or diameter smaller than 1 μm)
649	$\rho_{eff,f}$	Effective fine mode van de Hulst parameter (product of refractive index and effective
650		radius)
651	SDA	Spectral Deconvolution Algorithm
652	FMC	Fine Mode Curvature approach
653	PM_1	Particulate matter with diameter (or radius) smaller than 1 μm (also $\text{PM}_{2.5}$, PM_{10})
654	PSAP	Particle soot absorption photometer instrument
655
