14 **Abstract.**

15 Condensation of carboxylic acids on mineral particles will lead to coatings, and
16 impact on the particles' potential to act as cloud condensation nuclei (CCN). To
17 determine how the CCN activity of mineral particles is impacted by carboxylic acid
18 coatings, the CCN activity of CaCO₃ particles and CaCO₃ particles with oleic acid
19 and malonic acid coatings were compared in this study. The results revealed that small

20 amounts of oleic acid coating (volume fraction (vf) \leq 4.1%) decreased the CCN
21 activity of CaCO₃ particles, while more oleic acid coating (vf \geq 14.8%) increased the
22 CCN activity of CaCO₃ particles. This phenomenon has not been reported before. On
23 the other hand, malonic acid coating (vf = 0.4 - 42%) increased the CCN activity of
24 CaCO₃ particles regardless of the amount of the coating. The CCN activity of CaCO₃
25 particles with malonic acid coating increased with the amount of malonic acid coating.
26 Even smallest amounts of malonic acid coating (vf = 0.4%) significantly enhanced the
27 CCN activity of CaCO₃ particles from $\kappa = 0.0028 \pm 0.0001$ to $\kappa = 0.0123 \pm 0.0005$.
28 This supports that a small amount of water-soluble organic acid coating may
29 significantly enhance the CCN activity of mineral particles. The presence of about 50%
30 relative humidity during the coating process with malonic acid additionally increased
31 the CCN activity of the coated CaCO₃ particles, probably because more CaCO₃ reacts
32 with malonic acid at higher relative humidity.
33

34 1 Introduction

35 Atmospheric aerosols serve as cloud condensation nuclei and change the radiative
36 properties (cloud albedo effect) and lifetime (cloud lifetime effect) of clouds, thus
37 affecting the Earth's climate indirectly (Liu and Wang, 2010; Gantt et al., 2012;
38 Penner et al., 2004; Haywood and Boucher, 2000). Mineral aerosol is one of the most
39 abundant components of the atmospheric aerosol. It is estimated that 1500-2600 Tg of
40 mineral aerosol particles with radii between 0.1 and 8 μm are emitted annually into
41 the atmosphere on a global scale (Cakmur et al., 2006). Mineral aerosol particles are
42 mainly composed of substances that are slightly soluble or insoluble in water. Cloud
43 condensation nuclei (CCN) activity measurements show that the hygroscopicity
44 parameter κ (Petters and Kreidenweis, 2007) varies between 0.001 and 0.08 for
45 mineral aerosols, including CaCO_3 aerosol, clay aerosols and mineral dust aerosols
46 generated in the laboratory or sampled from various locations worldwide (Garimella
47 et al., 2014; Yamashita et al., 2011; Zhao et al., 2010; Koehler et al., 2009; Sullivan et
48 al., 2010; Herich et al., 2009). The low κ indicates that the CCN activity of mineral
49 aerosol is much lower than the CCN activity of water soluble salts like $(\text{NH}_4)_2\text{SO}_4$ (κ
50 = 0.61) and NaCl ($\kappa = 1.28$), which are also common in atmospheric aerosols (Petters
51 and Kreidenweis, 2007).

52 Mineral aerosol particles can be coated by organic gases during their residence and
53 transport in the atmosphere. Many individual particle measurements have shown that
54 mineral components and organic matter can coexist in the same individual aerosol
55 particle in the real atmosphere (Falkovich et al., 2004; Falkovich et al., 2001; Russell

56 et al., 2002; Li and Shao, 2010). Carboxylic acids are abundant species among the
57 organic matter that coexists with mineral particles. Russell et al. (2002) found that
58 $R(C=O)R$, $R(CH_n)R'$ and $R(C=O)OH$ are present in individual mineral (and sea salt)
59 aerosol particles, with enhanced concentration of $R(C=O)OH$. They also found that
60 Ca^{2+} , CO_3^{2-} , $R(C=O)OH$ and $R(C=O)R$ coexisted in some individual mineral aerosol
61 particles with a strong correlation between CO_3^{2-} and $R(C=O)OH$. These particles
62 could be formed by $CaCO_3$ particles (partly) coated with organic film. Falkovich et al.
63 (2004) also found that organic and inorganic components coexisted in individual
64 mineral aerosol particles with the organic component consisting of various short-chain
65 (C_1 - C_{10}) mono- and dicarboxylic acids (MCA and DCA). The concentration of
66 short-chain carboxylic acids in mineral aerosol particles increased with the increase of
67 the ambient relative humidity. A possible explanation for such observations could be
68 that when more water is condensed onto mineral particles at higher ambient relative
69 humidity, the adsorbed carboxylic acids are ionized in the aqueous environment and
70 react with mineral particles forming organic acid salts. Of the major components of
71 mineral aerosol particles (clay, calcite ($CaCO_3$), quartz, mica, feldspar, etc.), only
72 $CaCO_3$ with alkaline character can react with carboxylic acids in this way. Thus
73 $CaCO_3$ may play a key role in the uptake of carboxylic acids by mineral aerosol
74 particles.

75 Carboxylic acid coatings on mineral aerosol particles change their chemical
76 composition and thus may have an impact on their CCN activity. Many previous
77 studies have investigated the CCN activity of pure mineral aerosol (Garimella et al.,
78 2014; Yamashita et al., 2011; Zhao et al., 2010; Koehler et al., 2009; Sullivan et al.,
79 2010; Herich et al., 2009) and pure carboxylic acid aerosol (Kumar et al., 2003; Hori
80 et al., 2003; Cruz and Pandis, 1997; Hartz et al., 2006), but only a few studies have

81 investigated the CCN activity of mineral aerosol particles with carboxylic acid
82 coatings (Tang et al., 2015; Hatch et al., 2008; Gierlus et al., 2012).

83 In this study we used malonic acid and oleic acid as coating materials and CaCO₃
84 particles as cores, and investigated the CCN activity of the coated CaCO₃ particles.
85 Herein we varied the coating thickness and the relative humidity during the coating
86 process. Malonic acid is a representative of the class of dicarboxylic acids and oleic
87 acid is an example of surfactant like compounds. Dicarboxylic acids are ubiquitous in
88 the atmosphere (Kawamura et al., 1996; Kawamura and Ikushima, 1993; Ho et al.,
89 2007; Mkoma and Kawamura, 2013; Kawamura and Bikkina, 2016) and formed by
90 photochemical reactions and ozonolysis (Chebbi and Carlier 1996; Kawamura and
91 Bikkina, 2016; Kawamura et al., 1996; Khare et al. 1999; Mellouki et al., 2015). It has
92 been reported that dicarboxylic acids (C₂-C₁₀) account for 0.06-1.1% of the total
93 aerosol mass, with higher values in the summer, and 1.8% of the total aerosol carbon
94 (TC) in urban aerosol, in which oxalic acid, malonic acid, and succinic acid are the
95 most abundant species (Kawamura et al., 1996; Kawamura and Ikushima, 1993; Ho et
96 al., 2007; Mkoma and Kawamura, 2013). Oleic acid, which is emitted into the
97 atmosphere by the cooking of meat, wood burning, and automobile source (Schauer et
98 al., 1999; Rogge et al., 1998; Rogge et al., 1993), is present in atmospheric aerosols of
99 urban, rural, and forest areas (Cheng et al., 2004; Ho et al., 2010). The water
100 solubility of the two organic acids is complementary; it is high for malonic acid while
101 it is very low for oleic acid. Coatings of malonic acid and oleic acid could thus have
102 different effects on CCN activity of mineral particles.

103

104

105 **2 Experimental**

106 As general procedure, CaCO₃ aerosol was generated according to Zhao et al. (2010),
107 and then poly- or monodisperse CaCO₃ aerosol particles were coated by malonic or
108 oleic acid in a coating device. A flow tube was optionally applied to extend the
109 residence time. The particle size, chemical composition, and CCN activity of the
110 CaCO₃ particles were measured before and after coating. Figure 1 shows the
111 schematic of the experimental set up.

112 **2.1 Generation of CaCO₃ aerosol**

113 CaCO₃ aerosol was generated by spraying a saturated Ca(HCO₃)₂ solution. A sample
114 of CaCO₃ powder (2 g, pro analysis, ≥99%, Merck, Darmstadt, Germany) was
115 suspended in 1-L Milli-Q water (18.2 MΩcm, TOC <5 ppb). Then about 1.5 L min⁻¹
116 CO₂ (purity ≥99.995%, Praxair Industriegase GmbH & Co. KG, Magdeburg,
117 Germany) was bubbled into the suspension at room temperature for 3 h, while the
118 suspension was stirred using a magnetic stirrer. During bubbling, CO₂ reacted with
119 CaCO₃ to produce Ca(HCO₃)₂. After bubbling, the suspension was allowed to settle
120 for 10 min, the supernatant clear Ca(HCO₃)₂ solution was decanted and used for
121 spraying by a constant output atomizer (Model 3076, TSI, Shoreview, MN, USA)
122 using 1.75 L min⁻¹ high-purity N₂ (Linde LiPur 6.0, purity 99.9999%, Linde AG,
123 Munich, Germany).

124

125 The major portion (0.9 L min^{-1}) of the aerosol flow generated by spraying was dried
126 in a diffusion drier filled with silica gel. The relative humidity was below 10% after
127 drying. The remainder of the aerosol flow was drawn off by a pump and discarded.
128 The dry aerosol was passed through a tube furnace (Model RS 120/1000/12,
129 Nabertherm GmbH, Lilienthal, Germany) set at $300 \text{ }^\circ\text{C}$. The residence time of the
130 aerosol in the furnace was 5.2 s. Zhao et al. (2010) described this method for
131 generating CaCO_3 aerosol in detail. At room temperature dry $\text{Ca}(\text{HCO}_3)_2$ is
132 thermodynamically unstable and decays into CaCO_3 , CO_2 , and H_2O (Keiser and
133 Leavitt, 1908). With this method the aerosol still contained some $\text{Ca}(\text{HCO}_3)_2$ after
134 drying, but after heating at $300 \text{ }^\circ\text{C}$ it was completely converted into CaCO_3 (Zhao et
135 al., 2010). The CaCO_3 aerosol generated was either first size selected by a Differential
136 Mobility Analyzer (DMA, TSI 3081) with a neutralizer on the inlet or entered the
137 coating device directly as poly-disperse aerosol.

138 Figure 2 (upper panel) shows the total number concentration and mean size of the
139 bare CaCO_3 aerosol particles generated at different spraying time, which were
140 measured with the SMPS described below. The diameter size stabilized after about 50
141 min in the range 49.8-55.5 nm. Over the 232 min spraying time, the total number
142 concentration varied in the range 1.8×10^6 – $4.5 \times 10^6 \text{ cm}^{-3}$. The total number
143 concentration decreased by about 1/3 in the initial 70 min. The decrease became
144 slower after 70 min and the total number concentration tended to stabilize after 155
145 min. After 70 min the total number concentration varied in a smaller range of
146 1.8×10^6 – $2.9 \times 10^6 \text{ cm}^{-3}$, therefore, the measurements in this study typically started after

147 70 min spraying. The typical size distribution of the CaCO₃ aerosol particles after 70
148 min spraying is shown in Fig. 2 (lower panel). The CaCO₃ particles showed a single
149 mode distribution with a mode diameter at 32.2 nm. The number concentration was
150 more than 100 cm⁻³ for particles between 9.82 and 346 nm.

151 2.2 Organic acid coating

152 The coating device (Fig. 1, right hand side) used in this study was designed by Roselli
153 (2006), and showed good reproducibility, controllability, and stability. The glass
154 apparatus consisted of a small storage bulb (100 ml) holding the organic coating
155 substances which was directly connected to a mixing cell (about 35 ml). The storage
156 bulb and mixing cell were fully immersed in a flow-through water heater connected to
157 a thermostatic bath (F25, Julabo GmbH, Seelbach, Germany). The temperature range
158 of the thermostatic bath used in this study was 30-80 °C. An extra N₂ stream could be
159 passed through the storage bulb in order to enhance the organic vapors flowing into
160 the mixing cell. The outflow of the coating device was connected to a Liebig type
161 water cooler. The water cooler was controlled by another thermostatic bath (F25,
162 Julabo GmbH, Seelbach, Germany) operated at 25 °C throughout all of the
163 experiments.

164 The bottom of the storage bulb was filled with either 5.0 g malonic acid powder
165 (assay ≥98%(T), Fluka Chemika, Sigma-Aldrich, St Louis, MO, USA) or 10.0 ml
166 oleic acid (chemical purity (GC) 99.5%, Alfa Aesar, Ward Hill, MA, USA). A flow of
167 0.9 L min⁻¹ high purity N₂ was used to carry the organic acid vapor up into the mixing
168 cell. The flow of 0.9 L min⁻¹ CaCO₃ aerosol was passed through the mixing cell and
169 mixed with the 0.9 L min⁻¹ N₂ flow carrying the organic acid vapor. The mixed flow

170 then entered the water cooler. The organic acid vapor was condensed on CaCO₃
171 aerosol particles in both the mixing cell and the water cooler. Three identical coating
172 devices, with the same heating and cooling thermostatic bath, were used: one for
173 malonic acid coating, one for oleic acid coating, and a blank one without organic acid
174 for assessing the impact caused by heating the CaCO₃ aerosol in the coating device
175 without organic acid (Roselli, 2006).

176 The aerosol could enter the measuring instruments directly, or after passing through a
177 flow tube to increase its residence time. The flow tube was made of a straight circular
178 glass tube with a 2.5 cm internal diameter. The aerosol flow in the flow tube was
179 laminar flow. The residence time of the aerosol in the flow tube was 23.7 s.

180 The relative humidity of the aerosol at the outlet of the coating device at 80 °C was
181 below 5%. To investigate the impact of relative humidity on the coating process and
182 CCN activity, organic coating at a higher relative humidity was also performed. For
183 that a bubbling device filled with Milli-Q water placed in the N₂ stream before it
184 entered the storage bulb. The relative humidity of the aerosol at the outlet of the
185 coating device at 80 °C was ~47% when humidification was applied.

186 **2.3 Size and chemical composition measurements**

187 The number size distribution of the aerosol particles was measured using a Scanning
188 Mobility Particle Sizer (SMPS, TSI 3080 Electrostatic Classifier with TSI 3081 DMA,
189 TSI 3786 UWCPC). The sample flow was set to 0.6 L min⁻¹ and the sheath flow was
190 set to 6.0 L min⁻¹. The size range measured was 9.82-414.2 nm and the time
191 resolution was 3 min for a complete scan.

192

193 The chemical composition and the vacuum aerodynamic diameter of the aerosol
194 particles were measured using a High-Resolution Time-of-Flight Aerosol Mass
195 Spectrometer (HR-ToF-AMS, Aerodyne Research Inc., Billerica, MA, USA (DeCarlo
196 et al., 2006)). The aerosol particles were vaporized at 600 °C and ionized by 70 eV
197 electron impact ionization, i.e. we focused on the measurements of the organic
198 coatings and sacrificed a direct CaCO₃ determination by AMS (compare Zhao et al.
199 2010). The AMS was routinely operated in V-mode in two alternating modes: 1 min
200 MS mode to measure the chemical composition and 2 min PToF mode. Only MS
201 mode data were analyzed. AMS measurements and SMPS measurements were
202 synchronous and both were repeated at least four times for each sample. Size
203 information for bare CaCO₃ was taken from SMPS data in the blank coating device.

204 We used specific marker m/z to derive the amount of organic coating. For pure oleic
205 acid the signal at $m/z41$ (C₃H₅⁺) was reported to be the strongest signal in the mass
206 spectrum measured by Q-AMS at EI energy of 70 eV and vaporizer temperature of
207 600 °C (Sage et al., 2009). The signal at $m/z41$ was also strongest for oleic acid
208 coatings in our HR mass spectra. In order to get a high signal to noise ratio we
209 analyzed the signal at $m/z41$ in the MS mode of the AMS measurement as a marker
210 for oleic acid in the coated CaCO₃ particles. There was no significant signal at $m/z41$
211 for the uncoated CaCO₃ particles. The average background signal at $m/z41$ per single
212 aerosol particle corresponded to $2.4 \pm 0.79 \cdot 10^{-12}$ µg for bare CaCO₃. The average value
213 presented the baseline of the mass spectra and the standard deviation was derived
214 from the noise of the mass spectra at $m/z41$. Similarly, the signal at $m/z42$ (C₂H₂O⁺)
215 was one of the strongest signals in the mass spectrum of pure malonic particles
216 measured by Q-AMS with EI energy of 70 eV and vaporizer temperature of 600 °C
217 (Takegawa et al., 2007). That signal was also observed for malonic acid coatings in

218 our HR mass spectra and used as marker for malonic acid coatings. The average
219 background signal per aerosol particle at $m/z42$ for bare CaCO_3 particles was
220 $1.4 \pm 0.42 \cdot 10^{-12} \mu\text{g}$. The average value represented the baseline of the mass spectra at
221 $m/z42$ and the standard deviation was derived from the noise in the mass spectra.

222 The coating amount for both organic compounds was derived as follows. The
223 observed signal at the respective marker m/z was corrected for the background signal
224 from bare CaCO_3 and then scaled to the volume increase (per particle) calculated
225 from the shift of the mode diameter for the largest coating amount achieved at 80 °C
226 coating temperature. This assumed spherical core shell morphology, based on Zhao et
227 al. (2011) where we showed that the CaCO_3 particles generated by our spray drying
228 method are spherical. The baseline corrected marker signals at $m/z41$ or $m/z42$ per
229 particle were in direct proportion with the oleic acid mass per particle and malonic
230 acid mass per particle, respectively. Coating mass per particle was in direct proportion
231 with the coating volume per particle. So V_{OA} for coating temperatures of 30-70 °C
232 could be calculated from the largest V_{OA} and the marker signals per particle at $m/z41$
233 and $m/z42$.

234 Assumption of spherical geometry and sub-scale mode shift within the bin width of
235 the SMPS introduces uncertainties in the determination of the amount of coatings. We
236 therefore prefer to show the experimental data as a function of the controlling
237 parameter, the coating temperature. In the discussion we also use the coating mass per
238 particle to give an easier to imagine rationale to the finding and classification.

239

240 **2.4 CCN activity measurement**

241 The aerosol was dried to RH <3% by another diffusion drier before the CCN activity
242 was measured. To determine the CCN activity of the aerosol, the number
243 concentration of the cloud condensation nuclei (CCN) of the aerosol was measured
244 with a continuous flow CCN counter (CCNC, DMT-100, Droplet Measurement
245 Technologies, Boulder, CO, USA). The total number concentration (CN) of the
246 aerosol particles was synchronously measured using an ultrafine water-based
247 condensation particle counter (UWCPC, TSI 3786, cf. Zhao et al., 2010). The ratio of
248 CCN to CN (CCN/CN) is called the activated fraction (a_f). In cases where
249 poly-disperse aerosol was coated, the coated aerosol particles were size selected by
250 scanning a DMA between 10.6 and 478.3 nm, and the CCN and CN concentrations
251 were determined for each size bin while the super-saturation (SS) kept constant
252 (known as ‘Scanning Mobility CCN Analysis (SMCA)’, Moore et al., 2010). The
253 activated fraction was calculated after the CCN and CN concentrations were corrected
254 for the multiple charged particles.

255 The activated fraction as a function of the particle size was fitted with a cumulative
256 Gaussian distribution function (Rose et al., 2008). The turning point of the function is
257 the critical dry diameter (D_{crit} or D_{50}) at the set SS. The activation efficiency (i.e., the
258 activated fraction when aerosol particles are completely activated) was 83% for the
259 CCN instrument, determined using 150 nm $(\text{NH}_4)_2\text{SO}_4$ particles at SS=0.85%.
260 Besides CaCO_3 and coated CaCO_3 particles, the CCN activity of malonic acid
261 particles, oleic acid particles, and mixed particles of CaCO_3 and malonic acid was
262 also measured. The oleic acid particles were generated by heating 10.0 ml oleic acid
263 to 97 °C in the storage bulb and then cooling the vapor to 2 °C in the water cooler in a

264 clean coating device. 1.75 L min^{-1} high-purity N_2 was used as carrying gas and went
265 into the storage bulb through '1 N_2 in' entrance in Fig. 1; the '3 Aerosol in' entrance in
266 Fig. 1 was closed. This way, pure oleic acid particles with diameters up to 333 nm
267 were generated. Mixed CaCO_3 /malonic acid particles were generated by spraying the
268 supernatant clear solutions which were prepared by settling suspensions containing
269 CaCO_3 and malonic acid in molar ratios of about 1:1 and 3:1. The suspensions were
270 prepared with 0.020 g malonic acid and 0.021 g CaCO_3 and 0.025 g malonic acid and
271 0.076 g CaCO_3 in 1000 ml Milli-Q water, respectively. The suspensions were allowed
272 to stand for 24h.

273 For aerosols where monodisperse aerosol particles with a dry diameter D_p were coated,
274 the CCN concentration was measured at different SS and the CN concentration was
275 measured synchronously. Similarly, the activated fraction as a function of SS was
276 fitted with a cumulative Gaussian distribution function. The turning point of the
277 function is the critical super-saturation (SS_{crit}) and the corresponding to the dry
278 diameter D_p is also called the critical diameter, D_{crit} . The hygroscopicity parameter κ
279 (Petters and Kreidenweis, 2007) was then calculated from the $D_p(D_{\text{crit}})$ - SS_{crit} or
280 $\text{SS}(\text{SS}_{\text{crit}})$ - D_{crit} data set. The SS settings of the CCN counter were calibrated weekly
281 using $(\text{NH}_4)_2\text{SO}_4$ aerosol based on the theoretic values in the literature (summarized
282 by Rose et al., 2008).

283

284 **3 Results and discussion**

285 **3.1 CCN activity of CaCO₃ aerosol**

286 Before the coating experiments we determined the CCN activity of the bare CaCO₃
287 aerosol particles generated. It was measured by the scanning method (SMCA) using
288 poly-disperse CaCO₃ aerosol particles. The value of the hygroscopicity parameter κ of
289 the CaCO₃ aerosol was 0.0028 ± 0.0001 derived by the least-square-fitting of D_{crit} as a
290 function of SS (SS_{crit}). This κ value is quite small, indicating that the CCN activity of
291 the CaCO₃ aerosol is low. In previous studies κ for the CaCO₃ aerosol was found in
292 the range 0.0011 ± 0.0004 to 0.0070 ± 0.0017 (Zhao et al., 2010; Sullivan et al., 2009;
293 Gierlus et al., 2012) and our κ value is somewhat higher but still in this range. The
294 CCN activity for CaCO₃ aerosol passed through the blank coating device exposed to
295 temperatures of 60 °C and 80 °C was measured using the same method. The κ value
296 remained 0.0028 ± 0.0001 at 60 °C and increased to 0.0036 ± 0.0001 at 80 °C. The
297 CCN activity of the CaCO₃ aerosol after heating was the same or slightly higher than
298 that of the CaCO₃ aerosol without heating. The increased κ value of 0.0008 at 80 °C
299 was lower than the differences of reported κ values for CaCO₃ aerosol in various
300 studies, and much lower than the changes of κ values measured in this study when the
301 CaCO₃ aerosol particles were coated by malonic or oleic acid. So the effect of heating
302 the CaCO₃ aerosol during the coating process on the CCN activity of the CaCO₃
303 aerosol was neglected. The D_{crit} at different super-saturations (SS_{crit}) for the CaCO₃

304 aerosol and for the CaCO_3 aerosol passed through a blank coating device at heating
305 temperatures of 60 °C and 80 °C are shown in Fig. 5 (red, yellow and green circles).

306 **3.2 CCN activity of CaCO_3 particles with oleic acid coating**

307 For the coating with oleic acid, we selected monodisperse CaCO_3 aerosol particles of
308 101.8 nm diameter using the DMA, and measured the size and chemical composition
309 of the particles before (uncoated) and after (coated) coating with oleic acid. The
310 results are listed in the upper part of Table 1. In order to achieve coatings with various
311 amounts of oleic acids the CaCO_3 particles were passed through the coating device
312 containing 10.0 ml oleic acid held at different temperatures in a range of 30-80 °C.
313 The uncoated CaCO_3 particles passed through the blank (empty) coating device at the
314 same respective temperature.

315 The mode diameters of number size distribution for the uncoated CaCO_3 particles at
316 30-80 °C remained 101.8 nm, identical to that selected by the DMA. The mode
317 diameters of the CaCO_3 particles after coating with oleic acid in the range of 30-50 °C
318 stayed also in the pre-selected size bin at 101.8 nm, which means that the layers were
319 too thin to effectively grow the particles to the next size bin. However, the mode
320 diameters increased distinctively with the increase of the coating temperature in the
321 temperature range of 60-80 °C (Fig. 3, upper panel). This shows that temperatures of
322 60-80 °C were needed to sufficiently increase the vapor pressure of the oleic acid to
323 get significant amounts of oleic acid coating onto the CaCO_3 particles. Once the

324 coating temperature exceeded a certain value the amount of the coating increases with
325 the increase of the coating temperature.

326 The values of $m/z41$ [μg] per particle originating from the oleic acid coating for the
327 coated CaCO_3 particles at 30-80 °C were at all temperatures significantly larger than
328 for the bare CaCO_3 particles, and increased with the increasing coating temperature
329 ($3.3 \cdot 10^{-12}$ - $350 \cdot 10^{-12}$ μg per particle, compare Table 1 and Fig. 3, bottom panel, red
330 circles). The AMS detected increase at $m/z41$ showed that the CaCO_3 particles already
331 contained small amounts of oleic acid after coating with oleic acid at temperatures
332 below 60 °C although the mode diameter did not shift.

333 The organic volume fraction (vf) in the aerosol particles, $V_{\text{OA}}/V_{\text{par}}$ [%], was calculated.
334 Herein $V_{\text{par}} = (V_{\text{OA}} + V_{\text{CaCO}_3})$, V_{OA} is the oleic acid volume derived by AMS and
335 V_{CaCO_3} the volume of the bare CaCO_3 before coating (101.8 nm). $V_{\text{OA}}/V_{\text{par}}$ for the
336 uncoated CaCO_3 particles is by definition zero. The vf for the coated CaCO_3 particles
337 at 30-80 °C increased with the increase in the coating temperature from 0.7% at 30 °C
338 to 41.8% at 80 °C (Fig. 3, bottom panel, red crosses and Table 1). The AMS data thus
339 show that at 30-80 °C the CaCO_3 particles were indeed coated with a significant
340 amount of oleic acid and the amount of oleic acid coating increased with the increase
341 in the coating temperature. The experiments were repeated at least four times. The
342 mode diameters were identical each time and the according standard deviations for the
343 oleic acid mass per particle in Table 1 indicate that the repeatability of the
344 experiments was good and the performance of the coating device was stable.

345 The activated fractions at different SS for monodisperse CaCO_3 particles selected at
346 101.8 nm before and after oleic acid coating at 30-80 °C are shown in Fig. 4. The top
347 panel in Fig. 4 shows the results at 30-60 °C with small amounts of coating material
348 deposited on the CaCO_3 particles. At the lowest SS of 0.17% and 0.35%, the activated
349 fractions were very low and independent of the presence of the coating material
350 within the errors. When the SS increased to 0.52%, 0.70%, and 0.87%, the activated
351 fractions for the coated CaCO_3 particles were lower than those for the uncoated
352 particles. Interestingly the activated fractions for the coated CaCO_3 particles
353 decreased with the increase in the coating temperature at 30-50 °C, thus with the
354 increase in the coating material (vf 0.7-2.5%). The activated fractions for the CaCO_3
355 particles with different amounts of coating spread with larger SS applied. However
356 this trend reversed at the coating temperature of 60 °C and the oleic acid vf of 4.1%,
357 and the activated fractions at 60 °C became higher than those at 50 °C at the three
358 largest SS. Considering the invariant mode diameter at 30-50 °C, the increased mode
359 diameter at 60 °C, and the reduced activated fraction simultaneously, we found that
360 the CCN activity of the coated CaCO_3 particles at 30-60 °C was lower than that of the
361 uncoated CaCO_3 particles. The CCN activity of the coated CaCO_3 particles at 30-50
362 °C decreased with the increase in the coating temperature, i.e. the CCN activity
363 became lower when more coating material deposited on the CaCO_3 particles.

364 The activated fractions of CaCO_3 particles after coating with oleic acid at 70 and 80
365 °C (vf 14.8% and 41.8%, respectively) were considerably higher than that before
366 coating, as shown in Fig. 4 (bottom panel). The increased activated fractions resulted

367 from both the increase in particle size (Fig. 3) and the change in chemical
368 composition (hygroscopicity) of particles. At 70 and 80 °C, the activated fractions of
369 the CaCO₃ particles after coating increased with the increase of SS and reached a
370 plateau at high SS. The plateau indicated that the aerosol particles were completely
371 activated. Because the activation efficiency is 83%, the activated fractions appear at
372 values less than 100% at the points of full activation. SS_{crit} was determined by
373 Gaussian fitting of the activated fraction as a function of SS. The particle dry diameter
374 D_p which is D_{crit} in this cases was determined with SMPS and is given as the mode
375 diameter in Table 1. The hygroscopicity parameter κ was determined from D_p (D_{crit})
376 and the corresponding SS_{crit}. The κ values of the CaCO₃ particles coated with vf of
377 oleic acid of 14.8 % (70 °C) and 41.8% (80 °C) were 0.0237 ± 0.0006 and 0.0673 ±
378 0.0016, respectively. The respective κ values for the CaCO₃ particles with a diameter
379 of 101.8 nm without coating and after coating with oleic acid at 30-60 °C (oleic acid
380 vf ≤ 4.1%) could not be determined by this method because these particles could not
381 be fully activated at the highest SS reachable by the CCN counter. Therefore we can
382 only give as upper limit κ = 0.0028 ± 0.0001 for the uncoated CaCO₃ particles
383 determined by scanning the size of the poly-disperse CaCO₃ aerosol particles as
384 described above (see Fig. 5). So we conclude that for vf of oleic acid of 0.7-2.5% the
385 CCN activity of CaCO₃ particles after coating is lower than that of uncoated CaCO₃
386 particles and decreases with the fraction of oleic acid. The trend turns at a vf of about
387 4.1%. CCN activity was higher than that of the bare CaCO₃ particles at vf of oleic
388 acid of 14.8% and 41.8% with CCN activity κ = 0.0237 ± 0.0006 and κ = 0.0673 ±

389 0.0016), respectively. In addition, the enhanced and reduced CCN activity of CaCO₃
390 particles coated with oleic acid at 80 °C and 60 °C, respectively, was also evident
391 from the CCN activity measurement using *poly-disperse* aerosols (Fig. 5).

392 The results presented above show that the CCN activity of the CaCO₃ particles
393 decreased after coating with small amounts of oleic acid at 30-60 °C (oleic acid vf ≤
394 4.1%), but increased after coating with larger amounts of oleic acid at 70 and 80 °C
395 (oleic acid vf of 14.8 and 41.8%). The coating temperature of 60 °C, at which the
396 oleic acid vf of the coated CaCO₃ particles was 4.1%, seemed to be near the turning
397 point but we could not determine it precisely. The activated fractions indeed began to
398 increase at 60 °C, but the mode diameter also increased at 60 °C. Therefore we cannot
399 differentiate if the increase in the activated fractions is due to higher CCN activity or
400 the increase in the particle size. In any case our findings indicate that different
401 amounts of oleic acid coating have different impacts on the CCN activity of CaCO₃
402 particles.

403 A possible explanation for our observation can be based on the amphiphilic character
404 of oleic acid, namely that one end of the oleic acid molecule is hydrophobic (the
405 hydrocarbon chain), while the other is hydrophilic (the carboxyl group). When CaCO₃
406 particles are coated with only a small amount of oleic acid, the hydrophilic end of the
407 oleic acid molecule tends to combine with the hydrophilic sites on the surface of
408 CaCO₃. As a result, the hydrophobic end of the molecule is exposed on the particle
409 surface, hence increases the hydrophobicity of the particle surface. This can hinder the

410 uptake of water. When CaCO_3 particles are coated with more oleic acid, a kind of
411 bilayer may be formed with a portion of the hydrophilic ends of oleic acid molecules
412 pointing outward be exposed on the particle surface. The particle surface then
413 becomes more hydrophilic. This suggestion is supported by very low CCN activity of
414 pure oleic acid if one assumes that in pure oleic acid particles the hydrophobic tail is
415 exposed at the outside. Kumar et al. (2003) found that oleic acid particles up to 140
416 nm do not activate at 0.6% SS, and Broekhuizen et al. (2004) found that particles up
417 to 300 nm do not activate at 1% SS. Our CCN activity measurements showed that
418 oleic acid particles up to 333 nm do not activate at 0.87% SS. These data set the upper
419 limits of κ of pure oleic acid to 0.012 and $<10^{-6}$, respectively, comparable to our
420 thinly coated particles and more than a factor of two smaller than for our thickly
421 coated particles. Another factor that can contribute to the enhanced CCN activity at
422 high oleic acid fractions is the decrease of surface tension. Surface of tension of pure
423 oleic acid is only $\sim 30 \text{ mN m}^{-1}$ (Chumpitaz et al., 1999).

424 Garland et al. (2008) studied sub-monolayer deposition of oleic acid on both
425 hydrophobic and hydrophilic surfaces. Their results suggested that individual oleic
426 acid molecules were oriented vertically on the surfaces and the hydrocarbon chain of
427 the oleic acid molecule was facing away from the surface. According to the
428 measurements and calculations of the length of oleic acid molecule, the thickness of
429 oleic acid sub-monolayer on solid surface, and the thickness of deuterated oleic acid
430 monolayer at the air-water interface (Garland et al., 2008; King et al., 2009; Iwahashi
431 et al., 2000), we determined 2.3 nm as the likely thickness of oleic acid monolayer on

432 CaCO_3 particles. The mode diameters of the coated CaCO_3 particles at 30-60 °C show
433 that the oleic acid coating layers must have been sub-monolayers. As a consequence
434 small but increasing amounts of oleic acid coatings passivated the CaCO_3 surface by
435 pointing outward the hydrophobic tails. The mode diameters of the coated CaCO_3
436 particles at 70-80 °C show that the oleic acid coating layers were thicker than
437 monolayer. Although we cannot proof the structures of the oleic acid coating layers in
438 this case, we suppose that hydrophilic ends of a certain fraction of the oleic acid
439 molecules could be exposed on the particle surface.

440 The phenomenon described above is reported for the first time in the studies on the
441 CCN activity of multicomponent aerosols. This phenomenon also shows a limitation
442 of the otherwise very useful mixing rule (Petters and Kreidenweis, 2007) for
443 multicomponent aerosols with specific morphologies.

444 In Fig. 5 we additionally show the influence of the relative humidity on CCN activity
445 of CaCO_3 particles coated with oleic acid for the highest coating temperature (80 °C)
446 and thus largest oleic acid amount. Herein we determined D_{crit} at different
447 super-saturations (SS_{crit}) for *poly-disperse* CaCO_3 aerosol particles (by SMCA). The
448 experiments at a coating temperature of 80 °C at $\text{RH} \leq 5\%$ and at $\text{RH} 47\%$ were
449 performed. The presence of water in the coating process increases κ somewhat and
450 enhances the CCN activity. This is of importance since often RH will larger than 5%
451 if coating appears in the atmosphere. This will be discussed further in context of
452 malonic acid coatings at $\text{RH} 47\%$.

453 **3.3 CCN activity of CaCO₃ particles with malonic acid coating**

454 For the study with malonic acid coatings, the CaCO₃ particles were also size selected
455 with a diameter of 101.8 nm. The size and chemical composition of CaCO₃ aerosol
456 particles are listed in Table 1 before and after coating with malonic acid at
457 temperatures in a range of 30-80 °C. The mode diameter did not shift after coating in a
458 temperature range of 30-60 °C, but it increased for coatings at 70 and 80 °C with
459 increasing coating temperature.

460 Values of $m/z42$ per particle originating from malonic acid coating were significantly
461 larger for CaCO₃ particles after coating at 30-80 °C and increased with the increase of
462 the coating temperature (Table 1). The organic volume fraction v_f of malonic acid
463 ($V_{MA}/(V_{MA}+V_{CaCO_3})[\%]$) was calculated as in the case of the oleic acid. The malonic
464 acid v_f of the CaCO₃ particles after coating increased with the increase of the coating
465 temperature. At 30-60 °C, the organic v_f increased but this is not reflected in the mode
466 diameters. At these coating temperatures the layer of malonic acid coating was too
467 thin to effectively grow the particles to the next size bin. The AMS results however
468 showed that in the whole range of coating temperatures of 30-80 °C the CaCO₃
469 particles were coated by a significant and increasing amount of malonic acid. As in
470 the case of oleic acid the malonic acid experiments were repeated at least four times
471 and the repeatability and stability were good (see standard deviations in Table 1).

472 The activated fractions at different SS for 101.8 nm CaCO₃ particles before and after
473 coating with malonic acid at 30-80 °C are shown in Fig. 6. SS_{crit} was determined from

474 Gaussian fitting of the data and the κ value was calculated from the D_p (D_{crit}) and the
475 corresponding SS_{crit} . The results are listed in Table 1. The κ values of the $CaCO_3$
476 particles after coating with malonic acid at 30-80 °C were higher than the κ value of
477 the uncoated $CaCO_3$ particles ($\kappa = 0.0028 \pm 0.0001$), and increased with the
478 increasing coating temperature and thus increasing malonic acid vf of 0.5-42%. The
479 CCN activity of the $CaCO_3$ particles increased monotonically after coating with
480 increasing malonic acid vf. This result differs from that of oleic acid which is not
481 surprising since malonic acid is easily soluble in water.

482 The κ value for the $CaCO_3$ particles after coating with malonic acid at 30 °C was
483 0.0123 ± 0.0005 , which was considerably larger than the κ value for the uncoated
484 $CaCO_3$ particles ($\kappa = 0.0028 \pm 0.0001$). The $CaCO_3$ particles after coating with
485 malonic acid at 30 °C contained only 0.4% (vf) organic matter. This suggests that
486 already a small amount of malonic acid can significantly enhance the CCN activity of
487 $CaCO_3$ particles. Such phenomenon, that traces of water soluble substances can
488 strongly affect droplet activation has been reported before (Bilde and Svenningsson,
489 2004).

490 The D_{crit} at different super-saturations (SS_{crit}) for *poly-disperse* $CaCO_3$ aerosol
491 particles before and after coating with malonic acid are shown in Fig. 7. Our
492 observation of $\kappa = 0.25 \pm 0.04$ for pure malonic is consistent with the κ derived from
493 the data of Kumar et al. (2003) ($\kappa = 0.20-0.25$) and Prenni et al. (2001) ($\kappa = 0.24$), but
494 significantly lower than the κ derived from the data of Giebl et al. (2002) ($\kappa =$

495 0.41-1.04). The CCN activity of the CaCO_3 particles after coating at 60 and 80 °C was
496 higher than that of the uncoated CaCO_3 particles, and the CCN activity at 80 °C
497 (yellow triangles) was higher than that at 60 °C (green triangles). The behavior of
498 poly-disperse coated aerosol was similar to the result obtained from the monodisperse
499 CaCO_3 aerosol particles.

500 In Fig. 7 we added results for coating at $\text{RH} = 47\%$ and aerosols generated by
501 spraying mixtures of malonic acid and CaCO_3 . At the coating temperature of 60 °C,
502 when the RH increased from $\leq 5\%$ to 47%, the CCN activity of the coated CaCO_3
503 particles increased substantially (compare $\leq 5\%$ (blue triangles) and 47% (lilac
504 triangles) in Fig. 7). The effect is more distinct than for the oleic acid coating shown
505 in Fig. 5, and κ increases by about an order of magnitude. At a higher RH, the
506 reaction between CaCO_3 and malonic acid is obviously more efficient and forms more
507 calcium malonate and this may be the reason for the higher CCN activity at the higher
508 RH. The hypothesis of efficient malonate formation is supported by the CCN activity
509 of “calcium malonate” aerosols, generated by spraying solutions containing CaCO_3
510 and malonic acid with molar ratios of about 1:1 and 3:1. Here the CCN activity is
511 similar to that arising in the coating process at 47% RH. The change of the
512 Ca/malonate ratio from 3:1 to 1:1 had no large effects. But taking the data of pure
513 malonic acid particles also into account there is a trend to lower κ with increasing Ca
514 in the initial solution.

515

516 The increasing of residence time (by 23.7 s) had no significant impact on CCN
517 activity for both oleic acid coating and malonic acid coating at both dry and 47% RH
518 conditions, probably because the coating process was already completed in the
519 coating device and no further reactions occurred in the flow tube.

520 Our findings may be important for aging processes of mineral particles in the
521 atmosphere. The dependence of CCN activity of the coated particles on RH during the
522 coating process will help to enhance the increase of the CCN activity by the coating
523 process as water will be abundant in many instances. The effect probably will be
524 relatively small for oleic acid and similar organics, which are hardly water soluble,
525 but strong for malonic acid and similar organic acids, which are highly water soluble.

526 **4 Conclusions**

527 The CCN activity of CaCO₃ particles with oleic acid and malonic acid coatings was
528 investigated in this study. The results show that oleic acid coating and malonic acid
529 coating have different impacts on the CCN activity of CaCO₃ particles. This can be
530 attributed to the amphiphilic property of oleic acid in contrast to the high water
531 solubility of malonic acid. Small amounts of oleic acid coating ($v_f \leq 4.1\%$) decreased
532 the CCN activity of the CaCO₃ particles, while more oleic acid coating ($v_f \geq 14.8\%$)
533 increased it. This phenomenon was reported here for the first time, and attributed to
534 stepwise passivating the active sites of CaCO₃ by oleic acid. Once all active sites are
535 occupied we suggest the formation of a bi-layer (micelle like) with the carboxylic
536 groups point outwards.

537 On the other hand, malonic acid coating (0.4-41.8%) increased the CCN activity of
538 CaCO_3 particles regardless of the amount of the coating. The CCN activity of CaCO_3
539 particles with malonic acid coating increased with the increase of the amount of the
540 coating. Even a small amount of malonic acid coating (0.4%) significantly enhanced
541 the CCN activity of CaCO_3 particles from $\kappa = 0.0028 \pm 0.0001$ to $\kappa = 0.0123 \pm$
542 0.0005 . Increasing the relative humidity during the coating increased the CCN activity
543 of the CaCO_3 particles with malonic acid coating, probably because more CaCO_3
544 reacted with malonic acid at a high relative humidity. This process will help to
545 increase the CCN activity.

546 Mineral aerosol is one of the most abundant components of the atmospheric aerosol,
547 but its low water solubility limits its CCN activity. This study showed that
548 water-soluble organic acid coating might significantly enhance the CCN activity of
549 mineral aerosol particles. This could lead to mineral aerosol playing a more important
550 role in cloud formation.

Table 1. Mode diameters, chemical compositions, and κ values of CaCO_3 aerosol particles (size selected by DMA at 101.8 nm) before (uncoated) and after coating with oleic (OA) or malonic acid (MA) at 30–80 °C.

	Mode diam. [nm]	OA per particle (marker <i>m/z</i> 41) [10 ⁻¹² µg]	MA per particle (marker <i>m/z</i> 42) [10 ⁻¹² µg]	Organic volume fraction [%]	κ
Uncoated					
CaCO_3 30–80 °C	101.8	(backgr.: 2.4±0.79)	(backgr.: 1.4±0.42)	0.0	0.0028±0.0001
Oleic acid					
CaCO_3 +Oleic acid 30 °C	101.8	3.3±1.7		0.7	
CaCO_3 +Oleic acid 40 °C	101.8	6.3±2.6		1.3	
CaCO_3 +Oleic acid 50 °C	101.8	13±3.3		2.5	
CaCO_3 +Oleic acid 60 °C	105.5	21±1.1		4.1	
CaCO_3 +Oleic acid 70 °C	109.4	86±3.3		14.8	0.0237±0.0006
CaCO_3 +Oleic acid 80 °C	121.9	350±12		41.8	0.0673±0.0016
Malonic acid					
CaCO_3 +Malonic acid 30 °C	101.8		3.5±0.30	0.4	0.0123±0.0005
CaCO_3 +Malonic acid 40 °C	101.8		7.1±1.2	0.8	0.0231±0.0008
CaCO_3 +Malonic acid 50 °C	101.8		14±1.9	1.6	0.0380±0.0012
CaCO_3 +Malonic acid 60 °C	101.8		40±1.7	4.5	0.1056±0.0023
CaCO_3 +Malonic acid 70 °C	109.4		170±8.5	15.5	0.1813±0.0031
CaCO_3 +Malonic acid 80 °C	121.9		640±26	41.8	0.3001±0.0062

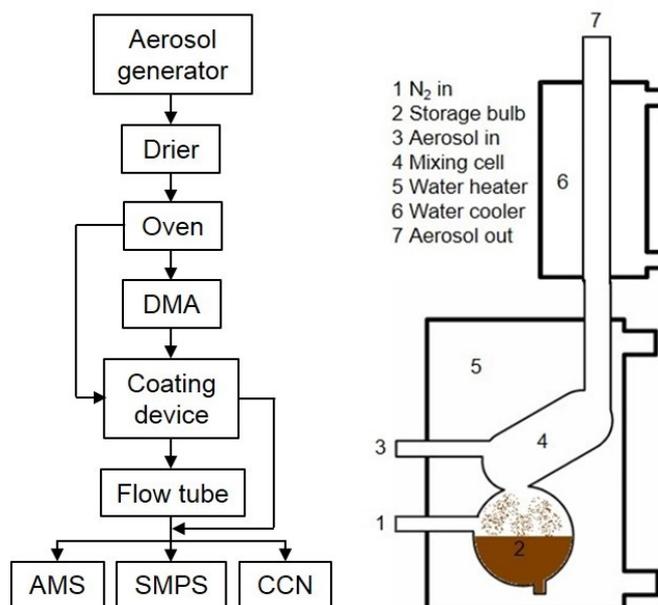

Figure 1. Schematics of the experimental set up (left side). CaCO_3 aerosol is generated by spray-drying of saturated $\text{Ca}(\text{HCO}_3)_2$ solutions and tempering the aerosol passing through an oven at 300°C . The *poly-disperse* CaCO_3 aerosol is either led directly to the coating device (right side, after Roselli, 2006) or led to a differential mobility Analyzer (DMA) for size selection first. Optional, a flow tube can be switched into the pass to enhance the reaction time of the coated particles. The stream of coated particles is finally split to the analytical instruments, namely aerosol mass spectrometer (AMS), scanning mobility particle sizer (SMPS) and CCN counter.

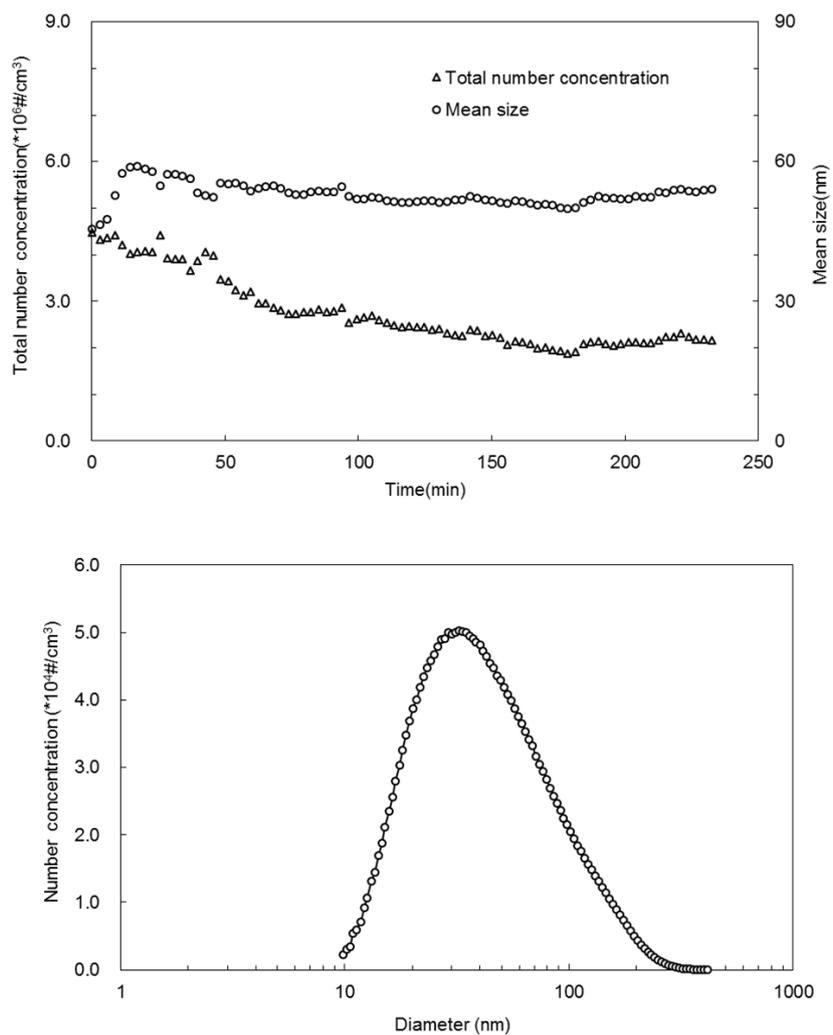

Figure 2. Total number concentration and mean diameter of CaCO_3 aerosol particles generated as a function of the spraying time (upper panel). Typical size distribution of the CaCO_3 aerosol after 70 min spraying (lower panel).

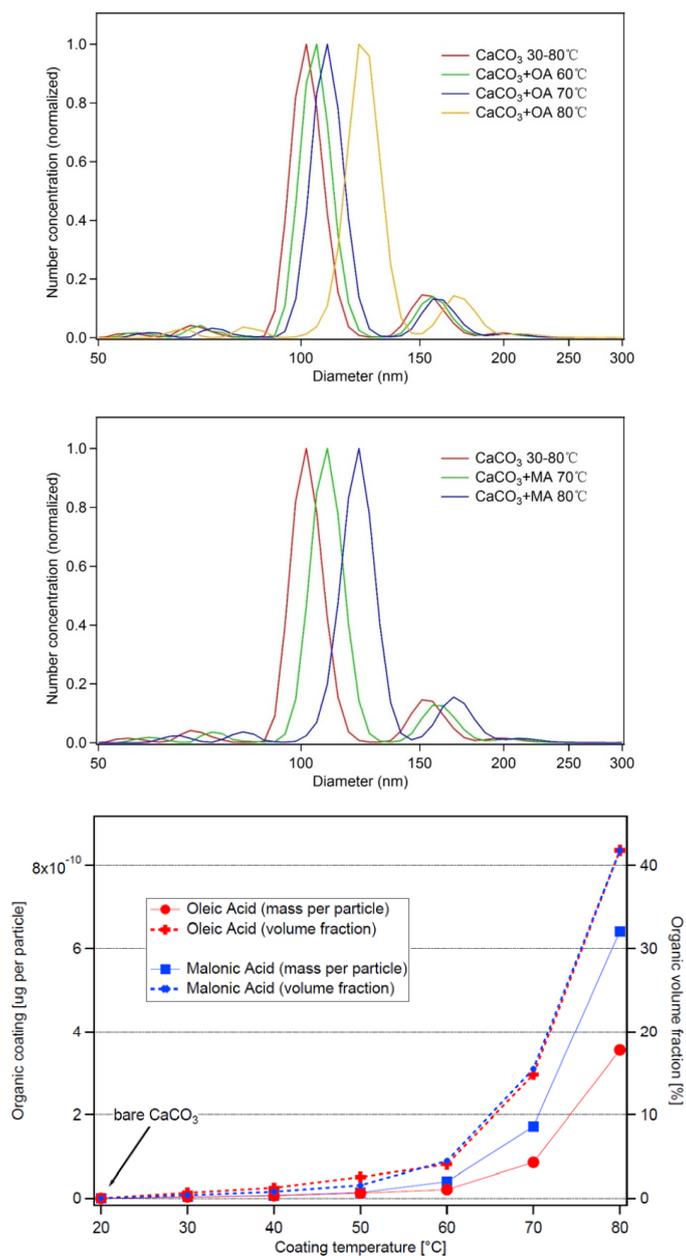

Figure 3. Size distribution of monodisperse CaCO₃ aerosol particles with mode diameter 101.8 nm of the CaCO₃ core before and after coating with oleic acid (top panel) or malonic acid (middle panel). Coating amount and organic volume fraction for oleic and malonic acid as a function of the coating temperature for the same experiments (bottom panel, compare Table 1).

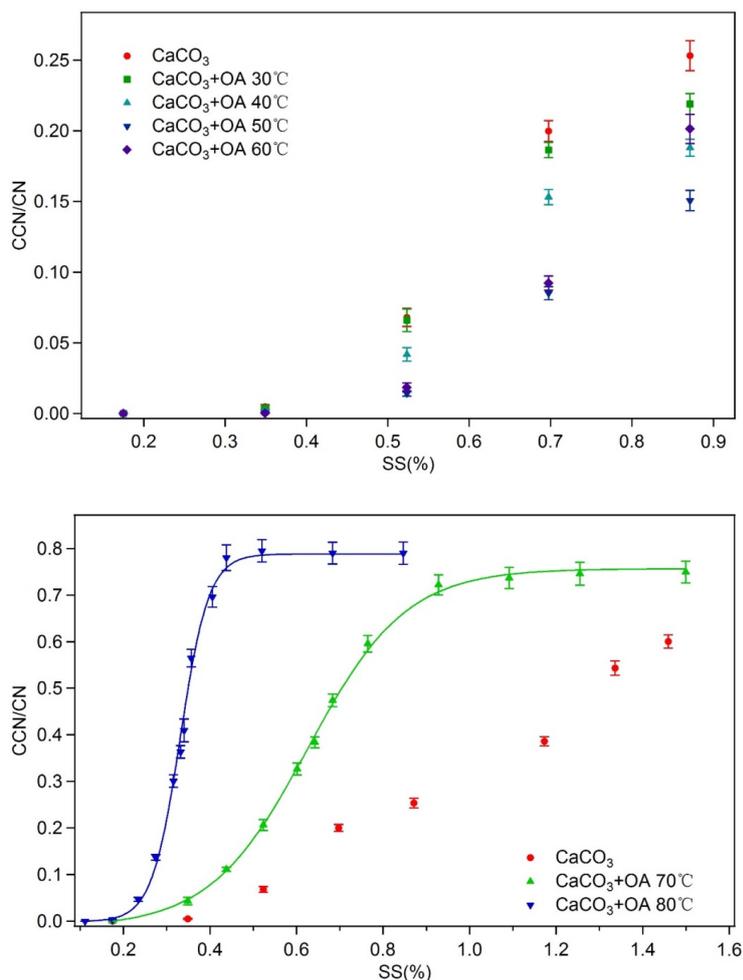

Figure 4. Activated fractions (CCN/CN) of *monodisperse* CaCO₃ aerosol particles (size selected at 101.8 nm) at different supersaturations before and after oleic acid coating. With increasing coating temperatures of 30-50 °C the activated fraction decreases. At 60 °C this trend turns. Considering the invariant mode diameter at 30-50 °C, the increased mode diameter at 60 °C, and the reduced activated fraction simultaneously, the CCN activity of the coated CaCO₃ particles at 30-60 °C was lower than that of the uncoated CaCO₃ particles (top panel). At coating temperatures of 70-80 °C the activated fractions, thus CCN activities, are higher than for bare CaCO₃ and increase with coating temperature. In these two cases all particles are activated at the highest SS and SS_{crit} and κ can be determined from the turning point of the Gaussian fit (bottom panel, compare Table 1).

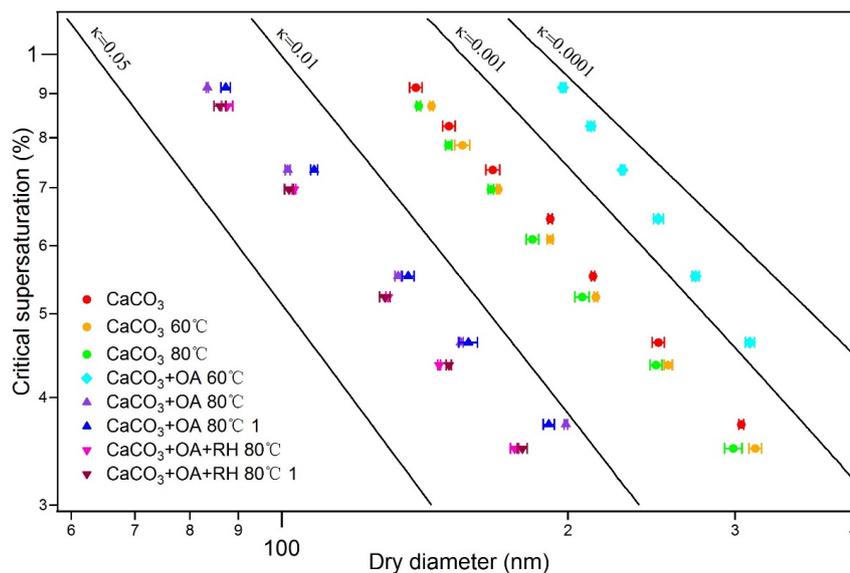

Figure 5. Critical dry diameters at different super-saturations (SS) of *poly-disperse* CaCO_3 aerosol before (circles) and after oleic acid coating. Experiments were performed at 60°C (turquoise diamond) and 80°C (triangles) coating temperatures. The flow tube experiments at 80°C were performed (indicated by the 1) at dry (normal) case (blue triangles) and at 47% RH (brown triangles). The effect of the coating temperature on the CaCO_3 core is negligible (red, green, and orange circles). As for the monodisperse case in Figure 4, at 60°C coating temperature the particles are less CCN active than bare CaCO_3 while at 80°C the coated particle more CCN active. The presence of water in the coating process enhances CCN activity. The increasing of residence time (23.7 s) of the coated aerosol in the flow tube had no significant effect on CCN activity in both experiments.

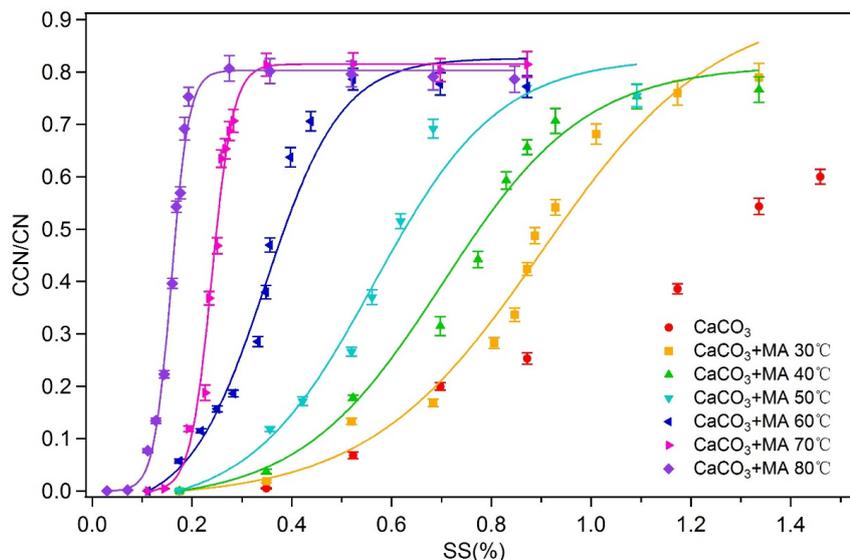

Figure 6. Activated fractions (CCN/CN) of *monodisperse* $CaCO_3$ aerosol particles (size selected at 101.8 nm) at different supersaturations before and after malonic acid coating. With increasing coating temperatures of 30–80 °C the activated fraction, thus CCN activity, increase compared to bare $CaCO_3$ particles. All coated particles can be activated at sufficiently high SS and SS_{crit} and κ can be determined (compare Table 1).

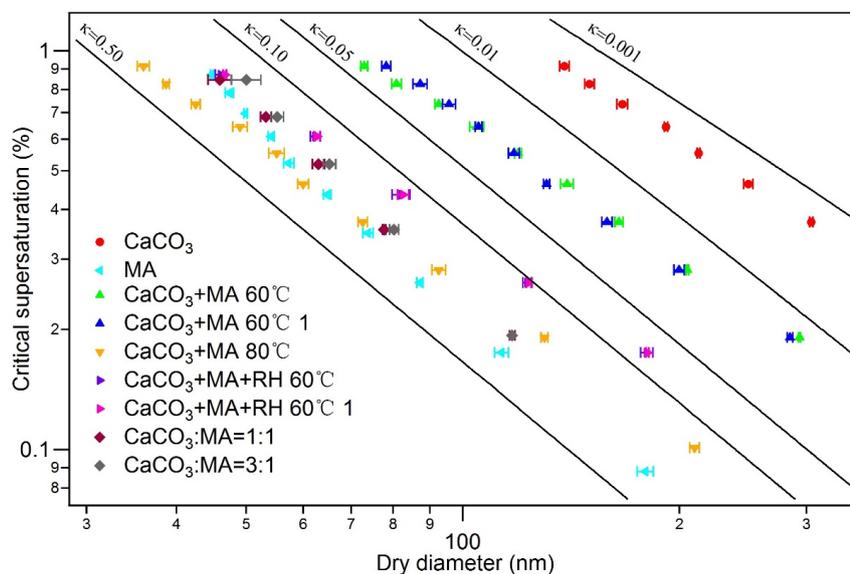

Figure 7. Critical dry diameters at different super-saturations (SS) of *poly-disperse* CaCO_3 aerosol before (circles) and after malonic acid coating (triangles). Experiments were performed at 60°C and 80°C coating temperatures. The results are similar to the monodisperse case in Figure 6. Critical dry diameters as a function of SS are also shown for malonic acid particles and particles that were generated by spraying mixed solution with molar ratios of CaCO_3 /malonic acid of 1:1 and 3:1. The CCN activity decreases with increasing CaCO_3 content. The flow tube experiments at 60 °C were performed (indicated by the 1) at dry (normal) condition (blue triangles) and at 47% RH (magenta triangles). The presence of water in the coating process enhances CCN activity. The increasing of residence time (23.7 s) of the coated aerosol in the flow tube had no significant effect on CCN activity in both experiments.
