**Abstract.** Wet deposition driven by precipitation is an important sink for atmospheric aerosols and soluble gases. We investigate the sensitivity of atmospheric aerosol lifetimes to precipitation intensity and frequency in the context of global climate change. Our study, based on the GEOS-Chem model  
15 simulation, shows that the removal efficiency and hence the atmospheric lifetime of aerosols have significantly higher sensitivities to precipitation frequencies than to precipitation intensities, indicating that the same amount of precipitation may lead to different removal efficiencies of atmospheric aerosols. Combining the long-term trends of precipitation patterns for various regions with the sensitivities of  
atmospheric aerosols lifetimes to various precipitation characteristics allows us to examine the potential  
20 impacts of precipitation changes on atmospheric aerosols. Analyses based on an observational dataset show that precipitation frequency in some regions have decreased in the past 14 years, which might increase the atmospheric aerosol lifetimes in those regions. Similar analyses based on multiple reanalysis meteorological datasets indicate that the precipitation changes over the past 30 years can lead to perturbations in the atmospheric aerosol lifetimes by 10% or higher at the regional scale.

### 25 1 Introduction

Wet scavenging is a major removal process for aerosols and other atmospheric elements [*Atlas and Giam*, 1988; *Radke et al.*, 1980]. Global climate change implies significant perturbations of precipitation, which can directly affect the wet scavenging process. *Salzmann* [2016] found that the global mean

precipitation did not change significantly in the past, while *Trenberth et al.* [2007] reported that the total  
30 precipitation amount increased over land north of 30°N in the past century and decreased in the tropical  
region after the 1970s. *Trenberth* [2011] also noted that a warmer climate could lead to less frequent but  
more intense precipitation.

The impacts of long-term changes in precipitation characteristics on air quality have not been well  
studied. Most previous studies focused on the correlation between air pollution and the total precipitation  
35 amount or precipitation intensity [*Cape et al.*, 2012; *Pye et al.*, 2009; *Tai et al.*, 2012]. For example,  
*Dawson et al.* [2007] found a strong sensitivity of the concentrations of PM<sub>2.5</sub> (particulate matter with  
diameter less than 2.5 μm) to precipitation intensity over a large domain of the eastern US. Only a few  
studies focused on precipitation frequency. *Jacob and Winner* [2009] noted that precipitation frequency  
could be more important than precipitation intensity for air quality, because the wet scavenging process  
40 due to precipitation is very efficient [*Balkanski et al.*, 1993]. *Fang et al.* [2011] projected that wet  
deposition has a stronger spatial correlation with precipitation frequency than intensity over the US in  
January, although they concluded that frequency has a minor effect on wet deposition in the context of  
climate change.

In this study, we first use GEOS-Chem, a global 3-D chemical transport model (CTM), to examine the  
45 sensitivities of atmospheric aerosol lifetimes to various precipitation characteristics, including the  
precipitation intensity, frequency, and total amount. By isolating these precipitation characteristics from  
other meteorological fields through a suite of perturbation simulations, we are able to better understand  
the sensitivities of atmospheric aerosols to various precipitation characteristics. We focus on black  
carbon (BC) as a proxy for atmospheric aerosols to examine the impacts of changes in precipitation  
50 characteristics. BC is nearly inert in the atmosphere [*Ramanathan and Carmichael*, 2008], making it a  
good tracer for studying the transport and deposition of atmospheric species. We also analyze the  
long-term trends of the precipitation characteristics over various regions around the world, based on the  
observational and reanalysis meteorological datasets for the past decades. We then combine the  
long-term trends in the precipitation patterns for various regions with the sensitivities of BC to  
55 precipitation characteristics to quantify their potential impacts on atmospheric aerosols in the context of  
global climate change.

## 2 Methods

We utilize a global 3-D chemical transport model (CTM), GEOS-Chem version 9-02-01 ([www.geos-chem.org](http://www.geos-chem.org)), to carry out a suite of perturbation tests to examine the sensitivities of atmospheric aerosols to precipitation characteristics. As a chemical transport model, the GEOS-Chem model does not simulate meteorology; instead it is driven by assimilated meteorological data from the Goddard Earth Observing System (GEOS) of NASA GMAO. We use the GEOS-5 meteorological dataset in this study. We conduct global simulations with a horizontal resolution of 4° latitude by 5° longitude and 47 vertical layers. All the model simulations in this study run from 1 July 2005 to 1 January 2007, i.e., for one and half years, with the first half year serving as the model spin-up.

The wet deposition scheme in GEOS-Chem includes scavenging in convective updrafts, in-cloud scavenging (rainout), and below-cloud scavenging (washout), which were described in details by *Liu et al.* [2001] and *Wang et al.* [2011]. The efficiency of wet scavenging is very sensitive to the hydrophilicity of BC. GEOS-Chem assumes the ratio between hydrophobic BC (BCPO) and hydrophilic BC (BCPI) to be 4:1 in fresh emissions and BCPO converts to BCPI with an e-folding lifetime of 1.15 days.

The washout rate constant ( $k$ ) is affected by the particle size and the form of precipitation. For washout by rain with precipitation rate  $P$ ,  $k = 1.1 \times 10^{-3} P^{0.61}$  for accumulation mode (aerosols with diameters between 0.04  $\mu\text{m}$  and 2.5  $\mu\text{m}$ ) and  $k = 0.92 P^{0.79}$  for coarse mode (aerosols with diameter between 2.5  $\mu\text{m}$  to 16  $\mu\text{m}$ ); for washout by snow with precipitation rate  $P$ ,  $k = 2.8 \times 10^{-2} P^{0.96}$  for accumulation mode and  $k = 1.57 P^{0.96}$  for coarse mode [*Feng, 2007, 2009*]. The coefficients for accumulation-mode are used in calculating  $k$  for fine particles including BC in GEOS-Chem.

Our study focuses on three precipitation characteristics: the precipitation intensity, frequency, and total amount. We define precipitation events as the data points with "significant" (we use precipitation rate more than 1 mm/day as the criterion in this study) precipitation. Precipitation intensity is the average precipitation rate on precipitation events, with a unit of mm/day. Precipitation frequency is the fraction of precipitation events during the study period (i.e., the probability of any given data points with more than 1 mm/day precipitation rate), which is dimensionless. Total precipitation amount is defined as the average amount of precipitation rate during the study period, with a unit of mm/day. Assuming that precipitation is negligible on data points with no "precipitation events", we would have

$$\text{total precipitation amount} \cong \text{precipitation intensity} \cdot \text{precipitation frequency} \quad (1)$$

85 For sensitivity tests focused on precipitation intensity, we scale the base GEOS5 precipitation values from control run by a uniform factor for each grid box. For the sensitivity tests focused on precipitation frequency, we use a stochastic function to turn off the precipitation at a given data point. For example, in a simulation where we reduce the precipitation frequency by 25%, for a data point  $(i, j, t)$ , we modify the initial precipitation rate  $P_0(i, j, t)$  to

$$P(i, j, t) = \begin{cases} P_0(i, j, t); & R(i, j, t) \geq 0.25 \\ 0; & R(i, j, t) < 0.25 \end{cases} \quad (2)$$

90 where  $R$  is a random function with a range of  $(0, 1)$ . In this way, we decrease the precipitation frequency of each grid box to 75% of its base value across the whole study domain and keep the base spatiotemporal precipitation patterns over each specific region.

For convenience in identifying and describing all the simulation tests, we name them after their precipitation frequency and intensity scaling factors. For instance, the case `f0.5i2` represents the  
95 simulation with half the base precipitation frequency and twice the base precipitation intensity, while the case `f1i1` indicates the control simulation with a base frequency and intensity. We carry out more than 20 sensitivity model simulations to cover various precipitation intensities and frequencies.

The abundance of atmospheric aerosols is determined by both the aerosol emission rate and their atmospheric residence times, i.e., their lifetimes. The average atmospheric lifetimes of aerosols are  
100 calculated as

$$\text{lifetime} = \frac{\text{burden}}{\text{removal rate}} = \frac{\text{burden}}{\text{dry deposition rate} + \text{wet deposition rate}} \quad (3)$$

Therefore, more efficient wet scavenging would lead to shorter atmospheric aerosol lifetimes.

We then examine the long-term changes in precipitation characteristics for various regions around the world in past decades. We first analyze changes in the precipitations between two 7-yr periods (2008-2014 vs. 2001-2007) based on an observational dataset, the 3-Hour Realtime Tropical Rainfall  
105 Measuring Multi-Satellite Precipitation Analysis version 7 (TRMM3B42v7, short for TRMM, <https://pmm.nasa.gov/TRMM>). TRMM (3B42v7) performances better than the previous version of satellite products (3B42v6), though there are still problems in detecting precipitation events with low precipitation rates [Maggioni et al., 2016] We then examine three reanalysis datasets with longer temporal coverage (2001-2010 vs 1981-1990): the National Centers for Environmental Prediction

110 (NCEP) reanalysis dataset [Kalnay *et al.*, 1996], the NCEP-DOE AMIP-II (NCEP2) reanalysis dataset  
[Kanamitsu *et al.*, 2002], and NASA's Modern-Era Retrospective Analysis (MERRA) database  
[Rienecker *et al.*, 2011]. These datasets have different resolutions and spatial coverage. TRMM only  
covers 60°N-60°S, while other datasets cover the whole globe. The resolutions (°lon x °lat x hour) for  
TRMM, NCEP, NCEP2, and MERRA are 0.25x0.25x3, 2.5x2.5x6, 2.5x2.5x6, 2.5x2x1, respectively.  
115 We regrid the TRMM dataset from 0.25x0.25 to 2.5x2.5 (°lon x °lat) to reduce the computational cost  
and the relative errors at small precipitation rates [Huffman *et al.*, 2007; Gehne *et al.*, 2016]. By  
combining the resulting sensitivities of BC lifetimes to precipitation characteristics with the results of the  
long-term trends in precipitation characteristics, we then estimate the impacts of long-term changes in  
precipitation characteristics on the atmospheric lifetime of BC.

### 120 3 Results

The global annual mean lifetime of BC is calculated at 5.29 days in our control simulation (Fig. 1). This  
value is similar to the results of a previous study, which stated that the lifetime of BC would be around  
one week [Ramanathan and Carmichael, 2008]. Our result also agrees with the lifetime of  $5.8 \pm 1.8$  days  
simulated by the GEOS-Chem model [Park *et al.*, 2005] and the 5.4 days result simulated by the  
125 ECHAM5-HAM model [Stier *et al.*, 2005].

We first compare the results of control run with other simulations with the same precipitation frequency  
(f1i0.25, f1i0.5, f1i1, f1i2, and f1i4) to examine the sensitivity of BC lifetime to precipitation intensity  
(Fig. 1a). We find that an increase in precipitation intensity leads to decreases in both the BC lifetime and  
the sensitivity of the BC lifetime to precipitation intensity. That is, the impact of precipitation intensity  
130 on BC aerosols is saturated when the intensity is very high, which is consistent with a previous study  
[Fang *et al.*, 2011]. We then compare the control run with other simulations with the same precipitation  
intensity (f0.1i1, f0.25i1, f0.5i1, f0.75i1, and f1i1) to study the sensitivities of the BC lifetime to  
precipitation frequency (Fig. 1b). Again, the BC lifetime responds non-linearly to the changes in  
precipitation frequency, and the sensitivity decreases with increases in precipitation frequency.

135 When we compare the simulations with a common precipitation amount (f0.1i10, f0.25i4, f0.5i2,  
f0.75i1.33, and f1i1), we find that the BC lifetime increases with increasing precipitation intensity (Fig.

1c). For example, case f0.1i10 has an annual average BC lifetime of 7.86 days, which is much longer than the 5.29 days of the control simulation (case f1i1). This indicates that the sensitivity of the BC lifetime to precipitation frequency is stronger than that to the precipitation intensity.

140 The efficiency of wet scavenging can be affected by model parameterization. We first examine the impacts on our results from the parameterization on the hygroscopicity of aerosols. We compare the changes in the BC lifetime between two scenarios (f1i1 vs. f0.75i1.33) with alternative parameterization schemes. We find that with the default setting in GEOS-Chem (20% BC in fresh emissions are hydrophilic), the atmospheric lifetime of BC under the f0.75i1.33 scenario is slightly higher than the f1i1  
145 scenario by 0.4%. If all the BC emission is assumed to be hydrophilic, the BC lifetime under the f0.75i1.33 scenario would be 3.6% higher. This implies that for hydrophilic aerosols, the sensitivity to precipitation frequency would be even higher.

We also evaluate the impacts on wet scavenging from aerosol size with sensitivity simulations. If we assume the aerosols to be in coarse mode, we find that would lead to more efficient scavenging and  
150 consequently much shorter lifetime (compared to the default setting in GEOS-Chem that all BC aerosols are in accumulation mode). However, there are no significant effects on the relative sensitivities to precipitation frequency vs. intensity – the percentage change in BC lifetime between the f1i1 and f0.75i1.33 scenarios is very similar to the cases with parameterization for accumulation mode (0.3% vs. 0.4%). This indicates that the relative sensitivity of the BC lifetime to precipitation frequency and  
155 precipitation intensity is not significantly affected by the parameterization of particle size in the wet scavenging scheme in GEOS-Chem. It is worth noting that our model does not resolve the size of precipitation droplet, which can also affect the efficiency of wet scavenging.

The stronger sensitivity of the BC lifetime to precipitation frequency than that to intensity implies that an increase in the total precipitation amount does not necessarily lead to a decrease in the BC lifetime. This  
160 is better illustrated in Fig 2, which shows the BC lifetime as a function of the precipitation intensity and frequency based on 20 cases (f0.25, f0.5, f0.75, f1 versus i0.5, i1, i1.33, i2, i4). Compared with the control scenario (i.e., the base precipitation intensity and frequency, as labeled by the black star), any point in the area between the two solid curves (the green one shows a constant total precipitation amount and the red one shows a constant BC lifetime) would have a higher total precipitation amount and a

165 longer BC lifetime. This indicates that, even with an increased total precipitation, the BC lifetime (and hence the atmospheric concentrations of BC) can still increase if the precipitation frequency decreases significantly. This feature may help explain the decrease of the wet deposition flux found in wetter future climate simulations, despite their slightly increased total precipitation amounts (Xu and Lamarque, personal communication; manuscript under review).

170 The lifetime contour plot in Fig. 2 can be employed as a simple tool to help us understand the impacts of long-term changes in precipitation on atmospheric aerosols, so we also investigate the long-term trends in the precipitation characteristics over the past decades for various regions around the world. In considering the spatial variations of precipitation patterns and their long-term trends, we divide the global continental regions into multiple subcontinental areas to better resolve the spatial variations (Fig.

175 3). We first carry out an analysis based on precipitation data from the TRMM dataset. The changes in the average precipitation intensities and frequencies between the periods of 2008-2014 and 2001-2007 for each region are shown as ratios in Fig. 4. The width and height of the blocks in Fig. 4 indicate the standard deviations of precipitation frequency and intensity, respectively. We find that during these 14 years, the average precipitation intensity has increased over most regions, but the average precipitation  
180 frequency has decreased over more than one third of the total regions including western North America (nwNA and swNA), southern South America (sSA), western Europe (wEU), southern Africa (sAF), and southwestern Asia (swAS).

By combining these precipitation changes for various regions as shown in Fig. 4 with the relationship between precipitation characteristic and the BC lifetime as illustrated in Fig. 2, we can analyze the  
185 long-term changes in the atmospheric aerosol lifetimes driven by precipitation changes. With given perturbations in precipitation intensity and frequency for a specific region, the potential change in the BC lifetime can be estimated based on the lifetime-contour plots in Fig. 4. The design of the sensitivity tests with precipitation frequency only allows us to carry out “one-way” sensitivity tests (i.e. with reduced precipitation frequency compared to the control run), as a consequence, all the contours in Fig.  
190 2, Fig. 4, and Fig. 5 end at the level of base precipitation frequency. Based on the TRMM dataset, we find that almost all (5 out of 6) of the regions with decreasing precipitation frequency are expected to experience longer atmospheric aerosol lifetimes.

Since the TRMM data only cover a relatively short period, we make similar analyses with three reanalysis datasets (NCEP, NCEP2, and MERRA) to cover a longer time period (2001-2010 vs. 1981-1990) (Fig. 5). We find that, similar to the TRMM data, all the three reanalysis datasets show increasing trends for precipitation intensity over most regions but more divergent trends for precipitation frequency in the past decades. The NCEP data show that precipitation frequency has decreased over about two thirds of the total regions while NCEP2 and MERRA data show decreasing precipitation frequency over one third and half of the total regions, respectively. In addition, even when the different datasets indicate same direction for the precipitation change over a specific region, the magnitude of the changes may vary significantly across datasets. For example, the derived changes in the average precipitation intensity over neNA (northeastern North America) based on NCEP, NCEP2, and MERRA data are +8%, +12%, and +3% respectively. These variations across different data sources reflect the significant uncertainties associated with these datasets, as reported earlier [e.g., Trenberth *et al.*, 2011; Gehne *et al.*, 2016].

On the other hand, previous analysis on global land-average precipitation showed that various reanalysis datasets have similar trends and interannual variability with other gauge- and satellite-based datasets during 2001-2010, though the estimated trend of precipitation varies based on temporal and spatial scales [Gehne *et al.*, 2016]. In addition, our study focuses on the changes over continental regions, where the precipitation data in the reanalysis datasets are found to be more reliable than over the ocean regions [Trenberth *et al.*, 2011]. Therefore despite the uncertainties associated with each meteorological dataset, we can use Fig. 5 to estimate the expected changes in the atmospheric BC lifetimes for certain regions, especially for those regions showing consistent trends across different datasets. Assuming the effects of precipitation on wet deposition is the only factor that affects the atmospheric BC aerosol lifetimes, all three datasets indicate that atmospheric BC aerosol lifetimes could have decreased in the northern regions of North America (neNA and nwNA), the northwestern and southern regions of South America (nwSA and sSA), South Africa (sAF), and North Oceania (nOC). All three meteorological datasets show increasing trends in aerosol lifetimes over southwestern North America (swNA), Middle Africa (MAF), and South Oceania (sOC), which imply increasing trends for the concentrations of particulate matter

220 (PM) over these regions, driven by changes in precipitation. At the regional scale, precipitation changes  
over the past 30 years can easily lead to perturbations in atmospheric BC lifetimes by 10% or higher.

#### 4 Conclusions and Discussion

The efficiency of the wet scavenging of atmospheric aerosols is affected by not only the precipitation  
amount but also the precipitation patterns. Our results, based on sensitivity simulations with the  
225 GEOS-Chem model, show that the atmospheric lifetimes of BC are more sensitive to precipitation  
frequency than precipitation intensity, and as a consequence, increases in the total precipitation amount  
do not always lead to a more efficient wet scavenging of atmospheric aerosols. The sensitivities of the  
atmospheric lifetimes of aerosols to the precipitation characteristics derived from our model simulations  
offer simple and convenient tools for us to better examine the implications of long-term changes in  
230 precipitation (including the total amounts and patterns) for atmospheric aerosols in various regions.

Analysis of satellite data (TRMM) for the past 14 years (2001-2014) reveal that precipitation intensity  
have increased in most regions. On the other hand, decreasing precipitation frequency are found in some  
regions such as western North America, southern South America, western Europe, southern Africa, and  
southwestern Asia. The decreases in precipitation frequency could lead to increases in atmospheric  
235 aerosol lifetimes over these regions. Our further analyses based on three meteorological datasets (NCEP,  
NCEP2, and MERRA) for the past decades (1981-2010) show increases in precipitation intensities over  
most continental regions, but significant decreases in precipitation frequency are identified over some  
regions. These changes in precipitation characteristics affect the wet deposition of aerosols and  
consequently the total burdens of aerosols and their atmospheric lifetimes. Despite the significant  
240 uncertainties associated with meteorological data, we find that the precipitation changes over the past 30  
years could have led to perturbations in the regional atmospheric aerosol lifetimes by 10% or higher. We  
also find that all three meteorological databases are consistent to show that precipitation changes over  
the past decades have led to decreases in atmospheric aerosol lifetimes over the northern regions of North  
America, northwestern and southern regions of South America, South Africa, and North Oceania. They  
245 are also consistent in indicating increasing trends of atmospheric aerosol lifetimes in the southwestern  
region of North America, Middle Africa, and South Oceania. The increasing trends in atmospheric

aerosol lifetimes over these regions driven by precipitation changes in the context of global climate change could pose challenges for the local PM air qualities. It should be noted that the results from this work can be affected by the parameterization in the GEOS-Chem model and have certain limitations. Our study does not account for the impacts of precipitation on wildfires which can emit massive amount of aerosols including BC [Dawson *et al.*, 2014]. In addition, our study does not account for the feedbacks from aerosols on radiation and precipitation. It may be worthy to carry out some future work accounting for these indirect effects and feedbacks to further evaluate the impacts of long-term changes in precipitation on atmospheric aerosols.

#### 255 **Acknowledgements**

We thank all those who have contributed to the datasets we used in this study. The NCEP reanalysis data and NCEP-DOE AMIP-II reanalysis data were provided by NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, and were accessed through their web site at <http://www.esrl.noaa.gov/psd/>. The MERRA data used in this study were provided by the Global Modeling and Assimilation Office (GMAO) at the NASA Goddard Space Flight Center through the NASA GES DISC online archive. We thank Dr. Hongyu Liu and Dr. Bo Zhang for fruitful discussion. Superior, a high performance computing cluster at Michigan Technological University, was used to obtain the results presented in this publication. **Figure 1: Impacts of the precipitation characteristics on the atmospheric lifetime of BC under given a) constant precipitation frequency; b) constant precipitation intensity; and c) constant precipitation amount.**

345 The top x-axis reflects the precipitation frequency set in each perturbation test, shown as fractions of base precipitation frequency. Base precipitation frequency is the precipitation frequency used in control case. Similarly, the bottom x-axis reflects the settings of precipitation intensity in the perturbation tests. The box plot shows the probability distribution of BC lifetime for each case, where the top and bottom edges of each box show the third and first quartiles, respectively; the green central bar shows the median; the whisker shows the range of the non-outliers that cover 99.3% of the data, assuming normally distributed data; and the red plus shows the outliers.

Figure 2: Model calculated BC atmospheric lifetime as a function of precipitation intensity and frequency. The dashed contour lines indicate the atmospheric lifetimes of the black carbon aerosols from the interpolation of 20 cases, which show the potential changes of BC lifetimes from the base BC lifetime (in the control run) driven by the changes of precipitation intensity and frequency. The green solid line represents a total precipitation equal to that of the base simulation (control run). The red solid line indicates the conditions leading to atmospheric black carbon aerosol lifetimes that match the base simulation (control run).

**Figure 3:** The definitions of the continental regions in this study. The uppercase letters in the region names represent the names of their continents: North America (NA), South America (SA), Europe (EU), Africa (AF), Asia (AS), and Oceania (OC). The lowercase letters in the region names represent the subregions inside the continent: north (n), south (s), west (w), east (e), middle (m), northwest (nw), northeast (ne), southwest (sw), and southeast (se).

370 Figure 4: The potential change of atmospheric BC aerosol lifetime driven by the changes between the two periods (2008-2014 and 2001-2007) in precipitation characteristics based on meteorological datasets TRMM. The dashed contours are the same as in Fig. 2, which indicate the atmospheric lifetimes of the black carbon aerosols from the interpolation of 20 cases and show the potential changes of BC lifetimes from the base BC lifetime (in the control run) driven by the changes of precipitation intensity and frequency. Red blocks show the changes of precipitation intensities and frequencies, with the size of the block showing the standard error of the mean changes.

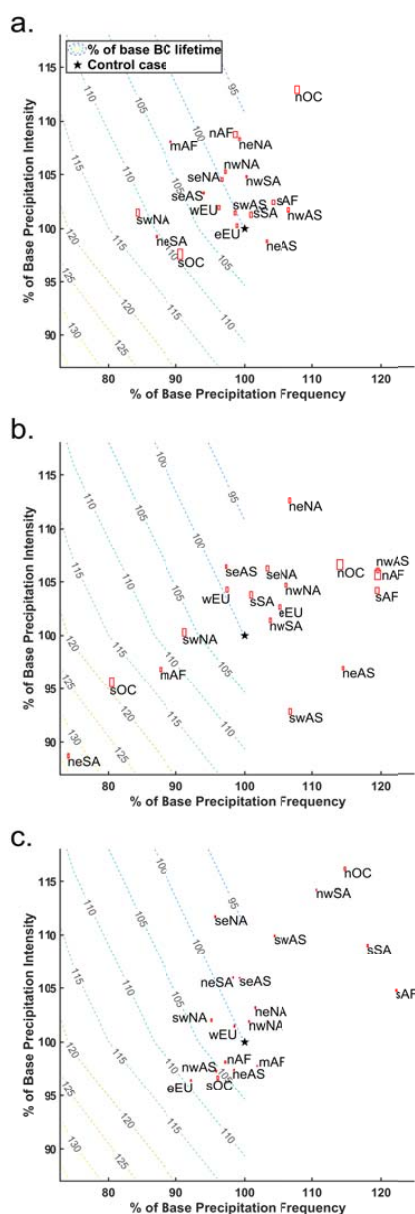

Figure 5: The potential change of atmospheric BC aerosol lifetime driven by the changes between the two periods (2001-2010 and 1981-1990) in precipitation characteristics based on multiple meteorological datasets: a). NCEP; b). NCEP2; c). MERRA. The dashed contours are the same as in Fig. 2, which indicate the atmospheric lifetimes of the black carbon aerosols from the interpolation of 20 cases and show the potential changes of BC lifetimes from the base BC lifetime (in the control run) driven by the changes of precipitation intensity and frequency. Red blocks show the changes of precipitation intensities and frequencies, with the size of the block showing the standard error of the mean changes.
