**Abstract.** We measured amines in boreal forest air in Finland both in gas and particle phase with 1-hour time resolution using an online ion chromatograph (instrument for Measuring AeRosols and Gases in Ambient Air, MARGA) connected to an electrospray ionization quadrupole mass spectrometer (MS). The measurements covered about 8 weeks between March 15 2015 and December 2015. With MARGA-MS we were able to separate and detect 7 different amines: monomethylamine (MMA), dimethylamine (DMA), trimethylamine (TMA), ethylamine (EA), diethylamine (DEA), propylamine (PA) and butylamine (BA). The amines were found to be an inhomogeneous group of compounds, showing different seasonal and diurnal variability. Total MMA peaked together with the sum of ammonia and ammonium ion already in March, possibly due to evaporation from melting snow and ground. In March monthly means for MMA were  $<2.4 \text{ ng m}^{-3}$  and  $6.8 \pm 9.1 \text{ ng m}^{-3}$  in gas and aerosol phase, respectively, and for  $\text{NH}_3$  and  $\text{NH}_4^+$ ,  $52 \pm 16 \text{ ng m}^{-3}$  and  $425 \pm 371 \text{ ng m}^{-3}$ , respectively. Monthly medians in March for MMA,  $\text{NH}_3$  and  $\text{NH}_4^+$ , were  $<2.4 \text{ ng m}^{-3}$ ,  $19 \text{ ng m}^{-3}$  and  $90 \text{ ng m}^{-3}$  respectively. DMA and TMA had summer maxima indicating biogenic sources. We observed diurnal variation for DMA but not for TMA. The highest concentrations of these compounds were measured in July. In July monthly means for DMA were  $<3.1 \text{ ng m}^{-3}$  and  $8.4 \pm 3.1 \text{ ng m}^{-3}$  in gas and aerosol phase, respectively, and for TMA  $0.4 \pm 0.1 \text{ ng m}^{-3}$  and  $1.8 \pm 0.5 \text{ ng m}^{-3}$ . Monthly medians in July for 20 DMA were  $<\text{DL}$  and  $4.9 \text{ ng m}^{-3}$  in gas and aerosol phase, respectively, and for TMA  $0.4 \text{ ng m}^{-3}$  and  $1.4 \text{ ng m}^{-3}$ . When relative humidity of air was  $>90\%$ , gas phase DMA correlated well with 1.1-2 nm particle number concentration ( $R^2=0.63$ ) suggesting that it participates in new particle formation. 0.63 EA concentrations were low all the time, July means were  $<0.36 \text{ ng m}^{-3}$  and  $0.4 \pm 0.4 \text{ ng m}^{-3}$  in gas and aerosol phase respectively, but they correlated well with monoterpene concentrations in July. Monthly means of PA and BA were all the time below detection limits.

## 1. Introduction

Amines are gaseous bases, whose general formula is  $\text{RNH}_2$ ,  $\text{R}_2\text{NH}$  or  $\text{R}_3\text{N}$ . Models based on quantum chemistry data have shown that they could participate in aerosol particle formation with sulfuric acid even at very low mixing ratios (Kurtén et al. 2008, Paasonen et al. 2012). Also the recent laboratory experiments at CLOUD chamber shows that already minute concentrations of dimethylamine (DMA) are able to produce new particles with sulphuric acid (Almeida et al. 2013, Kürten et al. 2016) Atmospheric aerosol particles affect the climate, because they can act as cloud condensation nuclei (IPCC 2014). They also scatter and absorb sun radiation. Amines also affect hydroxyl radical (OH) reactivity and therefore atmospheric chemistry (Hellén et al. 2014, Kieloaho et al. 2013).

Ambient gas phase amines have been measured earlier using different methods. Samples have been collected in phosphoric acid-impregnated fiberglass filters (Kieloaho et al., 2013), to solid phase micro extraction fiber (Parshintsev et al. 2015) and to ion exchange resin (Dawson et al. 2014) and they have been percolated through acidic solution (Akyüz M., 2007). Samples have been analyzed later in the laboratory with various chromatographic techniques, such as gas chromatography coupled to mass spectrometry (GC-MS) (Akyüz 2007, Parshintsev et al., 2015), ion chromatography (IC) (Dawson et al. 2014) and high pressure liquid chromatography coupled to mass spectrometry (HPLC-MS) (Kieloaho et al. 2013). The mentioned techniques have various shortcomings: quantitation based on collection on fibers is problematic, collecting in filters requires long sampling times (usually several days), percolating in acidic solutions requires intensive sample pretreatment. Dawson et al. (2014) used weak cation exchange resin as a substrate for collection of gas-phase ammonia and amines. The method minimizes sample losses on walls during sampling and has quite short sampling times (less than an hour), but the detection limits remain too high for the boreal forest environment.

Also novel in-situ methods for measuring ambient air gas-phase amines have been developed, usually based on mass-spectrometric detection: chemical ionization mass spectrometry (CIMS), (Sellegrì et al. 2005, You et al. 2014), ambient pressure proton transfer mass spectrometry (AmPMS) (Hanson et al. 2011, Freshour et al. 2014), chemical ionization atmospheric pressure interface time-of-flight mass spectrometry (CI-APi-TOF) (Kulmala et al. 2013, Sipilä et al. 2015, Kürten et al. 2016) and TOF-CIMS (Zheng et al 2015). These in-situ techniques have short time resolution and the limits of detections are small. However, these methods cannot separate amines with same masses (e.g. DMA and EA) and identification of the measured compounds remains uncertain. Chang et al. (2003) used high-efficiency planar diffusion scrubber IC (HEDS-IC) to successfully separate amines with identical masses.

Particle phase amines have been sampled to filters and analyzed later in laboratory with similar techniques: LC-MS (Ruiz-Jiménez et al. 2012), GC-MS (Huang et al. 2014) and IC (Huang et al. 2014, van Pinxteren et al. 2015). With these methods sampling time was long (24 – 133 h) and biases may be introduced due to transport and pretreatment of samples. VandenBoer et al. (2011) measured amine concentrations both in gas and particle phase with ambient ion monitor –IC

(AIM-IC). This method had 60 min sampling time and relatively low detection limits (5-9 ng m<sup>-3</sup>). However, it could not separate TMA and DEA from each other and detection limits remain too high for measurements in the boreal forest.

70 These methods have been utilized in short campaigns from couple of days to couple of weeks. Only Kieloaho et al. (2013) measured longer period, but their sampling time was long (24 – 72 h). Most of the measurements discussed previously were made in urban or sub-urban area, and only some (Sellegrì et al. 2005, Kieloaho et al. 2013, Kulmala et al. 2013 and Sipilä et al. 2015) were made in boreal forest site.

75 The in-situ method developed in this study for atmospheric amine measurements was used in the boreal forest, where amines are expected to affect aerosol particle formation even at extremely low concentrations (Kurtén et al. 2008, Paasonen et al. 2012). We report seasonal and diurnal variations of amines in boreal forest air and their partitioning between gas and particle phase. To our best knowledge our measurements constitute the longest time series of amine concentration measurements that have been made.

## 2. Experimental

### 2.1 Measurement site

Measurements were performed in a Scots pine forest at the SMEAR II station (Station for Measuring Forest Ecosystem-  
85 Atmosphere Relations) in Hyytiälä, Southern Finland (61°51'0"N, 24°17'0"E, 180 m a.s.l., Hari and Kulmala, 2005). The largest nearby city is Tampere, situated 60 km southwest from the station with approximately 364 000 inhabitants. The instrument was located in a container about 4 meters outside the forest in a small opening. In addition to pines, also small spruces (*Picea abies*) were growing nearby. The forest was planted about 50 years ago and its current tree height is about 19 m. We measured amine and ammonia concentrations from March to May, July to August and November to December 2015.

90

### 2.2 Meteorological conditions

Data for the meteorological parameters were obtained from the SmartSmear AVAA portal (Junninen et al. 2009). Table 1 shows the meteorological conditions during measurements periods.

95

Table 1. Mean temperature and average wind speed and humidity during measurements. We have used only the data that was measured at the same time as our amine data for the calculations.

Month	Mean Temperature (°C)	Average Wind speed (m/s)	Average Humidity (%)
March	0.4	2.6	87
April	3.7	2.4	75
May	9.7	1.8	69
July	13.8	1.5	75
August	17.8	1.4	74
November	2.7	2.9	95
December	-0.1	1.9	94

### 2.3 Measurement methods

In the present study we used MARGA (instrument for Measuring AeRosols and Gases in Ambient air, Metrohm-Applikon, Schiedam, Netherlands) (ten Brink et al. 2007) for sampling and measuring. MARGA is an online ion chromatograph (IC) connected to a sampling system. In addition, this system was connected to an electrospray ionization quadrupole MS (Shimadzu LCMS-2020, Shimadzu Corporation, Kyoto, Japan) to improve sensitivity of amine measurements. This new set-up enabled amine concentration measurements in ambient air both in aerosol and gas phases. With MARGA-MS we sampled, separated and detected 7 different amines: monomethylamine (MMA), dimethylamine (DMA), trimethylamine (TMA), ethylamine (EA), diethylamine (DEA), propylamine (PA) and butylamine (BA).

110

The sampling air flow was  $16.7 \text{ l min}^{-1}$  for a sampling time of 1 hour. We used PM10 inlet (URG 1032,  $16.7 \text{ l min}^{-1}$ ) with polyethylene tubing (ID 0.5" and length ~1 m). The eluent used was oxalic acid ( $3.2 \text{ mol l}^{-1}$ , Merck, Darmstadt, Germany) with a flow of  $0.7 \text{ ml min}^{-1}$ . We used a concentration column (Metrosep C PCC 1 VHC/4.0) before the analytical column (Metrosep C4-100/4.0). Detection limits (DL) were calculated from signal-to-noise ratios (3:1) for most of the compounds and they were similar in gas and particle phase (Table 2). However, DLs for DMA and TMA were calculated from blank-values (3 times standard deviations of blank-values) and the DLs were different for gas and particle phase measurements.

115

Table 2. Detection limits (DL) of different amines, ammonia and ammonium. Conversions from ( $\text{ng m}^{-3}$ ) to  $\text{ppt}_v$  has been made using conversion factor  $\text{ppt}_v = c(\text{ng m}^{-3}) : (0.0409 * (\text{MW}))$  by Finlayson-Pitts (2000).

Amine		DL ( $\text{ng/m}^3$ )	DL ( $\text{ppt}_v$ )
<b>MMA</b>		2.4	1.9
<b>DMA (March to August)</b>	<b>gas</b>	3.1	1.7
	<b>particles</b>	1.1	
<b>(November to December)</b>	<b>gas</b>	0.37	0.20
	<b>particles</b>	0.76	
<b>TMA</b>	<b>gas</b>	0.2	0.1
	<b>particles</b>	0.5	
<b>EA,</b>	<b>both gas and particle</b>	0.36	0.19
<b>DEA,</b>	<b>both gas and particle</b>	0.24	0.08
<b>PA,</b>	<b>both gas and particle</b>	0.31	0.13
<b>BA,</b>	<b>both gas and particle</b>	0.26	0.09
<b>NH<sub>3</sub></b>		11.4	16.4
<b>NH<sub>4</sub><sup>+</sup></b>		2.9	

120

Deuterated diethyl-d<sub>10</sub>-amine (Sigma-Aldrich: Isotec™; Sigma-Aldrich, St. Louis, MO, USA) was used as an internal standard for all amines and a 3-point external calibration was used for all measured alkyl amines (concentration levels ca. ~10, 50 and 300  $\text{ng m}^{-3}$ ). The system was calibrated every two weeks, by stopping the air flow of MARGA and directing standard solutions to the sample syringe pumps, before analysis by IC-separation and MS-detection. Ammonia (NH<sub>3</sub>) and ammonium (NH<sub>4</sub><sup>+</sup>) were also measured with MARGA at the same time with the method described in Makkonen et al. (2012 and 2014). For these a conductivity detector was used and the internal standard was lithium bromide (Acros Organics, New Jersey, USA). Instrumental blank values were measured every month or every other month with MARGA's blank-mode: the sample airflow was stopped, and the analysis cycle was running for 6 hours without sampling.

130

In the figures we used moving average for DMA, because every other measured DMA concentration was a little higher than the other one. The system used different syringes for sample collection every other hour and the reason for differences are expected to be losses or contamination in the syringes.

135 To study the role of amines in atmospheric particle formation, particle number concentration measurements were utilized. The particle number size distribution between 3 and 1000 nm was measured with a twin- Differential Mobility Particle Sizer (DMPS) system (Aalto et al., 2001). From these measurements, the particle concentration between 3 and 25 nm ( $N_{3-25 \text{ nm}}$ ), referred to as nucleation mode, and the total particle concentration between 3 and 1000 nm ( $N_{\text{tot}}$ ) were obtained. In addition, the concentrations of sub-3 nm particles were measured with an Airmodus Particle Size Magnifier (PSM A11; Vanhanen et al., 2011). The PSM is a mixing-type condensation particle counter, in which particles are first grown to 90 nm size by condensation of diethylene glycol, after which butanol is used to grow them to detectable sizes. The cut-off size of the PSM can be changed by altering the mixing ratios of saturated and sample flows, which allows the measurement of particle size distribution in the sub-3 nm size range. In this study, the particle concentration obtained for the size range between 1.1 and 2.0 nm ( $N_{1.1-2\text{nm}}$ ) was used. In addition, the particle concentration between 2 and 3 nm ( $N_{2-3\text{nm}}$ ), was obtained by subtracting  
140 the total particle concentration measured with the highest cut-off size of the PSM from the total particle concentration measured with the DMPS. For the more discussion about the particle concentration measurements and their uncertainties, see Kontkanen et al. (2017) who have published the data set used in this study.

## 2.4 Regression calculations

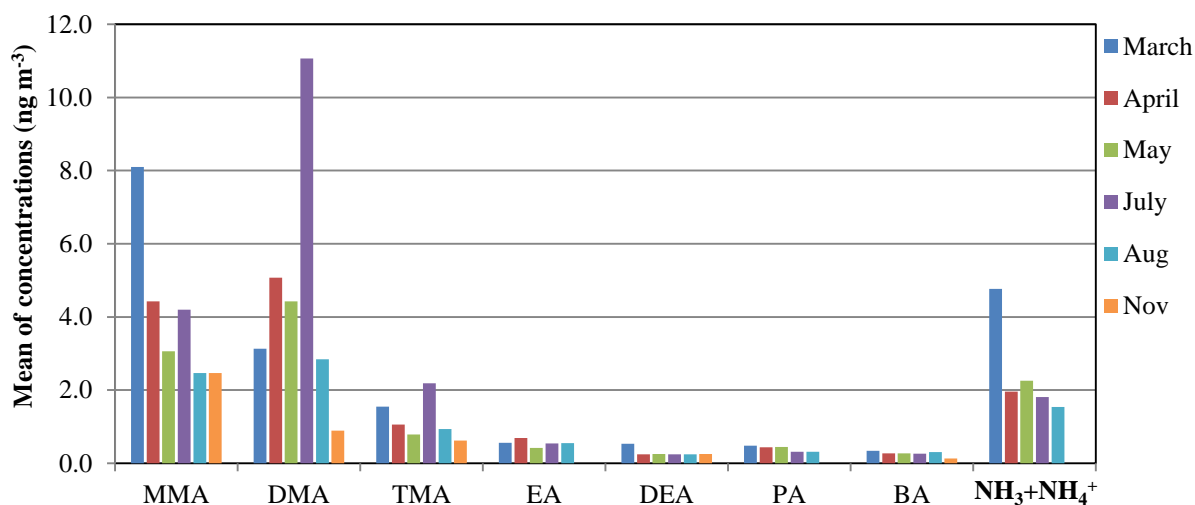

150 Simple linear regressions were calculated to find out whether the basic meteorological conditions affect the amine concentrations. The statistical significance of the slope of the linear regression of the amine concentration  $y$  vs. the ambient condition  $x$ , i.e.  $y = \beta_1 x + \beta_0$  was estimated. The null hypothesis, which means that the slope  $\beta_1$  is not dependent on the ambient condition  $x$  (i.e.,  $\beta_1 = 0$ ), was examined using test statistics given by the estimate of the slope divided by its standard error ( $t = \beta_1/\text{s.e.}$ ). The test statistics were compared with the Student's  $t$  distribution on  $n - 2$  (sample size - number of  
155 regression coefficients) degrees of freedom. The analysis yields also the  $p$  value of the slope. The lower the  $p$ -value is, the stronger the evidence against the null hypothesis is. The statistical significance of the slope can be interpreted so that if  $p > 0.1$  there is no evidence against the null hypothesis, and  $p$ -values in the ranges 0.05-0.1, 0.01-0.05, and  $< 0.01$  suggest respectively a weak, moderate and strong evidence against the null hypothesis in favor of the alternative. The regressions were calculated for amine concentrations vs. air temperature, relative humidity, wind speed, soil temperature and soil  
160 humidity.

### 3. Results

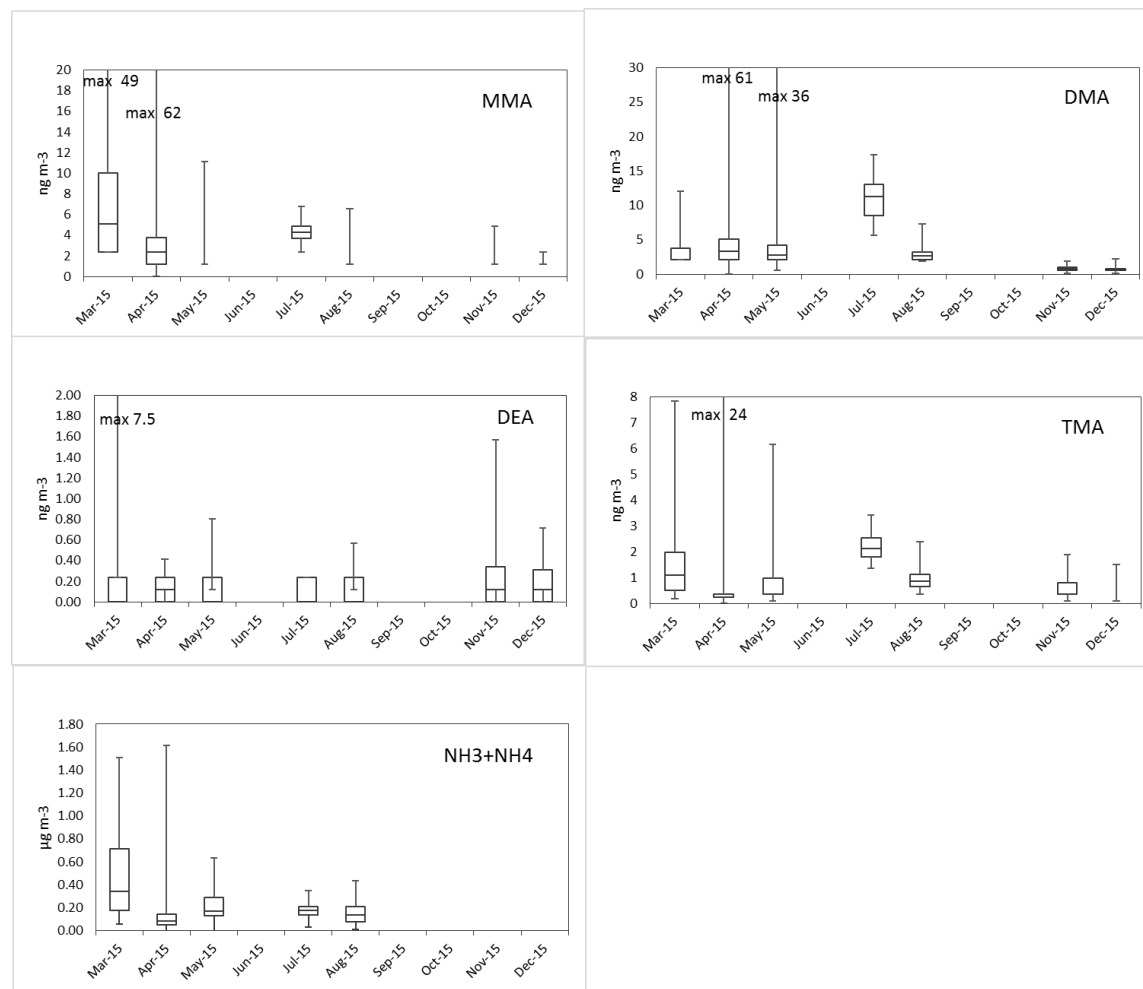

#### 165 3.1 Variability of the concentrations

Figure 1 shows the monthly means and medians of total amine concentrations (sum of gas and aerosol phases) and Figure 2 shows the box and whisker plots to describe the statistics of the measured concentrations. Amines were mainly in aerosol phase (Table 3 and 4). Different seasonal patterns were found for different amines and they are described below.

170

Figure 1. Monthly means of total amine and summed up ammonia and ammonium ( $\text{NH}_3+\text{NH}_4^+$ ) concentrations ( $\text{ng}/\text{m}^3$ ).  $\text{NH}_3+\text{NH}_4^+$  concentrations have been divided by 100, to fit the scale.

175 Figure 2: Monthly box and whisker plots of the most abundant amines (sum of gas and particle phases) and summed up ammonia and ammonium. Boxes represent second and third quartiles and vertical lines in the boxes median values. Whiskers show the highest and the lowest observations.

180 Table 3. Ratio of gas and aerosol phases. N=number of data above detection limit, ratio=gas/(gas+aerosol).

	DEA	BA	DMA	TMA	PA	EA	MMA	NH <sub>3</sub>

### 3.1.1 MMA

185 A spring maximum was observed for MMA (max. 50 ng m<sup>-3</sup>) and the concentrations correlated with the sum of NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup> (R<sup>2</sup>=0.52, Fig. 3). During spring we observed two occasions when MMA and the sum of NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup> concentrations increased considerably at the same time. The concentration increase in March is characterized with rain (Fig. 4) and the later increase in April took place during night with decreasing wind speed and higher temperature. This increase could be due to evaporation from melting snow and ground.

190

Figure 3. Concentrations ( $\text{ng m}^{-3}$ ) of total MMA (y-axis) vs concentrations of  $\text{NH}_3 + \text{NH}_4^+$  (x-axis) in March and April 2015.

195

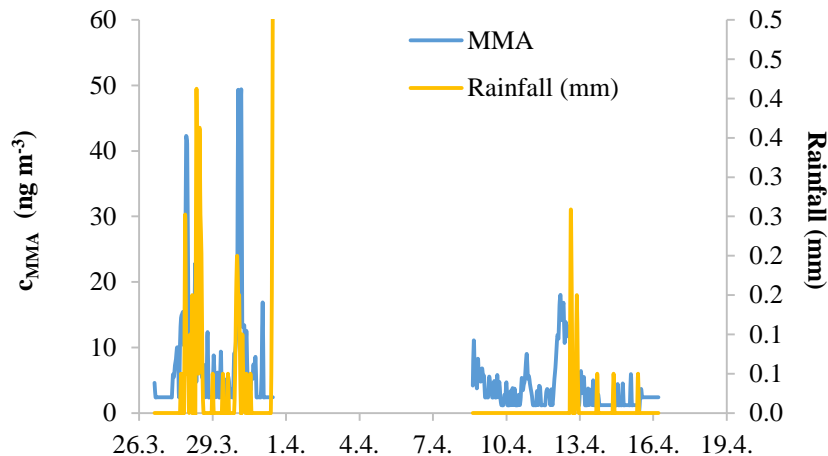

Figure 4: MMA concentrations (gas and aerosol phase) and rainfall measured in Hyytiälä during spring 2015.

Most of the MMA was in particle phase (Table 3 and 4): monthly mean of aerosol phase MMA varied between  $<2.4$  and  $6.8$   $\text{ng m}^{-3}$  (Table 4), while monthly means of gas phase MMA were below DL throughout the measurements. In early winter (late November to early December) MMA was not detected. Ammonia showed similar seasonal variation as MMA with the maximum in March and lower concentrations towards the end of summer. During spring ammonia was also mainly in aerosol phase. In earlier studies You et al. (2014) detected gaseous MMA with CIMS in Alabama forest in summer, at about

200

205 the same level as our measurements (maximum  $\sim 3.8 \text{ ng m}^{-3}$ ). Also Freshour et al. (2014) measured MMA with AmPMS in 3 different sites in USA, and their mean concentrations were at the same level than ours (4-5 ppt<sub>v</sub>, ca.  $5.1\text{-}6.4 \text{ ng m}^{-3}$ ). Akyüz (2007) took urban outdoor air samples in Turkey during summer times 2004-2005 and winter times 2005-2006, and analysed them later with GC-MS. MMA mean results were  $0.26$  and  $1.30 \text{ ng m}^{-3}$ , respectively. Values are in same level with our measurements. That is surprising, because in urban area there are lots of MMA-sources (e.g. industry and automobiles, Ge et al. 2011), so higher mean concentrations would have been expected.

### 210 3.1.2 TMA

TMA had higher concentrations in March after which they declined, before increasing again in July to their maximum concentrations (Fig. 2). TMA concentrations also peaked at the end of March during rain simultaneously with MMA and the sum of  $\text{NH}_3$  and  $\text{NH}_4^+$  increasing from about  $1.5$  to  $6.0 \text{ ng m}^{-3}$ . During summer measurements TMA increased again concomitant with the sum of  $\text{NH}_3$  and  $\text{NH}_4^+$  in July. This increase was not due to rain, and it happened simultaneously with  
215 the increase in nucleation mode particle concentration. The share of the gas phase was throughout the measurements roughly half of the particle phase concentration (Table 3 and 4). TMA did not show a clear diurnal variation.

Kieloaho et al. (2013) collected filter samples of gaseous amines from the same boreal forest as we did from May to October 2011 and they also measured low concentrations for the sum of TMA and PA in July. In their measurements the  
220 concentrations increased during fall. You et al. (2014) measured gaseous  $\text{C}_3$ -amines (TMA and PA) with CIMS in a forest in Alabama from June to early July in 2013 and their highest concentration ( $\sim 15$  ppt<sub>v</sub>, ca.  $36 \text{ ng m}^{-3}$ ) was  $\sim 10$  times higher than ours ( $3.5 \text{ ng m}^{-3}$ ). Dawson et al. (2014) collected TMA-samples in ion resin cartridges from late August to middle September near cattle farm in Chino, California, and analysed the samples with IC. Their results varied from  $1.3\text{-}6.8 \text{ ppm}_v$  (ca.  $3.1\text{-}16.4 \mu\text{g m}^{-3}$ ), so they measured  $\sim 1000$  times higher concentrations than we did. This is not surprising, because cattle are a known  
225 source of amines. Sellegri et al. (2014) measured amines in March 2002 with CIMS in same boreal forest than we did. They found TMA with mixing ratios  $34\text{-}80$  ppt<sub>v</sub> (ca.  $82\text{-}193 \text{ ng m}^{-3}$ ), so their results are  $\sim 30$  times higher than ours. Ambient conditions were different than ours when they measured TMA, and that could be one reason for higher concentrations they observed.

### 3.1.3 EA

230 EA concentrations were low throughout the measurements, but showed a clear diurnal variation in July with a maximum at night (Fig. 5). Monoterpene concentrations were measured simultaneously at the same site and had similar diurnal pattern. This type of diurnal variation is typical for many reactive compounds having local sources in boreal forest (Hakola et al. 2012). Low daytime concentrations are due to efficient mixing and OH radical sink reactions. The rate coefficients of alkyl amines are slightly lower, but comparable to monoterpene reactions with OH radical. The most common monoterpenes in  
235 the boreal forest are  $\alpha$ -pinene, 3-carene and  $\beta$ -pinene (Hakola et al. 2012). Their OH radical rate coefficients are  $53.7 \cdot 10^{-12}$ ,

88·10<sup>-12</sup>, and 78.9·10<sup>-12</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, respectively (Atkinson 1994), whereas MMA, EA, DMA and TMA rate coefficients with OH radicals are 22.26·10<sup>-12</sup>, 29.85·10<sup>-12</sup>, 65.53·10<sup>-12</sup>, and 69.75·10<sup>-12</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, respectively (U.S. EPA, 2017). Similar diurnal patterns and reactivities indicates that EA has a biogenic source. Kürten et al. (2016) measured C<sub>2</sub>-amines (i.e. DMA and EA) with CI-APi-TOF in Germany near 3 dairy farms and forest from May to June 2014. They did not observe clear diurnal variation for C<sub>2</sub>-amines. In our measurements, EA and DMA had opposite diurnal variations (see chapter 3.1.4). That could be the one reason for results of Kürten et al. (2016).

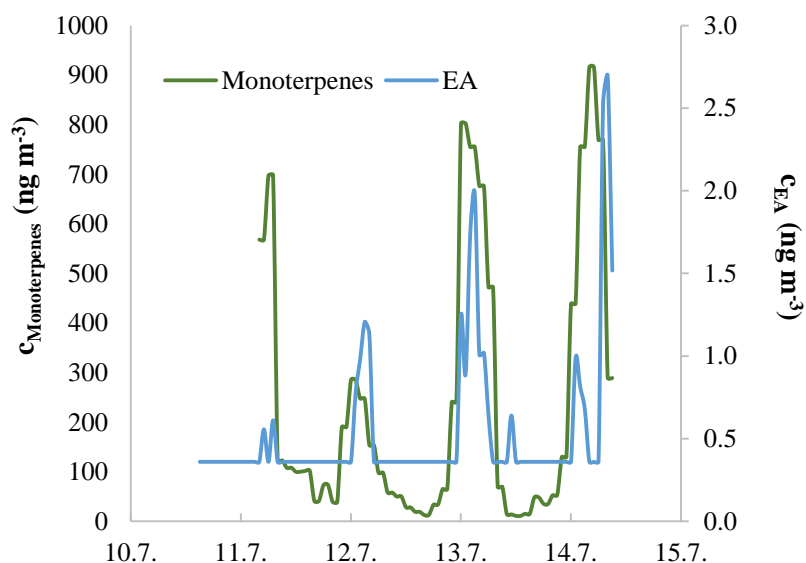

Figure 5. Total EA and monoterpene concentrations in Hyytiälä in July 2015.

### 3.1.4 DMA

DMA concentrations also increased from about 3 to 6 ng m<sup>-3</sup> during the MMA episode in April. Moreover, both particulate and gas phase DMA had maximum concentrations in July (highest value in particle phase 14.5 ng m<sup>-3</sup> and in gaseous phase 7.5 ng m<sup>-3</sup>). The particulate fraction was again generally more abundant than the gaseous fraction average. Because amines can be expected to partition in the aqueous aerosols (Ge et al. 2010), it is not surprising to find them mostly in the particle phase, considering the high average relative humidity measured (<68%). In August the concentrations decreased, and they were lowest during early winter. Kieloaho et al. (2013) measured also high gas phase concentrations of the sum of DMA and EA in July, reaching a maximum of ~75 ppt<sub>v</sub> (ca. 138 ng m<sup>-3</sup>). In their measurements the concentration levels decreased in August similar to our measurements. High DMA and TMA concentrations in summer could indicate biogenic sources. However, these amines concentrations did not correlate with monoterpene concentrations like EA, although they react faster

with OH radicals than EA (see chapter 3.1.3). VandenBoer et al. (2011) measured gaseous DMA with AIM-IC from late June to early July 2009 in an urban area, with highest concentration of 2.5 ppt<sub>v</sub> (ca. 4.6 ng m<sup>-3</sup>) which was at the same level as our gaseous DMA in July (7.5 ng m<sup>-3</sup>). Hanson et al. (2011) also measured DMA concentrations with AmpMS in an urban area with a little higher gas phase concentrations (maximum of 10 ppt<sub>v</sub>, ca. 19 ng m<sup>-3</sup>) than in the studies mentioned earlier. Ge et al. (2010) gives DMA also urban sources (e.g. tobacco smoke, automobiles), so that can explain results from Hanson et al. (2011).

In August DMA had diurnal variation with a daytime maximum (Fig. 6), but during some nights the concentrations also increased a bit. The DMA afternoon maxima could be caused by re-emission of DMA that has earlier deposited on surfaces and evaporates when temperature increases during afternoon. The maximum could also be related to direct biogenic emission. Usually ambient concentrations of biogenic volatile organic compounds peak during nighttime due to inefficient mixing and lack of hydroxyl radical reactions which only take place during daytime (Hakola et al. 2012). The concentrations of light dependent BVOC emissions such as isoprene have daytime maxima because they are emitted only during daytime. Thus, DMA source could be light dependent.

Figure 6. Average diurnal variation of total DMA (blue), total TMA (green) concentrations and temperature (yellow) in August 2015.

### 3.2 Correlation with meteorological parameters and nano-particle concentrations

280 We noticed that especially concentrations of DMA vary with temperature (Fig. 7), so we decided to calculate linear regressions of amines, ammonia and ammonium with different ambient conditions (air relative humidity (RH) and temperature (T) as well as soil temperature (ST) and soil humidity (SH)). Gas phase DMA had the strongest correlation with ambient conditions (Table 5).

285 Figure 7. Time series of DMA, air temperature (air T), soil temperature (ST) and soil humidity (SH) during the whole measurement period.

290

Table 5. Regression statistics ( $y = \beta_1 x + \beta_0$ ) of amine and ammonia concentrations in the gas phase vs. ambient conditions.  $R^2$ : the square of the Pearson's correlation coefficient; s.e.: standard error of  $\beta_1$ ; d.f.: degrees of freedom;  $t = \beta_1/\text{s.e.}$ ; p: p-value of the Student's t distribution; air T: air temperature; RH: relative humidity of air; WS: wind speed at 16.8 m; soil T: soil temperature; soil Hum: soil humidity. The slopes, standard errors and t-values are shown only for those regressions that have a p value  $< 0.1$ . Very low p-values are highlighted by bold font.

295 The results of the linear regression analyses of the amines, ammonia, ammonium, and the ambient conditions are presented  
in Tables 5 and 6. In the gas phase the p values are especially low for DMA vs. any of the ambient condition parameters,  
suggesting that DMA concentrations increase with increasing air temperature, soil temperature and soil humidity but  
decrease with increasing atmospheric humidity and wind speed. The second strongest correlations are those of TMA vs  
environmental conditions. Interestingly, TMA concentration seems to decrease with increasing air and soil temperature,  
opposite to the relationship of DMA vs. temperature. As already mentioned TMA concentrations were high in spring and  
they are likely to originate partly from melting snow and ground, whereas DMA might have biogenic sources in summer,  
300 which could explain different correlation behavior. The ammonia concentration increased with the air temperature in line  
with Makkonen et al. (2014) and decreased with increasing relative humidity. The latter suggests that at high humidity  
surfaces are moist and ammonia gets adsorbed on the water.

305 All the gas phase amines except MMA were found to have positive correlation with soil water content. The studied amines  
are water soluble and therefore negative correlation would be expected if the soil would act only as a sink. However, our  
results suggest that soil processes are producing amines and they may be enhanced with increasing humidity. Forest soils are  
a reservoir of the alkyl amines (Kieloaho et al. 2016) and modelling studies have shown that they can act as a source of alkyl  
amines to the atmosphere (Kieloaho et al. 2017). With their model Kieloaho et al. (2017) found positive correlation with soil  
temperature for soil-to atmosphere flux of DMA, but correlation with soil water content was opposite.

330 In addition to the dependency of amine concentrations on ambient conditions, the relationships between particle number and  
amine concentrations were studied with a similar regression analysis. The amine concentrations were compared with the  
total number concentration integrated from the size distributions measured with the DMPS ( $N_{\text{tot}}$ ), with the particle number  
concentrations in the size ranges 1.1-2 nm and 2-3 nm, measured with the PSM ( $N_{1.1-2\text{nm}}$  and  $N_{2-3\text{nm}}$ , respectively) and with  
the particle number concentrations between 3 and 25 nm measured with the DMPS ( $N_{3-25\text{nm}}$ ). The regression analysis results  
335 for the gas-phase amines and aerosol phase amines are presented in Tables 7 and 8, respectively.

The period during which both the MARGA-MS detected gas-phase DMA concentrations above detection limit and the PSM  
detected cluster-mode particles simultaneously was short. There were 33 data points for the regression analysis. There was a  
weak positive correlation between them (Fig. 8) even though the correlation was statistically not significant ( $R^2 = 0.06$ ,  $p =$   
340  $0.18$ , Table 7). The correlation had some dependence on the ambient conditions: air relative humidity (RH) and temperature  
(T) as well as soil temperature (ST) and soil humidity (SH). The correlation was more significant when both soil and air  
were humid ( $\text{RH} > 90\%$ ,  $\text{SH} > 0.3\text{ m}^3\text{ m}^{-3}$ ) but it has to be noted that there were only 10 simultaneous data points at the high  
RH. There was no correlation between the slightly larger particles ( $N_{2-3\text{nm}}$ ) and DMA in the gas phase (Table 7), suggesting  
that DMA took part in the initial steps of particle formation. This is qualitatively in agreement with an experimental CLOUD  
345 chamber study where it has been demonstrated that even very small amounts of DMA greatly enhance the formation of  
nano-particles (Lehtipalo et al., 2016). In the aerosol phase DMA was the only amine that had a statistically significant  
correlation with the cluster-mode particle number concentrations and as for the gas-phase the correlation coefficient was  
higher at high relative humidity (Table 8, Fig. 9). Other ambient condition parameters apparently did not affect this  
relationship (Fig. 8).

350

355 Figure 8. Cluster-mode particle number concentration ( $N_{1,1-2nm}$ ) as a function of dimethyl amine (DMA) concentration in the gas phase, air temperature (T), air relative humidity (RH), soil temperature (ST) and soil humidity (SH).

360 Table 7. Regression statistics ( $y = \beta_1 x + \beta_0$ ) of aerosol number concentrations vs. amine and ammonia concentrations in the gas phase. Detailed column description as in Table 5.  $N_{\text{tot}}$ : particle number concentration integrated from the size distributions measured with the DMPS;  $N_{1,1-2 \text{ nm}}$  and  $N_{2-3 \text{ nm}}$ : particle number concentrations in the size ranges 1.2 – 2 nm and 2 – 3 nm, measured with the PSM;  $N_{3-25 \text{ nm}}$ : particle number concentrations between 3 and 25 nm of the DMPS. The line of DMA(\*) was calculated by using only those data that were measured when RH > 90%.

Figure 9. Cluster-mode particle number concentration ( $N_{1,1-2nm}$ ) as a function of dimethyl amine (DMA) concentration in the aerosol phase, air temperature (T), air relative humidity (RH), soil temperature (ST) and soil humidity (SH).

375 There were considerably more simultaneous data points of the cluster-mode particle number concentration and ammonia ( $\text{NH}_3$ ). The correlation  $N_{1,1-2nm}$  vs.  $\text{NH}_3$  was statistically significant ( $R^2 = 0.13$ ,  $p = 9.1 \cdot 10^{-10}$ , Table 7). In addition, this correlation apparently also depended on the ambient conditions so that in warm ( $T > 15^\circ\text{C}$ ,  $ST > 14^\circ\text{C}$ ) and dry ( $RH < 60\%$ ,  $SH < 0.25 \text{ m}^3 \text{ m}^{-3}$ ) conditions the positive correlation was more obvious (Fig. 10). In the aerosol phase ammonium ( $\text{NH}_4^+$ ) did not correlate at all with the cluster mode particles but positively with the total number concentration (Table 8).

380

Figure 10. Cluster-mode particle number concentration ( $N_{1,1-2nm}$ ) as a function of ammonia ( $NH_3$ ) concentration, air temperature ( $t$ ), air relative humidity (RH), soil temperature (ST) and soil humidity (SH).

385

The other amines did not have any significant correlations with the particles in the smallest particle size ranges.

#### 4. Conclusions

390 In situ amine and ammonia measurements were conducted in SMEAR II station (Hyytiälä, Finland) from March 2015 to  
December 2015, covering altogether about 8 weeks. Concentrations of 7 different amines and ammonia in particle- and gas-  
phase were measured with 1-hour time resolution.

The amines turned out to be a heterogeneous group of compounds; different amines are likely to have different sources. All  
395 amines had higher concentrations in aerosol phase. MMA and TMA concentrations were highest in spring. Melting of snow  
and ground can be the source of these compounds. Measured concentrations of summed up ammonia and ammonium were  
also highest in spring and the share of ammonia increased towards summer.

TMA has an additional maximum simultaneously with DMA during summer, which could indicate biogenic source.  
400 However, unlike EA, they did not show similar diurnal variation as monoterpenes. This missing daytime minimum can be  
due to light dependent biogenic source, or TMA and DMA might be re-emitted from surfaces during daytime, when  
temperature increases.

All amines except MMA are positively correlated with soil humidity, which could indicate humidity dependent production  
405 mechanism. Gas phase DMA correlated with small 1.1-2 nm particles, when both soil and air were humid. It did not  
correlate with slightly bigger particles at all, suggesting that gas phase DMA may be important in new particle formation.
