

Responses to Reviewers

We would like to thank the reviewers for your constructive comments. We have carefully revised this manuscript according to your comments, and the revisions in the revised manuscript were presented in red font. Enclosed please find the point-by-point responses to the reviewers' comments.

Responses to Referee #2's comments

General comment: I would like to thank the authors for the response and their efforts to improve and clarify this manuscript. The supplementary data is very useful and the discussion about the influence of the aerosol microphysics to the SOA formation provides a better understanding of the processes happening during guaiacol oxidation in the presence of SO₂ and seed aerosols. I still have a few comments about some of the updated paragraphs.

Response to comment: Many thanks for your constructive comments and valuable suggestions, which would be much helpful to improve the scientific merits of this manuscript. Your concerns have been carefully addressed in the revised manuscript.

Comment 1: l. 309 please provide the definition of CHO_{gt1}

Response to comment 1: The definition of CHO_{gt1} ion group has been added in the revised manuscript as follows.

Revision in the manuscript:

Line 311, Add: “containing more than one oxygen atom”

Comment 2: 1. 332 I would recommend to clarify this quantification by saying that these values were obtained if considering that all S-containing compounds are organosulfates and having the same response factor and fragmentation as methyl sulfate

Response to comment 2: According to your valuable suggestion, the descriptions of organosulfates concentration have been modified in the revised manuscript, shown in the following revisions.

Revisions in the manuscript:

Lines 335-336, Add: “assuming that all organic S-containing compounds are organosulfates and have the same response factor and fragmentation as methyl sulfate”

Lines 336-339, Change: “the conservative lower-bound concentration of organosulfates increased with the increase of SO₂ concentration, and was in the range of (2.1 ± 0.8) to (4.3 ± 1.7) ng m⁻³, calculated using the method described by Huang et al. (2015), shown in the Supplement.” **To** “the conservative lower-bound concentration of organosulfates was calculated to be in the range of (2.1 ± 0.8) to (4.3 ± 1.7) ng m⁻³ using the method described by Huang et al. (2015) shown in the Supplement, and increased with the increase of SO₂ concentration.”

Comment 3: 1. 340 Is SO₂ favorable for the uptake of low-MW species or at the contrary, sulfuric acid + SOA retain low-MW in the aerosol phase? It could be both.

Response to comment 3: According to your valuable suggestion, this sentence has been rewritten in the revised manuscript as follows.

Revision in the manuscript:

Lines 343-346, Change: “sulfuric acid formed from SO₂ may be favorable of the uptake of water-soluble low-MW species (e.g., small carboxylic acids and aldehydes)”

To “sulfuric acid formed from SO₂ may be favorable for the uptake of water-soluble low-MW species (e.g., small carboxylic acids and aldehydes) and also be helpful to retain them in aerosol phase”

Comment 4: l. 390 add value of O:C ratios in parenthesis

Response to comment 4: The O/C ratios have been added in parenthesis in the revised manuscript as follows.

Revisions in the manuscript:

Line 394, Add: “(0.94–0.99)”

Line 395, Add: “(0.90–0.93)”

Comment 5: l. 507 I would add “physic” and chemistry of SOA formation

Response to comment 5: According to your valuable suggestion, “chemistry” has been changed to “physics and chemistry” in the revised manuscript.

Revision in the manuscript:

Line 513, Change: “chemistry” **To** “physics and chemistry”

Comment 6: Figure 3. I would reverse the colors. Red more SOA and blue less SOA.

Response to comment 6: Colors in Figure 3 have been modified in the revised manuscript according to your valuable suggestion, shown as Figure R1.

Figure R1. Variations in $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio in the presence of various seed particles as a function of SO₂ concentration.

Revision in the manuscript:

Figure R1 has been added in the revised manuscript.

Comment 7: In the supplement:

- (1) 1.54 In Zhang et al., 2014, Avogadro was misspelled to Avagadro. Change to Avogadro and also Boltzman to Boltzmann.
- (2). Figure S7: make sure that the trace (NH₄)₂SO₄ blue triangles is not actually the NaCl data. Because SO₂ concentrations for ammonium sulfate seeds is 33 ppbv and for NaCl is 30 ppbv while in the figure the NaCl trace is higher than the (NH₄)₂SO₄ trace.
- (3). 1. 36 change to mass accommodation coefficient of vapors deposition to the wall
- (4). 1. 38 the coefficient of eddy diffusion will be chamber dependent. The k_e used here is the one corresponding to the chamber used in Zhang et al., 2014. Please explain your choice for this value that may or may not be the best fit for your study.
- (5). Please provide the same discussion for the choice of the mass accommodation

values (to the walls and particles).

Response to comment 7: Thank you very much. The detailed responses to these comments are listed as follows.

(1). “Avagadro” and “Boltzman” have been changed to “Avogadro” and “Boltzmann”, respectively.

(2). Figure traces in Figure S7 have been corrected in the revised Supplement, shown as Figure R2.

Figure R2. Decays of SO₂ as a function of irradiation time with different seed particles.

(3). “Mass accommodation coefficient of eddy diffusion” has been changed to “mass accommodation coefficient of vapors deposition to the wall”.

(4) and (5). We agree that the values of k_e and α_w are chamber dependent. In this work, considering that the chamber volume (30 m³) is very close to that (28 m³) used by Zhang et al. (2014), thus the values of k_e and α_w reported by them were selected to calculate the overall wall loss rate of organic vapor (k_w).

Revisions in the manuscript:

(1). Line 64, Change: “Avagadro” and “Boltzman” To “Avogadro” and “Boltzmann”,

respectively.

(2). Figure R2 has been added in the revised Supplement.

(3). Lines 36-37, Change: “mass accommodation coefficient of eddy diffusion” To “mass accommodation coefficient of vapors deposition to the wall”

(4) and (5). Lines 39-41, Add “Considering that the chamber volume in this work (30 m³) is very close to that (28 m³) used by Zhang et al. (2014), thus the values of k_e and α_w reported by them were applied to calculate k_w .”

Comment 8. The authors are not considering the vapor wall loss as a reversible process. Can you explain this choice? I would expect this process to be reversible.

Response to comment 8: Thank you very much. We agree that the vapor wall loss is a reversible process. In this work, we considered that the equilibrium was established for vapor wall losses after four hours photooxidation, because Matsunaga and Ziemann (2010) and Yeh and Ziemann (2014) reported the rapid equilibrium established within less than an hour for vapor wall losses in Teflon chambers. In addition, assuming that the chamber wall was essential an absorbing medium of infinite extent, the overall wall loss rate of organic vapor (k_w) could be calculated using Eq. (S3) (Zhang et al., 2015), shown in the Supplement. Since this method could not separate the evaporation of adsorbed organic materials from the wall, the effect of vapor wall loss in this calculation might be overestimated. The detailed descriptions have been added in the revised Supplement.

Revision in the manuscript:

Supplement, Lines 41-49, Add: “In addition, we considered that the equilibrium was established for vapor wall losses after 4 hours photooxidation, because Matsunaga and Ziemann (2010) and Yeh and Ziemann (2014) reported the rapid equilibrium established within less than an hour for vapor wall losses in Teflon chambers. Meanwhile, it was assumed that the chamber wall was essentially an absorbing medium of infinite extent. In this case, k_w could be calculated using Eq. (S3) (Zhang et al., 2015). Since this method could not separate the evaporation of adsorbed organic materials from the wall, the effect of vapor wall loss in this calculation might be overestimated.”

Comment 9: Typing errors: I would recommend that the authors read carefully their paper to make sure no typing errors remain in the paper.

l. 69 direct

l. 90 Smog

l. 269 trace of NH_3

l. 329 low-MW

l. 403, 404 change to “might explain”

l. 438 when SO_2 concentration raised from 0 to 30 ppbv for NaCl, M_o increased from 84.91 to 90.89 $\mu\text{g m}^{-3}$ and not from 63.62 to 90.89. Change the percentage too and the same changes has to be done for $(\text{NH}_4)_2\text{SO}_4$.

l. 487 add parenthesis before 26.37

l. 501 attention

1. 576 mass spectrometer

Response to comment 9: We have carefully checked the grammar and typing errors.

The mistakes mentioned above have been corrected in the revised manuscript, listed as follows.

Revisions in the manuscript:

Line 69, Change: “direact” To “direct”

Line 90, Change: “Somg” To “Smog”

Line 270, Change: “trace NH₃” To “trace of NH₃”

Line 331, Change: “low-WM” To “low-MW”

Line 409, Change: “might be potentially explain” To “might explain”

Line 445, Change: “63.62 ± 1.71” To “84.91 ± 2.01”

Line 446, Change: “42.86% and 55.39%” To “7.04% and 16.43%”

Line 448, Change: “63.62 ± 1.71” To “79.44 ± 1.86”

Lines 449-450, Change: “32.58% and 41.34%” To “6.18% and 13.19%”

Line 493, Add: “(”

Line 507, Change: “attenion” To “attention”

Line 590, Change: “aass spectrometer” To “mass spectrometer”

Responses to Referee #3's comments

Comment 1: Thank you for a very careful and thorough response to the suggestions presented in the review. I have one remaining concern: the mass spectra are communicated as being normalized to a sum of intensities of 1. However, when they are subtracted, there is net more intensity on one side. This is especially clear in Figure S13, please also check Figure 7c. If the mass spectra are normalized as described, the sum of the difference intensities should equal zero. Please double check this and the corresponding conclusions drawn from these figures.

Response to comment 1: Thank you very much. We are very sorry not to accurately response your comment in the previous version. In this work, the mass spectra were normalized to the mass concentration of SOA while not the sum intensity, which were obtained directly from AMS data analysis software (ToF-AMS analysis toolkit SQUIRREL 1.57I/PIKA 1.16I version, in Igor Pro version 6.37). Considering that the product distribution and SOA composition were different under different experimental conditions, the sum of difference intensities would not equal to zero. The similar phenomena were also reported by Tuet et al. (2017).

Abstract. 2-Methoxyphenol (guaiacol) is derived from the lignin pyrolysis and taken as a potential tracer for wood smoke emissions. In this work, the effect of SO₂ at atmospheric levels (0–56 ppbv) on secondary organic aerosol (SOA) formation and its oxidation state during guaiacol photooxidation was investigated in the presence of various inorganic seed particles (i.e., NaCl and (NH₄)₂SO₄). Without SO₂ and seed particles, SOA yields ranged from (9.46 ± 1.71) % to (26.37 ± 2.83) % and could be well expressed by a one-product model. According to the ratio of the average gas-particle partitioning timescale ($\bar{\tau}_{g-p}$) over the course of experiment to the vapor wall deposition timescale (τ_{g-w}), the determined SOA yields were underestimated by a factor of ~2 times. The presence of SO₂ resulted in enhancing SOA yield by 14.04 %–23.65 %. With (NH₄)₂SO₄ and NaCl seed particles, SOA yield was enhanced by 23.07 % and 29.57 %, respectively, which further increased significantly to 29.78 %–53.43 % in the presence of SO₂, suggesting that SO₂ and seed particles have a synergetic contribution to SOA formation. The decreasing trend of $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio in the presence of seed particles and SO₂ suggested that more SOA-forming vapors were partitioned onto particle phase, consequently increasing SOA yields. It should be noted that SO₂ was found to be in favor of increasing the carbon oxidation state (OS_C) of SOA, indicating that the functionalization reaction or the partitioning of highly oxidized products onto particles should be more dominant than oligomerization reaction. In addition, the average N/C ratio of SOA was 0.037, which revealed that NO_x participated in the photooxidation process, consequently leading to the formation of organic N-containing

40 compounds. The experimental results demonstrate the importance of SO₂ on the
41 formation processes of SOA and organic S-containing compounds, and also are helpful
42 to further understand SOA formation from the atmospheric photooxidation of guaiacol
43 and its subsequent impacts on air quality and climate.

1 Introduction

Biomass burning is considered as one of the major sources of gas and particulate pollutants in the atmosphere (Lauraguais et al., 2014b; Yang et al., 2016). Therefore, it has significant adverse impacts on regional and global air quality (Bari and Kindzierski, 2016; Lelieveld et al., 2001), climate (Chen and Bond, 2010), and human health (Naeher et al., 2007). The chemical species emitted by biomass burning is mainly dependent on fuel source and combustion conditions (O'Neill et al., 2014). Natural wood is composed of cellulose (40–50 wt.%), hemicelluloses (25–35 wt.%), and lignin (18–35 wt.%) (Nolte et al., 2001). During the burning process, lignin pyrolysis could result in the formation of methoxyphenols, mainly including guaiacol (2-methoxyphenol), syringol (2,6-dimethoxyphenol), and their derivatives (Nolte et al., 2001; Schauer et al., 2001). Due to the high emission rate of methoxyphenols (900–4200 mg kg⁻¹ wood), methoxyphenols are considered as the potential tracers for wood burning (Hawthorne et al., 1989, 1992; Simoneit et al., 1993).

As a representative type of methoxyphenols, guaiacol mainly exists in the gas phase and is widely found in the atmosphere (Schauer et al., 2001). Its emission factor of wood burning is in the range of 172–279 mg kg⁻¹ wood (Schauer et al., 2001). In recent years, the reactivity of gas-phase guaiacol toward OH radicals (Coeur-Tourneur et al., 2010a), NO₃ radicals (Lauraguais et al., 2016; Yang et al., 2016), **Cl** atom (Lauraguais et al., 2014a), and O₃ (El Zein et al., 2015) has been investigated, suggesting that its degradation by OH and NO₃ radicals might be predominant in the atmosphere.

Meanwhile, several studies have reported the significant SOA formation from guaiacol oxidation by OH radicals, produced from the photolysis of the OH precursors (i.e., H₂O₂ and CH₃ONO) (Ahmad et al., 2017; Lauraguais et al., 2014b; Yee et al., 2013). However, SOA formation from the photooxidation of guaiacol in the presence of NO_x has not been investigated without adding the **direct** OH precursor, even though it has been recently reported that the atmospheric level of NO_x could reach up to close 200 ppbv in the severely polluted climate in China (Li et al., 2017).

Although many studies concentrated on the SOA production from the oxidation of volatile organic compounds (VOCs), the reported SOA yields showed high variability for a given precursor (Chu et al., 2016, 2017; Ge et al., 2017a; Lauraguais et al., 2012, 2014b; Ng et al., 2007; Sarrafzadeh et al., 2016; Yee et al., 2013). This variability is mainly dependent on the numerous factors, e.g., pre-existing seed particles, SO₂ level, NO_x level, humidity, and temperature. Two of the critical factors are the impacts of pre-existing seed particles and SO₂ level on SOA formation (Chu et al., 2016, 2017; Ge et al., 2017a). In addition, the atmospheric concentration of SO₂ could be up to close 200 ppbv in the severely polluted atmosphere in China, and SOA from biomass burning and sulfate formation could significantly contribute to severe haze pollution (Li et al., 2017). During the transport process, smoke plumes from biomass burning would be inevitably mixed with suspended particles (e.g., (NH₄)₂SO₄ particles), SO₂, and NO_x in the atmosphere. However, the influences of these co-existed pollutants on the transformation of guaiacol and its SOA formation are still unclear. For these reasons,

the aim of this work was to investigate the SOA formation from guaiacol photooxidation in the presence of NO_x in a 30 m³ indoor smog chamber, as well as the effect of SO₂ on SOA formation with various inorganic seed particles.

2 Experimental section

2.1 Smog Chamber

The photooxidation experiments were performed in a 30 m³ indoor smog chamber (4 m (height) × 2.5 m (width) × 3 m (length)), which was built in a temperature-controlled room located at the Research Center for Eco-Environment Sciences, Chinese Academy of Sciences (RCEES-CAS). Its schematic structure is shown in Fig. S1. Briefly, 120 UV lamps (365 nm, Philips TL 60/10R) were taken as the light source with a NO₂ photolysis rate of 0.55 min⁻¹, which was comparable to the irradiation intensity at noon in Beijing (Chou et al., 2011). A maglev fan installed at the bottom center of the smog chamber was used to mix sufficiently the introduced gas species and seed particles. Temperature (T) and relative humidity (RH) in the chamber were (302 ± 1) K and (39 ± 1) %, respectively. Before each experiment, the chamber was flushed by purified dry zero air for ~36 h with a flow rate of 100 L min⁻¹ until the particle number concentration in the chamber was lower than 20 cm⁻³.

2.2 Experimental procedures

Gas-phase guaiacol was firstly introduced into the chamber by purified dry zero air flowing through the gently heated injector with a known volume of pure liquid guaiacol until guaiacol fully vaporized. Its concentration in the chamber was online monitored

by a high-resolution proton-transfer reaction time-of-flight mass spectrometer (HR-ToF-PTRMS) (Ionicon Analytik GmbH), and was calibrated by a commercial permeation tube (VICI AG INTERNATIONAL Valco Instruments Co., Inc.). When guaiacol concentration was stable, NO and SO₂ were introduced into the chamber by a mass flow meter using purified dry zero air as the carrier gas. Their concentrations were controlled by the injection time preset through the electromagnetic valve, and were measured by a NO_x analyzer (model 42i-TL, Thermo Fisher Scientific, Inc.) and a SO₂ analyzer (model 43i, Thermo Fisher Scientific Inc.), respectively. In this work, the initial ratio (V/V) of guaiacol concentration to NO_x concentration in the chamber was similar in all experiments (~1.2) (Tables 1 and 2). In addition, sodium chloride (NaCl) and ammonium sulfate ((NH₄)₂SO₄) were used as the inorganic seeds. The seed aerosols in the chamber were generated by the atomization of a 0.02 M aqueous solution. Through atomization, the size distribution of seed particles peaked at 51–58 nm was achieved, with a number concentration of 10100–11400 cm⁻³ (Table 2). After gas species and seed particles in the chamber were mixed well, the photooxidation experiment was carried out with the fan turned off. In this work, the OH concentrations in the chamber were $(1.3\text{--}2.2) \times 10^6$ molecules cm⁻³, calculated based on the degradation rate (7.53×10^{-11} cm³ molecule⁻¹ s⁻¹) of guaiacol with OH radicals (Coeur-Tourneur et al., 2010a). The chemicals and gas samples used in this work were described in Supplement.

2.3 Data analysis

The HR-ToF-PTRMS with a time resolution of 1 min was used online to measure the gas phase concentration of guaiacol, and its m/z range was 10–500 in the process of data acquisition. Before data collection, the peaks of the protonated water ($[H_3^{18}O]^+$) and protonated acetone ($[C_3H_7O]^+$) ions at m/z 21.0246 and 59.0491 were used for mass calibration, with the aim to obtain accurate mass determination during experimental process. All data obtained by the HR-ToF-PTRMS were analyzed with the PTR-MS Viewer software (version 3.1.0, IONICON Analytik).

An Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) was applied to online measure the chemical composition of particles and the non-refractory submicron aerosol mass (DeCarlo et al., 2006). For all experiments, the acquisition time of the HR-ToF-AMS was 2 min. The inlet flow rate, ionization efficiency, and particle sizing of the HR-ToF-AMS were calibrated at regular intervals, according to the standard protocols using the size-selected pure ammonium nitrate particles (Drewnick et al., 2005; Jimenez et al., 2003). All data obtained by the HR-ToF-AMS were analyzed by the ToF-AMS analysis toolkit SQUIRREL 1.57I/PIKA 1.16I version, in Igor Pro version 6.37. The size distribution and concentration of particles were monitored by a scanning mobility particle sizer (SMPS), which is composed of a differential mobility analyzer (DMA) (model 3082, TSI Inc.) and a condensation particle counter (CPC) (model 3776, TSI Inc.). Assuming that particles are spherical and non-porous, the average particle density could be calculated to be 1.4 g cm^{-3} using the equation $\rho = d_{va}/d_m$ (DeCarlo et al., 2004), where d_{va} is the mean vacuum

aerodynamic diameter measured by the HR-ToF-AMS and d_m is the mean volume-weighted mobility diameter measured by the SMPS. The mass concentration of particles measured by the HR-ToF-AMS was corrected by the SMPS data in this work using the same method as Gordon et al. (2014). In this work, the wall loss rate (k_{dep}) of $(\text{NH}_4)_2\text{SO}_4$ particles could be expressed as $k_{dep} = 4.15 \times 10^{-7} \times D_p^{1.89} + 1.39 \times D_p^{-0.88}$ (D_p is the particle diameter (nm)), which was measured according to the literature method (Takekawa et al., 2003) and was used to correct the wall loss of SOA. In addition, its wall loss rate was determined at predetermined time intervals, which only had a slight change among different experiments.

2.4 Vapor wall-loss correction

Previous studies have indicated that the losses of SOA-forming vapors to chamber wall can result in the substantial and systematic underestimation of SOA (Zhang et al., 2014, 2015). Therefore, SOA yields obtained in this work were also corrected by vapor wall loss. The effect of vapor wall deposition on SOA yields mainly depends on the competition between the uptake of organic vapors by aerosol particles and the chamber wall (Zhang et al., 2015). Thus, the ratio of the average gas-particle partitioning timescale ($\bar{\tau}_{g-p}$) over the course of experiment to the vapor wall deposition timescale (τ_{g-w}) could be reasonably used to evaluate the underestimation of SOA yields. The detailed calculation of $\bar{\tau}_{g-p}$ and τ_{g-w} was shown in the Supplement.

3 Results and discussion

3.1 SOA yields

A series of experiments were conducted at different guaiacol/NO_x concentrations under atmospheric pressure. The experimental conditions and results are shown in Table 1. SOA yield was calculated to be the ratio of SOA mass concentration (M_o , $\mu\text{g m}^{-3}$) to the consumed guaiacol concentration ($\Delta[\text{guaiacol}]$, $\mu\text{g m}^{-3}$) at the end of each experiment (Kang et al., 2007). The results showed that SOA yield was dependent on the initial guaiacol concentration ($[\text{Guaiacol}]_0$). Higher precursor concentration would result in higher amount of condensable products, subsequently enhancing SOA formation (Lauraguais et al., 2012). In addition, it should be noted that SOA mass could directly affect the gas/particle partitioning via acting as the adsorption medium of oxidation products, thus higher SOA mass generally leads to higher SOA yield (Lauraguais et al., 2014b).

SOA yield (Y) could be represented by a widely-used semi-empirical model based on the absorptive gas-particle partitioning of semi-volatile products, typically calculated using the following equation (Odum et al., 1996):

$$Y = \sum_i M_o \frac{\alpha_i K_{om,i}}{1 + K_{om,i} M_o} \quad (1)$$

where α_i is the mass-based stoichiometric coefficient for the reaction producing the semi-volatile product i , $K_{om,i}$ is the gas-particle partitioning equilibrium constant, and M_o is the total aerosol mass concentration.

The yield curve for guaiacol photooxidation is shown in Fig. 1, obtained by plotting the SOA yield data in Table 1 according to Eq. (1). The yield data were accurately reproduced by a one-product model ($R^2 = 0.97$), while two or more products used in the

model did not significantly improve the fitting quality. The obtained values of α_i and $K_{om,i}$ for one-product model were (0.27 ± 0.01) and $(0.033 \pm 0.008) \text{ m}^3 \mu\text{g}^{-1}$, respectively. In previous studies, the one-product model was widely applied to describe SOA yields from the oxidation of aromatic compounds including methoxyphenols (Coeur-Tourneur et al., 2010b; Lauraguais et al., 2012, 2014b). In this work, this simulation suggests that the products in SOA have similar values of α_i and $K_{om,i}$, i.e., the obtained α_i and $K_{om,i}$ are the average values. The plot shown in Fig. S2 is the relationship between M_o versus $\Delta[\text{guaiacol}]$, of which slope (0.28) is slightly higher than α_i value (0.27). This suggests that the formed low-volatile products almost completely partitioned on the particle-phase according to the theoretical partition model (Lauraguais et al., 2012, 2014b).

In the previous studies, the significant SOA formation from the OH-initiated reaction of guaiacol has been reported (Lauraguais et al., 2014b; Yee et al., 2013). In this work, SOA yields for guaiacol photooxidation range from $(9.46 \pm 1.71) \%$ to $(26.37 \pm 2.83) \%$, shown in Table 1. According to the ratios of $\bar{\tau}_{g-p} / \tau_{g-w}$ (0.61–0.93), the determined SOA yields were underestimated by a factor of ~ 2 times, suggesting that vapor wall loss in the chamber could significantly affect SOA formation. The similar results were reported previously by Zhang et al. (2014), who indicated that SOA yields for toluene photooxidation were substantially underestimated by factors as much as 4 times, caused by vapor wall loss. As shown in Fig. 1, the vapor wall-loss corrected SOA yields were in the range of $(15.24 \pm 0.85) \%$ to $(50.89 \pm 2.87) \%$, and could also be reproduced by a one-product model ($R^2 = 0.96$). This range overlaps SOA yields of

212 0.6 %–87 % for guaiacol oxidation under high NO_x condition (~10 ppmv NO), reported
213 by Lauraguais et al. (2014b), using CH₃ONO as the OH source. Under low NO_x
214 conditions (< 5 ppbv NO), SOA yields for guaiacol oxidation were in the range of
215 44 %–50 %, reported by Yee et al. (2013) using H₂O₂ as the OH source and (NH₄)₂SO₄
216 as seed particles; they also indicated that high NO_x concentration (> 200 ppbv NO)
217 played an opposite role in SOA formation. Overall, the vapor wall-loss corrected SOA
218 yields in this work are well in agreement with those reported previously (Lauraguais et
219 al., 2014b; Yee et al., 2013), but the determined SOA yields are much lower. Therefore,
220 the effect of vapor wall loss on SOA formation should be seriously taken into account.

221 In addition, the average N/C ratio of SOA for guaiacol photooxidation in the
222 presence of NO_x is 0.037, calculated according to the element analysis by the HR-ToF-
223 AMS. This indicates that NO_x incorporates in guaiacol photooxidation. This
224 phenomenon is well supported by the previous studies, which have reported that the
225 nitro-substituted products are the main products of the OH-initiated reaction of guaiacol
226 in the presence of NO_x (Ahmad et al., 2017; Lauraguais et al., 2014b). The relative low
227 volatility of these products could reasonably contribute to SOA formation (Duport et
228 al., 2016; Liu et al., 2016a). The average NO⁺ / NO₂⁺ ratio of SOA from guaiacol
229 photooxidation is 4.08, which is higher than that (2.06–2.54) for ammonium nitrate,
230 determined by the HR-ToF-AMS in this work. The possible explanation might be that
231 nitro-organics and organonitrates both exist in SOA (Farmer et al., 2010; Sato et al.,
232 2010). The relative abundance of organic N-containing compounds could be estimated

from the average N/C ratio. Assuming that the oxidation products in the SOA retain 7 carbon atoms, the yield of organic N-containing compounds is 25.9 %, which is the upper limit due to the possible C—C bond scission during photooxidation process.

3.2 Effect of SO₂ on SOA formation

3.2.1 SOA yields

In China, atmospheric SO₂ concentration is always in the range of several to dozens of ppbv, while in the severely polluted atmosphere it could be up to close 200 ppbv (Han et al., 2015; Li et al., 2017). In addition, a recent field measurement study has reported that the decrease of biogenic SOA mass concentration in the atmosphere has a positive correlation with SO₂ emission controls (Marais et al., 2017). Therefore, the effect of SO₂ at atmospheric levels on SOA formation from guaiacol photooxidation under atmospheric NO_x conditions was investigated. The experimental conditions and results are shown in Table 2. The formation of SOA, sulfate, and nitrate as a function of SO₂ concentration for guaiacol photooxidation is shown in Fig. S3, and the time-series variations in the concentrations of sulfate and nitrate are shown in Fig. S4. The decays of guaiacol, NO_x, and SO₂ are shown in Figs. S5a, S6a, and S7, respectively, which have the similar changing trends for different experiments. As illustrated in Fig. 2, the induction period became shorter with the increase of SO₂ concentration. The similar results caused by SO₂ have also been reported previously (Chu et al., 2016; Liu et al., 2016b). Meanwhile, M₀ for the experiment without SO₂ (Exp. 1 in Table 2) increased from (63.62 ± 1.71) to (71.88 ± 1.43) and (78.59 ± 2.06) μg m⁻³, enhanced by 12.98 %

and 23.53 %, respectively, when SO₂ concentration raised from 0 to 33 and 56 ppbv. The corresponding SOA yields were (21.60 ± 1.27) % and (23.42 ± 1.80) %, respectively. The similar results were reported by previous studies (Kleindienst et al., 2006; Lin et al., 2013; Liu et al., 2016b), which observed the significant enhancement of SOA yields for VOCs oxidation and the photochemical aging of gasoline vehicle exhaust in the presence of SO₂.

As shown in Fig. 3, $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio decreased from 0.82 to 0.71 and 0.61 when SO₂ concentration increased from 0 to 33 and 56 ppbv. It suggests that the formed sulfate via SO₂ oxidation could serve as seed particles (Jaoui et al., 2008) and increase the surface areas of particles (Xu et al., 2016). These roles are favorable to partition more SOA-forming vapors onto particle phase (Zhang et al., 2014), consequently enhancing SOA yields. At the same time, as shown in Fig. S4 and Table 2, the sulfate concentration increased significantly from 7.42 to 17.89 µg m⁻³ when SO₂ concentration increased from 33 to 56 ppbv. Nevertheless, the particle peak attributed to sulfate formed via SO₂ oxidation was not observed by the SMPS during experimental process due to the quick particle growth in the presence of organic vapors. In this work, it is difficult to completely remove **trace of NH₃** from zero air, thus the formed sulfate should be the mixture of H₂SO₄ and (NH₄)₂SO₄. The time-series changes in the concentration of ammonium salt at different SO₂ concentrations are shown in Fig. S8. Its concentration increased obviously with increasing SO₂ concentration, suggesting that the more **amount** of (NH₄)₂SO₄ was produced. The similar results have also been reported

recently by Chu et al. (2016). In addition, the surface area concentration of aerosol particles at the end time were calculated. As shown in Table 2, the final surface area of aerosol particles formed via guaiacol photooxidation increased from 1.25×10^3 to 1.68×10^3 and $2.04 \times 10^3 \mu\text{m}^2 \text{cm}^{-3}$ when SO_2 concentration increased from 0 to 33 and 56 ppbv. The increased surface area could be in favor of outcompeting the wall loss for low-volatility vapors produced from guaiacol photooxidation, i.e., more low-volatility vapors would be diverted from wall loss to the particles, consequently increasing SOA yields (Kroll et al., 2007). This is well supported by the decrease of $\bar{\tau}_{\text{g-p}} / \tau_{\text{g-w}}$ ratio with increasing SO_2 concentration, shown in Fig. 3.

The time-series changes in the mass concentrations of NO^+ and NO_2^+ are shown in Fig. S9a. The mass concentration of NO^+ increased more quickly than that of NO_2^+ , and had a positive correlation with SO_2 concentration. But, compared to the experiment without SO_2 , the presence of SO_2 had little impact on $\text{NO}^+ / \text{NO}_2^+$ and N/C ratios obtained at the end time, shown in Figs. S9b and S10b, respectively. These ratios indicated that organic N-containing compounds were also produced in this system (Farmer et al., 2010; Sato et al., 2010).

3.2.2 Oxidation state of SOA

The average carbon oxidation state ($\text{OS}_\text{C} = 2\text{O}/\text{C} - \text{H}/\text{C}$) of OA is widely used to represent the oxidation degree of atmospheric OA, because it takes into account the saturation level of carbon atoms in the OA (Kroll et al., 2011). As shown in Table 2, increasing SO_2 concentration (0–56 ppbv, Exps. 1–3) leads to the increase of OS_C

(0.11–0.18). The variations in H/C, O/C, and N/C ratios as a function of irradiation time are shown in Fig. S10. In order to further identify the effect of SO₂ on the chemical properties of SOA, positive matrix factorization (PMF) analysis for all AMS data obtained at different SO₂ concentrations over the **courses** of experiments was carried out. Two factors were obtained from the PMF analysis, and their mass spectra are shown in Fig. 4. The organic mass fraction of m/z 44 (CO₂⁺), named f_{44} , was 0.122 for Factor 2, which is higher than that (0.094) for Factor 1. Therefore, Factor 2 was tentatively assigned to the more-oxidized SOA, while Factor 1 was the less-oxidized SOA (Ulbrich et al., 2009). During the photooxidation process, these two factors had different variations as a function of irradiation time. As shown in Fig. S11, Factor 1 increased along with the reaction and then decreased, while Factor 2 had an increasing trend. Compared to Exps. 1 and 2 in Table 2, the higher fraction of Factor 2 mass obtained at 56 ppbv SO₂ (Exp. 3 in Table 2) suggests that the formed SOA mainly consists of more-oxidized products with relatively low volatility. This is well supported by the time-series variations in the fraction of organic ion groups (CH⁺, CHO⁺, and CHO_{gtl}⁺ (**containing more than one oxygen atom**)) (Fig. S12a), which shows the higher fraction of CHO_{gtl}⁺ and lower fraction of CH⁺ obtained at higher SO₂ concentration, consequently resulting in higher OS_C of SOA.

Previous studies mostly reported that the enhancement of SOA yield in the presence of SO₂ was ascribed to the functionalization and oligomerization reactions (Cao and Jang, 2007; Jaoui et al., 2008 ; Liu et al., 2016b; Xu et al., 2016). If the oligomerization

reaction plays a predominant role in the presence of SO₂ which will lead to particle phase H₂SO₄, the carbon number of oligomers will increase but their net O/C or H/C values have little change, consequently resulting in little change in the oxidation state of SOA (Chen et al., 2011). Nevertheless, we observed that SO₂ not only enhanced SOA yields, but also resulted in higher OS_C (Table 2 and Fig. 5). This suggests that the functionalization reaction might be predominant with SO₂, which leads to higher OS_C of products with low molecular weight (MW) (Ye et al., 2018), consequently resulting in an overall increase in OS_C and SOA yields. More recently, Ye et al. (2018) also found the similar results in the ozonolysis of limonene. Fig. S13 shows the differences among the normalized mass spectra of SOA formed at different SO₂ concentrations. As shown in Fig. S13a, the signal fractions from the low-MW species were enhanced significantly in the presence of SO₂, and were much higher than those from the high-MW species (m/z > 300). The similar results were also observed in Fig. S13b when increasing SO₂ concentration. In other words, SO₂ played a more important role in the formation of organic S-containing compounds and the formation or uptake of low-MW species, compared to the formation of high-MW species (i.e., oligomers) that should be reasonably produced via the acid-catalyzed heterogeneous reactions (Cao and Jang, 2007; Jaoui et al., 2008; Liu et al., 2016b; Xu et al., 2016).

In this work, assuming that all organic S-containing compounds are organosulfates and have the same response factor and fragmentation as methyl sulfate, the conservative lower-bound concentration of organosulfates was calculated to be in the range of (2.1

338 ± 0.8) to (4.3 ± 1.7) ng m⁻³ using the method described by Huang et al. (2015) shown
339 in the Supplement, and increased with the increase of SO₂ concentration. This
340 concentration range is close to those derived from the atmospheric oxidation of
341 polycyclic aromatic hydrocarbons and alkane (Meade et al., 2016; Riva et al., 2015).
342 Fig. S14 is the examples of the ions (i.e., CSO⁺, CH₃SO₂⁺, and CH₃SO₃⁺) of methyl
343 sulfate obtained at 56 ppbv SO₂ (Exp. 3 in Table 2). On the other hand, sulfuric acid
344 formed from SO₂ may be favorable for the uptake of water-soluble low-MW species
345 (e.g., small carboxylic acids and aldehydes) and also be helpful to retain them in aerosol
346 phase, which would result in the increase of OS_C. This is well supported by the time-
347 series variations in the concentrations of acetic acid at different SO₂ concentrations
348 measured by the HR-ToF-PTRMS (Fig. S15a), which shows that acetic acid
349 concentration decreased with the increase of SO₂ concentration (0–56 ppbv). These
350 results were in good agreement with those reported by Liggitto et al. (2005) and Liu et
351 al. (2010), who observed that the uptake of organic compounds under acidic conditions
352 would be enhanced significantly. Recently, Huang et al. (2016) have also reported that
353 acetic acid is present in SOA formed via α -pinene ozonolysis and its uptake would
354 increase in the presence of seed particles. In addition, Krapf et al. (2016) have indicated
355 that peroxides in SOA are unstable and liable to decompose into volatile compounds,
356 consequently leading to decrease SOA yield and OS_C. But, Ye et al. (2018) found that
357 the reactions of SO₂ with organic peroxides were the dominant sink of SO₂, initiated by
358 the heterogeneous uptake of SO₂ under humidity condition. These reactions would

result in the formation of organic S-containing compounds, consequently increasing SOA yields and OS_C.

3.3 Effect of inorganic seed particles on SOA formation

Seed particle is one of the critical factors influencing SOA formation (Ge et al., 2017a), thus the effects of inorganic seeds (i.e., NaCl and (NH₄)₂SO₄) on SOA formation from guaiacol photooxidation were investigated. As shown in Fig. 6, the presence of inorganic seed particles could accelerate SOA growth rate at the initial stage of photooxidation (i.e., shorten induction period), followed by the decrease of growth rate along with the reaction, because the presence of inorganic seeds could promote the condensation of SOA-forming organic products and consequently increase SOA formation (Yee et al., 2013). The results showed that M₀ for the experiment without seed particles (Exp. 1 in Table 2) increased from (63.62 ± 1.71) to (79.44 ± 1.86) and (84.91 ± 2.01) µg m⁻³ (Table 2), enhanced by 24.87 % and 33.46 %, respectively, with (NH₄)₂SO₄ and NaCl seed particles. The corresponding SOA yields were (23.31 ± 1.59) % and (24.54 ± 1.73) %, respectively. In previous work, the similar results about the enhancements of SOA formation by NaCl and (NH₄)₂SO₄ seed particles were reported in the oxidation of VOCs (Ge et al., 2017a, 2017b; Huang et al., 2013, 2017). As shown in Fig. 3, $\bar{\tau}_{g-p} / \tau_{g-w}$ ratios with (NH₄)₂SO₄ and NaCl seed particles were 0.62 and 0.54, respectively, which suggested that more SOA-forming vapors were partitioned onto particle phase in the presence of NaCl seed particles (Zhang et al., 2014), consequently resulting in relatively higher SOA yield.

380 As shown in Table 2 and Fig. 6, the SOA mass concentration in the presence of
 381 NaCl seed particles was higher than that in the presence of $(\text{NH}_4)_2\text{SO}_4$ seed particles.
 382 In addition, OS_C of SOA in the presence of NaCl seed particles is 0.29, slightly higher
 383 than that (0.20) in the presence of $(\text{NH}_4)_2\text{SO}_4$ seed particles. Recently, it has been also
 384 reported that the presence of $(\text{NH}_4)_2\text{SO}_4$ and NaNO_3 seed particles could enhance
 385 significantly the oxidation state of SOA, compared to without seed particles (Huang et
 386 al., 2016). In this work, the experimental conditions for seed experiments are almost
 387 the same (Table 2), including reactant concentration, temperature, RH, and the number
 388 and diameter of seed particles. Therefore, the differences in the yield and oxidation state
 389 of SOA were reasonably resulted from the different chemical compositions of SOA in
 390 the presence of different inorganic seeds. As shown in Figs. S12b and S12c, compared
 391 to $(\text{NH}_4)_2\text{SO}_4$ seed particles, the higher fraction of $\text{CHO}_{\text{gtl}}^+$ and lower fraction of CH^+
 392 were obtained with NaCl seed particles, consequently resulting in higher OS_C of SOA.
 393 The time-series evolution of O/C, H/C, and N/C ratios is shown in Figs. S16 and S17,
 394 which indicate that O/C ratios (0.94–0.99) with NaCl seed particles at the end of
 395 experiments are higher than those (0.90–0.93) with $(\text{NH}_4)_2\text{SO}_4$ seed particles. Fig. 7
 396 shows the mass spectra of SOA in the presence of NaCl and $(\text{NH}_4)_2\text{SO}_4$ seed particles
 397 obtained by the HR-ToF-AMS, as well as their difference mass spectrum. As shown in
 398 Fig. 7, f_{44} for SOA in the presence of NaCl seed particles was higher than that obtained
 399 in the presence of $(\text{NH}_4)_2\text{SO}_4$ seed particles, while the mass fractions of m/z 15 (CH_3)
 400 and 29 (CHO) fragments were both lower. The m/z 44 ion (CO_2^+) is mainly contributed

from acids or acid-derived species, such as esters (Ng et al., 2011). The higher f_{44} of SOA with NaCl than $(\text{NH}_4)_2\text{SO}_4$ seed particles suggests that the distribution of highly oxidized small carboxylic acids onto seed particles plays an important role in SOA formation, consequently resulting in higher oxidation state of SOA (Huang et al., 2016; Ng et al., 2011). Compared to $(\text{NH}_4)_2\text{SO}_4$, the hygroscopicity of NaCl is stronger (Ge et al., 2017a; Gysel et al., 2002). The molar ratio of H_2O to NaCl is about 0.1 at 40 % RH, and water is mainly adsorbed on NaCl particles (Weis and Ewing, 1999). Thus, the greater water content on the particle surface could facilitate the uptake of highly oxidized small carboxylic acids onto NaCl particles, which might explain the higher SOA oxidation state observed in the presence of NaCl seed particles (Huang et al., 2016). As shown in Fig. S15, the concentration of acetic acid in the gas phase with NaCl seed particles was lower than that with $(\text{NH}_4)_2\text{SO}_4$ seed particles. It suggests that the uptake of acetic acid on NaCl seed particles might be higher than that on $(\text{NH}_4)_2\text{SO}_4$ seed particles under the similar experimental conditions (i.e., NO_x and guaiacol concentrations, temperature, and RH). Moreover, the adsorbed acid products would also generate H^+ ions, which could catalyze heterogeneous reactions to produce more-oxidized products or oligomers with relatively low volatility (Fig. S18), consequently resulting in the enhancement of SOA formation (Huang et al., 2013, 2017; Cao and Jang, 2007; Jaoui et al., 2008; Liu et al., 2016b; Xu et al., 2016).

In addition, the possible formation of Cl atoms from the photolysis of nitryl chloride ($\text{ClNO}_2 \xrightarrow{h\nu} \text{Cl} + \text{NO}_2$, $k_1 = \sim 10^{-4} \text{ s}^{-1}$) (Mielke et al., 2011) and the reaction

of OH radical with Cl^- ($\text{Cl}^- + \text{OH} \rightarrow \text{Cl} + \text{OH}^-$, $k_2 = \sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$) (Fang et al., 2014) would also initiate a series of reactions to oxidize SOA composition, which might be another reason for higher OS_C observed with NaCl seed particles. According to the rate constant ($10^9 \text{ M}^{-1} \text{ s}^{-1}$) (Fang et al., 2014), the uptake coefficient (3.4×10^{-3}) of OH radicals on NaCl particles (Park et al., 2008), and the concentrations of OH radicals and Cl^- , the concentration of Cl atoms produced from the reaction of OH radical with Cl^- was estimated to be less than $38 \text{ molecules cm}^{-3}$, which was much higher than that from the photolysis of ClNO_2 due to the slow photolysis rate constant of $\sim 10^{-4} \text{ s}^{-1}$ (Mielke et al., 2011). Compared to OH concentration in the chamber, the oxidation of SOA composition by Cl atoms should be insignificant.

3.4 Synergetic effect of SO_2 and inorganic seed particles on SOA formation

According to the former results obtained in this work, it is clearly known that SO_2 and inorganic seed particles both have a positive role in enhancing SOA formation. Therefore, their possible synergetic effects on SOA formation were investigated. Considering the experiments performed under the comparable conditions (Table 2), the results should be reasonably reliable. The decays of guaiacol, NO_x , and SO_2 are shown in Figs. S5, S6, and S7, respectively, which have the similar changing trends for different experiments. Fig. S19 shows the time-series evolution in the sulfate concentration in the presence of different SO_2 concentrations and seed particles, which indicates that sulfate concentration is dependent on SO_2 concentration. As shown in Fig. 8, the addition of SO_2 into the chamber in the presence of inorganic seed particles

significantly promoted SOA formation from guaiacol photooxidation, but had an ignorable impact on the induction period. When SO₂ concentration raised from 0 to 30 and 54 ppbv in the presence of NaCl seed particles, M₀ increased from (84.91 ± 2.01) to (90.89 ± 2.28) and (98.86 ± 2.11) µg m⁻³, enhanced by 7.04 % and 16.43 %, respectively, and the corresponding SOA yields were (26.78 ± 1.97) % and (29.06 ± 1.82) %. For (NH₄)₂SO₄ seed particles, M₀ increased from (79.44 ± 1.86) to (84.35 ± 2.09) for 33 ppbv SO₂ and (89.92 ± 2.31) µg m⁻³ for 54 ppbv SO₂, enhanced by 6.18 % and 13.19 %, respectively, and the corresponding SOA yields were (24.58 ± 1.78) % and (26.37 ± 1.98) %. As shown in Fig. 3, $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio had a decreasing trend when increasing SO₂ concentration in the presence of seed particles, suggesting that the underestimation of SOA yields caused by vapor wall loss was weakened significantly because of the additional sulfate formed from SO₂ oxidation. Thus, inorganic seed particles and SO₂ have a synergistic effect on SOA formation.

As shown in Table 2 and Fig. 5, it should be noted that OS_C of SOA increased in the presence of SO₂, which was well supported by the time-series variations in H/C, O/C, and N/C ratios at different SO₂ concentrations with NaCl and (NH₄)₂SO₄ as seed particles, shown in Figs. S16 and S17. In addition, as shown in Figs. S12b and S12c, the higher fraction of CHO_{gtl}⁺ and lower fraction of CH⁺ were obtained at higher SO₂ concentration, consequently resulting in higher OS_C of SOA. Fig. S20 shows the mass spectra of SOA with NaCl and (NH₄)₂SO₄ as seed particles at different SO₂ concentrations obtained by the HR-ToF-AMS. As illustrated in Fig. S20, SO₂ addition

464 was in favor of increasing the value of f_{44} , suggesting that more products with higher
465 OS_C are produced by the functionalization reaction (Ye et al., 2018). Meanwhile, Table
466 2 shows that the final surface area of aerosol particles increased in the presence of SO_2 ,
467 which played a positive role in diverting more low-volatility vapors from wall loss to
468 the particles, consequently enhancing SOA yields (Kroll et al., 2007). In addition, the
469 presence of inorganic seeds could promote the condensation of SOA-forming organic
470 products and the heterogeneous uptake of SO_2 (Yee et al., 2013), providing favorable
471 conditions for the following reactions. Meanwhile, the higher hygroscopicity of NaCl
472 than $(NH_4)_2SO_4$ might be helpful to dissolve more acid substances on NaCl particle
473 surface (e.g., H_2SO_4 and organic acid), especially in the presence of SO_2 . This
474 hypothesis could be supported by the variations in acetic acid concentration in the
475 presence of different seed particles and SO_2 concentrations (Fig. S15), which shows
476 that acetic acid concentration decreased with the increase of SO_2 concentration (0–54
477 ppbv). The dissolved acid compounds might be helpful to catalyze heterogeneous
478 reactions (Cao and Jang, 2007; Huang et al., 2013, 2017; Jaoui et al., 2008; Liu et al.,
479 2016b; Xu et al., 2016). Figs. S21 and S22 show the differences among the normalized
480 mass spectra of SOA formed at different SO_2 concentrations with various seed particles.
481 The results indicated that the signal fractions from the low-MW species increased
482 significantly in the presence of SO_2 , and were much higher than those from the high-
483 MW species ($m/z > 300$). Compared to Exps. 2 and 3 in Table 2 with no seed particles,
484 the conservative lower-bound concentrations of organosulfates formed with seed

particles were similar and in the range of (2.2 ± 0.7) to (4.6 ± 1.8) ng m⁻³, which might be caused by the similar SO₂ concentrations applied for experiments. With NaCl and (NH₄)₂SO₄ as seed particles, SOA yields and OS_C both increased with the increase of SO₂, suggesting that the functionalization reaction should be more dominant than oligomerization reaction during photooxidation process.

4 Conclusions and atmospheric implications

In this work, SOA formation from guaiacol photooxidation in the presence of NO_x was investigated in a 30 m³ smog chamber. SOA yields for guaiacol photooxidation were in the range of (9.46 ± 1.71) % to (26.37 ± 2.83) %, and could be expressed well by a one-product model. These yields were underestimated by a factor of ~2 times according to $\bar{\tau}_{g-p} / \tau_{g-w}$ ratios. The presence of SO₂ could increase SOA yield and OS_C, indicating that the functionalization reaction should be more dominant than oligomerization reaction. Meanwhile, the similar effect of SO₂ was also observed with NaCl and (NH₄)₂SO₄ seed particles. But, SOA yield and OS_C in the presence of NaCl seed particles were both slightly higher than those in the presence of (NH₄)₂SO₄ seed particles. In addition, the results indicated the synergetic contribution of SO₂ and inorganic seed particles to SOA formation. The decreasing trend of $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio in the presence of seed particles and SO₂ suggested that more SOA-forming vapors were partitioned onto particle phase, consequently increasing SOA yields. The average N/C ratio (0.037) of SOA suggested that NO_x participated in the process of guaiacol photooxidation, resulting in the formation of organic N-containing compounds.

The significant SOA formation from guaiacol photooxidation at the atmospheric levels of SO₂ and NO_x in this work suggests that it should pay more attention to the SOA formation from biomass burning and its subsequent effects on haze evolution, especially in China with nationwide biomass burning, because recent studies have indicated that SOA formed from biomass burning plays an important role in haze pollution in China (Ding et al., 2017; Li et al., 2017). In addition, the results imply that the oxidation of SO₂ and VOCs should be tightly combined, and SO₂ has a direct impact on the physics and chemistry of SOA formation. Although guaiacol concentrations in the chamber study are higher than those in the ambient atmosphere, the results obtained in this work could provide new information for SOA formation from the photooxidation of methoxyphenols, and might be useful for SOA modeling, especially for air quality simulation modeling of the specific regions experiencing serious pollution caused by fine particulate matter. In addition, the results would help to further understand the photochemical aging process of smoke plumes from biomass burning in the atmosphere.

828 ^a The consumed guaiacol concentration at the end of each experiment. ^b N_s is the initial seed number. ^c D_s is the average diameter of seed particles.

829 ^d C_{seed} is the initial concentration of seed. ^e C_{sulfate} is the sulfate concentration formed by SO₂ oxidation. ^f The initial surface area of seed particles.

830 ^g The final surface area of aerosol particles (seed + organic aerosol), measured by the SMPS. ^h The ratio of the average gas-particle partitioning

831 timescale ($\bar{\tau}_{g-p}$) over the course of experiment to the vapor wall deposition timescale (τ_{g-w}). ⁱ M₀ is the mass concentration of SOA. ^j OS_C is the

832 average oxidation state of carbon of SOA.

833

834 **Figure 1.** SOA yield as a function of SOA mass concentration (M_o) for guaiacol
 835 photooxidation in the presence of NO_x at different guaiacol concentrations. The lines
 836 were fit to the experimental data using a one-product model. Values of α and $K_{om,i}$ used
 837 to generate the solid line were (0.27 ± 0.01) and (0.033 ± 0.008) , and their values for
 838 the dot line were (0.52 ± 0.03) and (0.025 ± 0.006) , respectively.

Figure 2. Time-dependent growth curves of SOA mass concentration for guaiacol photooxidation at different SO₂ levels (Exps. 1–3 in Table 2).

Figure 3. Variations in $\bar{\tau}_{g-p} / \tau_{g-w}$ ratio in the presence of various seed particles as a function of SO₂ concentration.

Figure 4. Mass spectra of Factor 1 (a) and Factor 2 (b) for the formed SOA identified by applying PMF analysis to the AMS data, obtained at different SO_2 concentrations over the **courses** of experiments.

849

850 **Figure 5.** OS_C of SOA formed in the presence of various seed particles as a function of

851 SO₂ concentration.

Figure 6. Time-dependent growth curves of SOA mass concentration for guaiacol photooxidation in the presence of inorganic seed particles (Exps. 1, 4 and 7 in Table 2).

Figure 7. Mass spectra of SOA with NaCl (a) and (NH₄)₂SO₄ (b) as seed particles obtained by the HR-ToF-AMS, as well as their difference mass spectrum (c) obtained by a minus b.

Figure 8. Time-dependent growth curves of SOA mass concentration for guaiacol photooxidation in the presence of SO₂ and inorganic seed particles (a: NaCl; b: (NH₄)₂SO₄) (Exps. 4–9 in Table 2).
