11 **Abstract**

12 The relatively short lifetimes of aerosols in the atmosphere result in climatic and health
13 effects that are strongly dependent on intra-annual variations in particle concentrations. While
14 many studies have examined the seasonal variations of regional aerosol optical depth (AOD),
15 understanding the temporal variations in aerosol vertical distribution and particle types is also
16 important for accurate computation of aerosol radiative effects. In this paper, we combine the
17 observations from four satellite-borne sensors and ground-based AOD and fine particle (PM_{2.5})
18 measurements to investigate the seasonal variations of aerosol column loading, vertical
19 distribution, and particle types over three populous regions: the Eastern United States (EUS),
20 Western Europe (WEU), and Eastern and Central China (ECC). In all three regions, column AOD,
21 as well as AOD higher than 800 m above ground level, peaks in summer/spring probably due to
22 accelerated formation of secondary aerosols and hygroscopic growth. However, AOD at height
23 below 800 m mostly peaks in winter except that a second maximum in summer occurs over the
24 EUS region, which is consistent with observed temporal trends in surface PM_{2.5} concentrations.
25 AOD due to fine particles (< 0.7 μm diameter) is much larger in spring/summer than in winter
26 over all three regions, whereas coarse mode AOD (> 1.4 μm diameter) generally shows less
27 variability, except for the ECC region where a peak occurs in spring, consistent with the prevalence
28 of airborne dust during this season. When aerosols are classified according to sources, the
29 dominant type is associated with anthropogenic air pollution, which has a similar seasonal pattern
30 as total AOD. Dust and sea-spray aerosols in the WEU region peak in summer and winter,
31 respectively, but do not show an obvious seasonal pattern in the EUS region. Smoke aerosols, as
32 well as absorbing aerosols, present an obvious unimodal distribution with a maximum occurring

33 in summer over the EUS and WEU regions, whereas they follow a bimodal distribution with peaks
34 in August and March (due to crop residue burning) over the ECC region.

35

36 **1 Introduction**

37 Aerosols have adverse effects on human health (Lelieveld et al., 2015) and play a key role
38 in Earth's climate through aerosol-radiation interactions (McCormick and Ludwig, 1967) and
39 aerosol-cloud interactions (Twomey, 1977; Albrecht, 1989; Garrett and Zhao, 2006). Compared
40 with long-lived climate forcers such as CO₂, aerosols have relatively short lifetimes and hence
41 large spatiotemporal variability (Unger et al., 2008; Shindell et al., 2009). Therefore, the climatic
42 and health effects of aerosols are not only induced by inter-annual concentration changes, but also
43 strongly depend on their intra-annual variability.

44 Aerosol optical depth (AOD) has been widely used to represent the column aerosol loading
45 and to assess the aerosol impacts on radiation, clouds, and precipitation (Ma et al., 2014; Niu and
46 Li, 2012; Zhao et al., 2018b; Song et al., 2017). However, the wide ranges of particle optical
47 properties and size distribution mean that even for the same AOD, different aerosol components
48 have different effects on not only the magnitude, but also the sign, of aerosol radiative forcing
49 (IPCC, 2013; Gu et al., 2006; Garrett et al., 2004). IPCC (2013) estimates that the historical global
50 mean direct radiative forcings due to sulfate, organic carbon (OC), black carbon (BC), and mineral
51 dust are -0.40 , -0.19 , $+0.36$, and -0.10 W m⁻², respectively. Furthermore, absorbing and non-
52 absorbing aerosols have been found to have very different impacts on the surface radiative cooling
53 effects (Yang et al., 2016) and the development of convective clouds (Massie et al., 2016;
54 Ramanathan et al., 2005; Rosenfeld et al., 2008). Besides aerosol type, the aerosol vertical
55 distribution influences its mass concentration within the planetary boundary layer (PBL) (Zheng

56 et al., 2017) and the vertical profile of heating rate (Johnson et al., 2008; Guan et al., 2010; Zhang
57 et al., 2013), which subsequently modifies the atmospheric stability and convective strength
58 (Ramanathan et al., 2007), with potential changes in cloud properties (Johnson et al., 2004).
59 Understanding aerosol variability as a function of height is also important because the indirect
60 effect of aerosols is mainly dependent on those mixed with the clouds (Zhao et al., 2018c).
61 Meanwhile, the health impacts of aerosols are only associated with those present near the surface,
62 where they are inhaled. For these reasons, systematic analyses of the intra-annual variations of
63 aerosol vertical distribution and particle types, in addition to total column AOD, are necessary to
64 improve our understanding of aerosol climatic and health effects.

65 Numerous studies have investigated the seasonal variations of AOD at global and regional
66 scales using satellite observations (e.g., Kim et al., 2007; Song et al., 2009; Mehta et al., 2016;
67 Mao et al., 2014). By comparison, most previous studies of the temporal variations of aerosol
68 vertical distributions and aerosol types have been confined to only a few sites due to coverage
69 limitations associated with reliance on ground-based instruments (e.g., Liu et al., 2012; Matthias
70 et al., 2004). Despite continuous advancement of remote sensing technology and emergence of
71 new spaceborne sensors, only limited number of studies have utilized satellite observations to
72 examine the seasonal variations of aerosol profiles and/or types at regional or larger scales (Huang
73 et al., 2013; Kahn and Gaitley, 2015; Yu et al., 2010; Li et al., 2016). Huang et al. (2013) analyzed
74 the seasonal variations of aerosol extinction profile and type distribution using 5-year observations
75 from the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO). Kahn
76 and Gaitley (2015) examined the spatiotemporal variations of aerosol types retrieved by the Multi-
77 angle Imaging Spectroradiometer (MISR). Different satellite-borne sensors, such as MISR,
78 CALIPSO, and Moderate resolution Imaging Spectroradiometer (MODIS), employ different

79 principles of measurement and retrieval, and therefore provide different sensitivities to column
80 AOD, aerosol types, and vertical profiles. Therefore, integration of data from multiple satellites
81 and ground-based observational networks makes it possible to deepen our understanding of the
82 intra-annual variations of aerosol loadings, profiles, and types.

83 In this study, we investigate the seasonal variations of aerosol column loading, vertical
84 distribution, and particle types using multiple satellite and ground-based observational datasets
85 covering the period from 2007 to 2016. The purpose is to assess the consistency among various
86 datasets and provide a comprehensive characterization of aerosol properties in polluted regions to
87 facilitate future studies of aerosol climate effects and local air quality issues. The data are from
88 MISR, MODIS, CALIPSO, Aerosol Robotic Network (AERONET), and surface PM_{2.5} monitors.
89 Consistent with our previous study (Zhao et al., 2017), we selected three populous regions which
90 have experienced substantial anthropogenic pollution (Wang et al., 2017; Wang et al., 2014) and
91 have received considerable attention in other climate studies: the Eastern United States (EUS; 29°-
92 45° N, 70°-98° W), Western Europe (WEU; 37°-59° N, 10° W-17° E), and Eastern and Central
93 China (ECC; 21°-41° N, 102°-122° E). The geographical boundaries of these regions are shown in
94 Fig. 1.

95 **2 Data and Methods**

96 2.1 Satellite data

97 We obtain retrievals of total column AOD as well as AOD for various height ranges and
98 aerosol types during 2007-2016 from MISR (flying on the Terra satellite), MODIS (Terra and
99 Aqua), and the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) on CALIPSO. The
100 aerosol retrievals from MISR and MODIS are only available for clear-sky conditions in the

101 daytime. CALIPSO provides retrievals during both day and night, but only clear-sky daytime
102 profiles are used in order to be consistent with the products from MISR and MODIS.

103 MISR observes the Earth with moderately high spatial resolution (275 m to 1.1 km) at 9
104 along-track viewing angles in each of 4 visible/near-infrared spectral bands, which enables the
105 partitioning of AOD by particle type over both land and ocean, in addition to retrieval of total
106 AOD (Kahn and Gaitley, 2015; Kahn et al., 2001). Its observations provide near-global coverage
107 every 9 days (Diner et al., 1998). We make use of the Level 3 daily global aerosol product
108 (MIL3DAE) version F15_0031, which is generated at a spatial resolution of $0.5^\circ \times 0.5^\circ$. The
109 variables used in the analysis are total AOD at 555 nm as well as AODs for six aerosol components,
110 namely small ($< 0.7 \mu\text{m}$ diameter), medium (0.7-1.4 μm diameter), large ($> 1.4 \mu\text{m}$ diameter),
111 spherical, non-spherical, and absorbing. Based on comparison with ground-based AERONET
112 measurements, the errors in MISR AOD data are on the order of ± 0.05 or $\pm(0.20 \times \text{AOD})$,
113 whichever is larger (Kahn et al., 2005; Kahn et al., 2010). In addition, retrieval of MISR particle
114 property information from individual retrievals is considered to be reliable when $\text{AOD} > 0.15$, and
115 has diminished sensitivity at smaller AOD (Kahn and Gaitley, 2015; Kahn et al., 2010). In this
116 study we use only monthly mean values, for which the uncertainties are expected to be smaller
117 than those for individual retrievals. Note that we did not do a relative humidity (RH) correction to
118 AOD retrievals from MISR as well as other sensors. The seasonal variations of AOD represent a
119 combined effect of variations in aerosol abundance, vertical distribution, chemical constituents,
120 and meteorological conditions.

121 The MODIS sensors onboard the Terra and Aqua satellites observe the Earth with multiple
122 wavelength bands over a 2330 km swath (King et al., 2003), which provides near-daily global
123 coverage. In this study we obtain column AOD data at 550 nm with a $1^\circ \times 1^\circ$ resolution from the

124 Level 3 daily atmosphere products Collection 6 (MOD08 and MYD08 for the Terra and Aqua
125 platforms, respectively). Comparison studies with AERONET have estimated the accuracy of
126 AOD retrievals to be about $\pm(0.05 + 0.15 \times \text{AOD})$ over land and $\pm(0.03 + 0.05 \times \text{AOD})$ over
127 ocean (Levy et al., 2010; Remer et al., 2005). For both MISR and MODIS data, we calculate
128 regional mean AOD by averaging valid AOD values over all grids within the three target regions.

129 CALIOP is a dual-wavelength polarization lidar on the CALIPSO satellite, and is designed
130 to acquire vertical profiles of aerosols and clouds at 532 and 1064 nm wavelengths [Winker et al.,
131 2007]. CALIPSO flies in formation with Aqua, and all three satellites employed in this paper fly
132 in orbits having 16-day repeat cycles. In addition to vertical extinction profiles, CALIPSO
133 categorizes an aerosol layer as one of seven types based on a number of parameters including
134 altitude, location, surface type, volume depolarization ratio, and integrated attenuated backscatter
135 [Omar et al., 2009]. The seven aerosol types are dust, smoke, clean continental, polluted
136 continental, polluted dust, clean marine, and dusty marine. For most profiles, this aerosol
137 classification is consistent with that derived from AERONET inversion data (Mielonen et al.,
138 2009). In this study, we adopt the Level 2 aerosol profile product (05kmAPro, V4.10), which has
139 an along-track horizontal resolution of 5 km and a vertical resolution of 60 m or 180 m, depending
140 on whether the aerosol height is below or above 20.2 km altitude. We do not use the CALIOP
141 Level 3 product because it is difficult to collocate with AERONET observations (see Section 2.2)
142 due to its coarse resolution ($2^\circ \times 5^\circ$). For each clear-sky profile, we calculate the column AOD at
143 532 nm by vertically integrating extinction coefficients of the features that are identified as
144 “aerosols” and have valid quality control (QC) flags, i.e., $-100 \leq \text{cloud aerosol discrimination}$
145 (CAD) score ≤ -20 , extinction QC = 0/1, and extinction coefficient uncertainty < 99.9 (Huang et
146 al., 2013). In addition, we employ two quality filters used in generating the Level 3 product in

147 order to eliminate features that probably suffer from surface contamination, i.e., near-surface
148 features with large negative extinction coefficients and contaminated features beneath the surface-
149 attached opaque layer (NASA CALIPSO team, 2011). Following the same method, we also bin
150 the 532 nm AODs into various height ranges, i.e., 0-200 m, 200-500 m, 500-800m, 800-1200 m,
151 1200-2000 m, and > 2000 m above ground level (AGL). Finally, we derive monthly mean AODs
152 by averaging all clear-sky aerosol profiles within each month over the three target regions.
153 Although aerosol extinction coefficients with heights below 200 m AGL are considered to be
154 uncertain despite the application of quality filters (NASA CALIPSO team, 2011), we include them
155 for completeness but exercise with caution when interpreting variations of AODs below 200 m. It
156 should be noted that CALIPSO AOD is reported at a different wavelength (532 nm) from those
157 used in the MISR and MODIS products (555 nm and 550 nm, respectively); this slight wavelength
158 difference is not expected to affect our conclusions regarding AOD seasonal variations.

159 2.2 AERONET and surface PM_{2.5} data

160 We use AOD observations from AERONET to compare with the AOD seasonal variations
161 derived from satellite datasets. AERONET sunphotometers directly measure AOD at seven
162 wavelengths (approximately 340, 380, 440, 500, 675, 870, and 1020 nm) with an estimated
163 uncertainty of 0.01-0.02 (Holben et al., 2001; Eck et al., 1999), which is much smaller than the
164 uncertainties associated with satellite measurements (Kahn et al., 2010; Levy et al., 2010; Schuster
165 et al., 2012). Therefore, we consider AERONET as “ground truth” for AOD temporal variations.
166 We adopt the AERONET Level 2 Version 2.0 direct-sun measurements of spectral AODs, which
167 are subsequently interpolated to 550 nm using a second-order polynomial fit to $\ln(\text{AOD})$ vs.
168 $\ln(\text{wavelength})$ as recommended by Eck et al. (1999). A fundamental difference between satellite
169 and AERONET AOD observations is that a satellite acquires data at a single overpass time (or

170 spread over 7 minutes for MISR's nine views) and over an extended spatial area in the case of
171 MISR and MODIS, whereas AERONET obtains a time series of point data at each surface station.
172 To match coincident measurements, the AERONET AOD retrievals for each site are averaged
173 within a 2 h window centered on the satellite overpass times (about 10:30 for MISR and
174 MODIS/Terra, and 13:30 for MODIS/Aqua and CALIPSO, depending on site location), and
175 compared with the satellite AOD retrievals in a $1^\circ \times 1^\circ$ grid box (consistent with the grids used in
176 the MODIS Level 3 products) that contains the corresponding AERONET site. Only those days
177 for which a satellite overpasses an AERONET site are used in the comparisons. Since AOD
178 variation has a large spatial correlation length of 40-400 km (Anderson et al., 2003), spatial
179 averaging over a $1^\circ \times 1^\circ$ grid should not bias the seasonal variations of AOD but has the benefit
180 of increase the number of data points with valid AOD retrievals that are used in the comparisons.
181 To assure data quality, only the AERONET sites that span at least 5 years with at least 10 months
182 of valid data in each year are included in the comparison. After screening, 28, 54, and 13 sites are
183 used in our analysis of the EUS, WEU, and ECC regions.

184 To provide additional information on the seasonal variations of satellite-observed aerosol
185 loadings near the surface, we obtain surface $PM_{2.5}$ concentrations from several observational
186 networks over the three target regions. Hourly $PM_{2.5}$ concentrations for 225 sites over the EUS
187 region are achieved from the Air Quality System (AQS), which is a large observational database
188 containing ambient air pollution data collected by the United States Environmental Protection
189 Agency (USEPA), as well as state, local, and tribal air pollution control agencies in the United
190 States (USEPA, 2015). For the ECC region, we obtain hourly $PM_{2.5}$ concentrations from the
191 Ministry of Environmental Protection of China (MEP, <http://datacenter.mep.gov.cn/>), which
192 provides continuous measurements at 496 sites located in 74 major cities in China. Hourly/daily

193 PM_{2.5} concentrations for 52 sites over the WEU region are taken from the European Monitoring
194 and Evaluation Programme (EMEP). Similar to the processing of AERONET data, we only include
195 sites whose data span ≥ 5 years with ≥ 10 months of data in each year, except in the case of the
196 ECC region where at least 2 years' data are required because the PM_{2.5} concentrations have been
197 only publicly available since January 2013.

198 **3 Results and Discussion**

199 3.1 Seasonal variations of column AOD

200 Figure 2 illustrates the monthly variations in column AOD observed by MISR,
201 MODIS/Terra, MODIS/Aqua, and CALIPSO during 2007-2016 in the three target regions. All
202 satellite-borne sensors show that AOD in the EUS region is the highest in summer and lowest in
203 winter, though CALIPSO reports a noticeably smaller difference between the summer and winter
204 extrema compared with the other three satellite instruments. For the WEU and ECC regions, MISR,
205 MODIS/Terra, and MODIS/Aqua also reveal consistent seasonal patterns in which AOD peaks in
206 spring and/or summer and reaches its lowest valley in winter. CALIPSO, however, shows little
207 intra-annual variation in AOD, with small peaks occurring in spring and fall.

208 As described in Section 2.1, MODIS provides near-daily global coverage but MISR and
209 CALIPSO do not. As a result, the monthly mean AOD from different sensors is calculated based
210 on different sets of days, which might lead to uncertainties in the estimation of monthly mean
211 AOD (Colarco et al., 2014; Wang and Zhao, 2017). To rule out the impact of spatio-temporal
212 sampling on seasonal variation patterns, we design two sensitivity cases: a “MODIS/Terra_match
213 MISR” case in which the monthly mean AOD of MODIS/Terra is calculated using only the days
214 when MISR overpasses, and a “MODIS/Aqua_match CALIPSO” case in which the monthly mean
215 AOD of MODIS/Aqua is calculated using only the overpassing days of CALIPSO. The results are

216 illustrated in Fig. 2. In all three regions, the monthly mean AODs are slightly different for
217 “MODIS/Terra” and “MODIS/Terra_match MISR”, but the seasonal variation patterns are largely
218 the same. The same results are found for “MODIS/Aqua” and “MODIS/Aqua_match CALIPSO”.
219 As such, we conclude that sampling has little effect on the AOD seasonal variation patterns
220 reported in this study. In fact, this conclusion is compatible with the findings of Colarco et al.
221 (2014). Colarco et al. (2014) revealed that the spatial sampling artifacts were significant for fine
222 aggregation grid (e.g., 0.5°), but they are reduced at coarse grid scales (e.g., 10°). In this study, we
223 use only the mean AOD over three large regions (about $20^\circ \times 20^\circ$) across 10 years, therefore the
224 sampling artifacts are expected to be even smaller.

225 In view of the substantial differences between CALIPSO and the other three sensors, we
226 compare satellite retrieved AOD seasonal variations with point-based ground measurements from
227 AERONET (Fig. 3). As in other studies, AERONET data are treated as “ground truth” for column
228 AOD due to its smaller uncertainty compared with satellite data (Kahn et al., 2010; Levy et al.,
229 2010; Schuster et al., 2012; Fan et al., 2018). Figure 3 shows that, in all three regions, the AOD
230 seasonal variations measured by AERONET are similar to those retrieved by MISR, MODIS/Terra,
231 and MODIS/Aqua, but are quite different from CALIPSO data. Reasons for the different seasonal
232 patterns between CALIPSO and other sensors will be discussed in Section 3.2. Considering the
233 high accuracy of AERONET, we conclude that AOD peaks in summer/spring and dips in winter.
234 An important reason for the higher AOD in summer is that the stronger radiation and higher
235 temperature accelerate the formation of secondary aerosols (Timonen et al., 2014), including
236 sulfate, nitrate, ammonium, and secondary organic aerosol (SOA). SOA is produced by photo-
237 oxidation of volatile organic compounds (VOCs) and intermediate volatility organic compounds
238 (IVOCs), as well as the chemical aging of primary organic aerosol (Zhao et al., 2016). Another

239 reason is that more abundant water vapor in summer favors the hygroscopic growth of aerosols
240 (Liu et al., 2012; Zheng et al., 2017). The different patterns of long range transport as a function
241 of season is also partly responsible for the seasonable variation of AOD (Tian et al., 2017; Yang
242 et al., 2018; Garrett et al., 2010).

243 While relative patterns of AOD seasonal variations from observations of MISR,
244 MODIS/Terra, and MODIS/Aqua are similar to each other and to those of AERONET, the
245 magnitude of AOD observed by these sensors shows considerable discrepancies. In all three
246 regions, the AOD retrieved from MODIS is larger than that from MISR, consistent with the results
247 of previous studies (de Meij et al., 2012; Zhao et al., 2017; Chin et al., 2014; Kang et al., 2016; Qi
248 et al., 2013). This is most likely due to differences in observing strategy, retrieval algorithms, and
249 spatio-temporal sampling (Kahn et al., 2009). The MISR-retrieved AOD agrees well with the
250 AERONET observations in EUS and WEU regions. In the ECC region, however, MISR
251 underestimates the AERONET AOD, probably because there is less signal from the surface at
252 higher AOD, which creates ambiguity that can result in the algorithm assigning too much of the
253 top-of-atmosphere radiance to the surface (i.e., a higher surface albedo), thereby underestimating
254 the AOD (Kahn et al., 2010). The MODIS/Terra and MODIS/Aqua overestimate the AERONET
255 AOD to some extent in all three regions. The overestimation was also reported in two previous
256 studies (de Meij et al., 2012; Ruiz-Arias et al., 2013) using the level 3 MODIS products (Collection
257 5 or 5.1). We show a relatively larger overestimation than that reported by de Meij et al. (2012)
258 and Ruiz-Arias et al. (2013), partly because we used the AERONET AOD averaged within a 2 h
259 window centered on the satellite overpass times while the two previous studies used the
260 daily/monthly mean AERONET AOD in the comparisons. The daily mean AOD observed by

261 AERONET is about 10% larger than the value during the satellite overpass times (Li et al., 2013).
262 The reasons for the overestimation are yet to be thoroughly elucidated in future studies.

263 3.2 Seasonal variations of aerosol loadings as a function of height

264 In addition to column AOD, the climatic effects of aerosols are also strongly dependent on
265 their vertical distribution. To explore intra-annual variations in aerosol vertical profile, Fig. 4
266 presents CALIPSO-observed monthly variations of AOD as a function of height in the three target
267 regions. A striking pattern is that the AOD seasonal variations are dramatically different at lower
268 and upper heights. Over the WEU and ECC regions, AODs of the vertical layers below 800 m
269 AGL generally peak in winter, while those above 800 m AGL peak in summer/spring. As a result,
270 the CALIPSO-observed column AOD for these two regions presents a rather uniform seasonal
271 pattern. For the EUS region, the maximum AOD above 800 m AGL also occurs in summer;
272 however, AOD below 800 m AGL shows two peaks, one in summer and the other in winter. The
273 integration of various layers thus yields a nearly unimodal distribution with maximum occurring
274 in summer.

275 To provide an independent evaluation of the CALIPSO-observed AOD variations at lower
276 heights, we examine the seasonal variations of near-surface PM_{2.5} concentrations at hundreds of
277 surface monitor locations within the three target regions (Figure 5). The aerosol extinction
278 coefficient, and hence AOD at lower heights is affected by not only the particle mass
279 concentrations, but also aerosol type (absorbing vs. nonabsorbing aerosols, coarse-mode vs. fine-
280 mode aerosols) and meteorological parameters such as RH, wind speed and direction, and
281 planetary boundary layer height (Zheng et al., 2017). Nevertheless, previous studies have reported
282 fairly good correlations between extinction coefficient/low-level AOD and PM_{2.5} concentrations
283 (Cheng et al., 2013; Zheng et al., 2017). For this reason, it is reasonable to qualitatively compare

284 the seasonal variation patterns of near-surface $PM_{2.5}$ concentrations and low-level AOD. We
285 calculate monthly mean $PM_{2.5}$ concentrations using only the days when CALIPSO overpasses an
286 observational site to enable a better comparison. Figure 5 shows that, over the ECC and WEU
287 regions, surface $PM_{2.5}$ concentrations are largest in winter and smallest in summer. In the EUS
288 region, the maximum $PM_{2.5}$ concentration occurs in summer and a second maximum occurs in
289 winter. These trends are generally consistent with the seasonal variations of AOD at low heights,
290 implying that CALIPSO data can generally capture the seasonal changes in low-level aerosol
291 abundance.

292 The aerosol vertical distribution is an important factor in reconciling CALIPSO and other
293 sensors with regard to AOD seasonal variations. MISR, MODIS, and AERONET all measure
294 column-integrated AOD using spectroradiometers, whereas CALIOP is an active lidar which
295 estimates vertically-resolved AOD based on vertical profiles of attenuated backscatter. By
296 comparing CALIPSO with the Atmospheric Radiation Measurement (ARM) program's ground-
297 based Raman lidars, Thorsen et al. (2017) showed that CALIPSO does not detect all relatively
298 significant aerosols due to insufficient detection sensitivity, and that the fraction of aerosols
299 detected in the upper levels (> 800 m AGL) is much smaller than that in the lower levels (< 800 m
300 AGL) because the upper-level aerosols tend to be optically thin. As a result, the CALIPSO-
301 observed AOD seasonal variations are significantly weighted toward lower heights. Note that the
302 aerosols with heights below 200 m AGL are frequently undetected because of surface
303 contamination (Kim et al., 2017; NASA CALIPSO team, 2011), but this does not alter the key
304 feature that the AOD is weighted toward lower heights. Over WEU and ECC regions, the unimodal
305 AOD distributions with a summer peak at higher levels are largely counteracted by the opposite
306 seasonal variations at lower levels, resulting in rather uniform seasonal variations of column AOD.

307 For the EUS regions, due to the bimodal AOD distribution at lower heights, the summer peak in
308 column AOD variations remain but the difference between peak and valley is smaller than implied
309 by the observations of MISR/MODIS/AERONET. Although the integrated CALIPSO column
310 AOD does not agree well with AERONET, it does provide valuable information with respect to
311 seasonal variations of aerosols within a specific height range, since the optical thickness and hence
312 the detection fraction has a smaller variability at a given height. This is supported by the fact that
313 the seasonal mean AOD within a specific height range differs by at most 3 times as a function of
314 season (Fig. 4), while it decreases by about 2 orders of magnitude with an increase of height (Kim
315 et al., 2017; Thorsen et al., 2017). Besides the seasonal variations, the difference in the magnitude
316 of AOD between CALIPSO and other sensors are also largely explained by the undetected aerosol
317 layers by CALIPSO (Kim et al., 2017; Thorsen et al., 2017) as well as the assumed lidar ratios in
318 CALIPSO retrievals (Ma et al., 2013).

319 Why are the AOD seasonal variations different between the lower and upper levels? The
320 atmosphere in winter is generally more stable and vertical mixing is weaker, therefore more
321 aerosols, particularly primary aerosols, are confined to lower heights, resulting in the peak of low-
322 level AOD in winter (Guo et al., 2016; Liu et al., 2012; Zheng et al., 2017). At higher levels, the
323 maximum AOD in summer can be explained by two reasons: (1) more aerosols, especially primary
324 aerosols, are transported to the upper levels in summer due to stronger vertical mixing (Guo et al.,
325 2016; Liu et al., 2012; Zheng et al., 2017), and (2) secondary aerosol formation is more rapid in
326 summer because of stronger radiation and higher temperature, and much of the secondary aerosols
327 are produced in the upper levels (de Reus et al., 2000; Minguillon et al., 2015; Heald et al., 2005).
328 In addition, the seasonal variations of AOD at different vertical levels may also be influenced by
329 the variations of water vapor amount which affects the hygroscopic growth (Liu et al., 2012; Zheng

330 et al., 2017) as well as the seasonal patterns of inter-regional transport of aerosols (Tian et al.,
331 2017; Yang et al., 2018; Garrett et al., 2010).

332 3.3 Seasonal variations of aerosol types

333 Besides column AOD and vertical profiles, another factor influencing aerosol climate
334 impact is aerosol type (i.e., partitioning by size and chemical composition). The MISR and
335 CALIPSO products classify aerosols based on distinct principles of measurement and retrieval
336 algorithms. Analysis of the two datasets in combination can potentially lead to a deeper
337 understanding of the factors driving temporal variations of aerosol type.

338 Figures 6 illustrates the seasonal variations of type-specific AODs retrieved by MISR.
339 MISR distributes AODs into three size ranges, i.e., small ($< 0.7 \mu\text{m}$ diameter), medium ($0.7\text{-}1.4$
340 μm diameter), and large ($> 1.4 \mu\text{m}$ diameter). The ambient aerosols are comprised of primary
341 aerosols (dust, sea-spray aerosols, and primary anthropogenic aerosols) and secondary aerosols
342 (sulfate, nitrate, ammonium, and SOA). Among these constituents, dust and sea-spray aerosols are
343 predominantly coarse particles and secondary aerosols are dominated by very fine particles, while
344 primary anthropogenic aerosols span a large size range, leading to a mean size intermediate
345 between dust/sea-spray and secondary constituents (Seinfeld and Pandis, 2006). Fig. 6 indicates
346 that the small-size AOD is much larger in spring/summer than in winter over all regions, primarily
347 due to accelerated secondary aerosol formation and enhanced hygroscopic growth (see Section
348 3.1). In contrast, large-size AOD generally shows rather uniform distributions, except for the ECC
349 region where a peak occurs in late winter/early spring. AOD of primary anthropogenic aerosols
350 are less influenced by seasonal effects than secondary aerosols, which partly accounts for the rather
351 uniform distributions of large-size AOD. Additionally, the seasonal variations of large-size AOD
352 are also affected by dust and sea-spray aerosols, as discussed below.

353 In contrast to MISR's partitioning of aerosol type by size and absorption, the CALIPSO-
354 retrieved aerosol types are characterized by emission source (Fig. 7). As discussed in Section 3.2,
355 relative variability in CALIPSO-derived AOD at different height ranges appears to be more
356 reliable than integrated column AOD, therefore we show aerosol types below and above 800 m
357 separately in Fig. 7. Particles associated with anthropogenic air pollution (polluted continental and
358 polluted dust) comprise the dominant type in all three regions. The seasonal variation patterns of
359 polluted continental/dust are in accordance with those of the total AOD. Specifically, at higher
360 levels, the maximum AOD of polluted continental/dust aerosols occurs in spring/summer in all
361 regions. At lower levels, however, the maximum occurs in winter (plus a second maximum in
362 summer in EUS).

363 With regard to dust and clean marine (sea-spray) aerosols, the AOD in the EUS region does
364 not show an obvious seasonal pattern. In the WEU region, AOD of dust aerosols peaks in summer,
365 consistent with previous surface-based observational studies which show that dust events in
366 Europe predominantly occur during summer due to transport from the Sahara region (Stafoggia et
367 al., 2016). The AOD of dust is primarily located above 800 m, supporting the conclusion that dust
368 aerosols in WEU mainly originate from long range transport. Since the dust AOD is subject to a
369 large inter-annual variability (denoted by the large error bars in Fig. 7), we use the Student's t-test
370 to demonstrate the statistical significance of the seasonal variations. The dust AOD in summer is
371 statistically larger than that in any other season at the 0.05 level, indicating the robustness of the
372 peak in summer. Contrary to dust, the AOD of sea-spray aerosols in WEU is much higher in winter
373 than in summer, probably because winter is the relative windy season with large low pressure
374 systems over the Atlantic Ocean and the North Sea (Manders et al., 2009). The offset of the
375 opposite variation trends in dust and sea-spray aerosols partly accounts for the rather uniform

376 distributions of large-size AOD in WEU (see Fig. 6). Over the ECC region, sea-spray aerosols
377 make a negligible contribution to total AOD. The dust AOD is much larger in spring than in any
378 other season (significant at the 0.05 level), which is tied to the outburst of springtime Gobi desert
379 dust storms (China Meteorological Administration, 2012). The high dust AOD explains the peak
380 in large-size AOD in spring over the ECC region (see Fig. 6).

381 Smoke aerosols are predominantly located above 800 m in all regions. Over the EUS and
382 WEU regions, smoke aerosols present a unimodal distribution with maximum occurring in summer.
383 The differences between smoke AOD in summer and the other three seasons are all statistically
384 significant at the 0.05 level, except for the difference between summer and spring over the WEU
385 region, which is statistically significant at the 0.10 level. In the ECC region, the smoke AOD
386 follows a bimodal distribution with peaks occurring in March and August and valleys occurring in
387 May and December. The differences between either of the peak months and either of the valley
388 months are statistically significant at the 0.05 level. MISR's independent retrieval of absorbing
389 AOD (Fig. 6) presents a highly similar seasonal pattern (statistically significant at the 0.05 level)
390 as the CALIPSO smoke AOD. In fact, smoke and absorbing aerosols are closely correlated with
391 each other, since smoke consists of a much larger fraction of absorbing aerosols (Dubovik et al.,
392 2002), such as BC and light-absorbing organic aerosol (Kirchstetter and Thatcher, 2012), as
393 compared to other aerosol types. Besides, the MISR absorbing AOD and CALIPSO smoke AOD
394 are also consistent in the order of magnitude. The variability of MISR absorbing AOD (shown in
395 the right Y-axis of Fig. 6) is about 0.002-0.005, while the variability of smoke AOD from
396 CALIPSO is about 0.01-0.03. The smoke AOD includes the contributions of both the absorbing
397 and scattering portions. The MISR absorbing AOD, which is calculated using $\text{total AOD} \times (1 -$
398 $\text{single scattering albedo})$, represents only the absorbing portion but includes contributions from

399 aerosol types other than smoke (Bull et al., 2011). Considering that the single scattering albedo of
400 smoke is about 0.80-0.94 (Dubovik et al., 2002), we are able to reconcile the magnitude of MISR
401 absorbing AOD and CALIPSO smoke AOD. For the preceding reasons, the seasonal patterns of
402 smoke and absorbing aerosols act as a cross-validation and strengthen the reliability of the
403 observed trends. Over the EUS and WEU regions, the largest smoke AOD in summer could be
404 explained by the highest emissions from forest and grassland fires (van der Werf et al., 2017).
405 Over the ECC region, an additional peak occurs in March because agricultural residue burning
406 makes a substantial contribution to total smoke emissions (van der Werf et al., 2017), and such
407 burning takes place more frequently in March due to burning of crop residues left on the fields
408 from the previous growing season (Shon, 2015).

409 **4 Conclusions and implications**

410 This study investigated the seasonal variations of aerosol column loading, vertical
411 distribution, and particle types using multiple satellite and ground-based observational datasets
412 during 2007-2016 over EUS, WEU, and ECC regions. Retrievals from MISR and MODIS reveal
413 that column AOD in all three regions peaks in spring/summer and reaches its low in winter, which
414 is consistent with observations from AERONET. This seasonal pattern is probably explained by
415 accelerated formation of secondary aerosols in spring/summer due to stronger insolation and
416 higher temperature. In contrast, CALIPSO shows a much weaker seasonal variability in column
417 AOD, probably because CALIPSO-retrieved AOD is weighted toward lower heights since some
418 thin aerosol layers in high levels are undetected due to insufficient detection sensitivity. Despite
419 the discrepancy in integrated column AOD, CALIPSO does provide valuable information with
420 respect to intra-annual variations of AOD as a function of height. Over the WEU and ECC regions,
421 AODs of the vertical layers below 800 m generally peak in winter, while those above 800 m mostly

422 peak in summer. For the EUS region, the maximum AOD above 800 m also occurs in summer;
423 however, AOD below 800 m shows two peaks, one in summer and the other in winter. The seasonal
424 variations of AOD at low heights are consistent with seasonal patterns of measured surface PM_{2.5}
425 concentrations.

426 When aerosols are binned into different size ranges, the small-size AOD is much larger in
427 spring/summer than in winter over all three regions. Large-size AOD generally shows rather
428 uniform distributions, except for the ECC region where a peak occurs in spring, consistent with
429 the largest dust AOD in this season. When aerosols are classified according to sources, the aerosols
430 associated with anthropogenic air pollution (as well as mixtures of anthropogenic pollution and
431 dust) are the dominant type in all three regions. AOD of polluted aerosols has a similar seasonal
432 pattern as total AOD. Dust and clean marine aerosols in the WEU region peak in summer and
433 winter, respectively, whereas they do not show an obvious seasonal pattern in the EUS region.
434 Smoke aerosols, which CALIPSO indicates are predominantly located at heights above 800 m,
435 present an obvious unimodal distribution with maximum occurring in summer over EUS and WEU
436 regions, and a bimodal distribution with peaks in August and March over the ECC region. This
437 pattern is in good agreement with the seasonal variations of absorbing AOD derived from MISR.

438 The combination of multiple satellite and ground-based observations facilitate a systematic
439 and deeper understanding of the seasonal variations of aerosols, particularly their vertical and type
440 distribution. Comparison of multiple measurement and retrieval methodologies enables reducing
441 the uncertainties in the estimation of aerosol direct effects by providing improved information
442 about aerosol vertical and type distributions, which significantly affect the aerosol-induced
443 scattering and absorption of radiation. More importantly, the intra-annual variations of vertical
444 distributions and types of aerosols are important for understanding their impact on atmospheric

445 dynamics, cloud fields, and precipitation production. For example, both absorbing and non-
446 absorbing aerosols could invigorate deep convection by serving as cloud condensation nuclei and
447 affect convection by reducing downward solar radiation and causing surface cooling (Rosenfeld
448 et al., 2008). However, absorbing aerosols play unique roles in convection and cloud development
449 by heating the atmosphere. This inhibits convection in most situations (Ramanathan et al., 2005;
450 Massie et al., 2016; Zhao et al., 2018a) but may enhance convection and cloud formation above
451 the PBL (Wang et al., 2013; Bond et al., 2013), depending on the vertical distribution of absorbing
452 aerosols. Finally, the data and variation patterns presented in this study can be used to evaluate
453 and improve model simulations, with the ultimate goal of improving model assessment of the
454 climatic and health effects of aerosols.

720

721 **Figures**

722 **Figure 1.** Target regions for this study: the Eastern United States (EUS), Western Europe (WEU),
723 and Eastern and Central China (ECC).
724

725

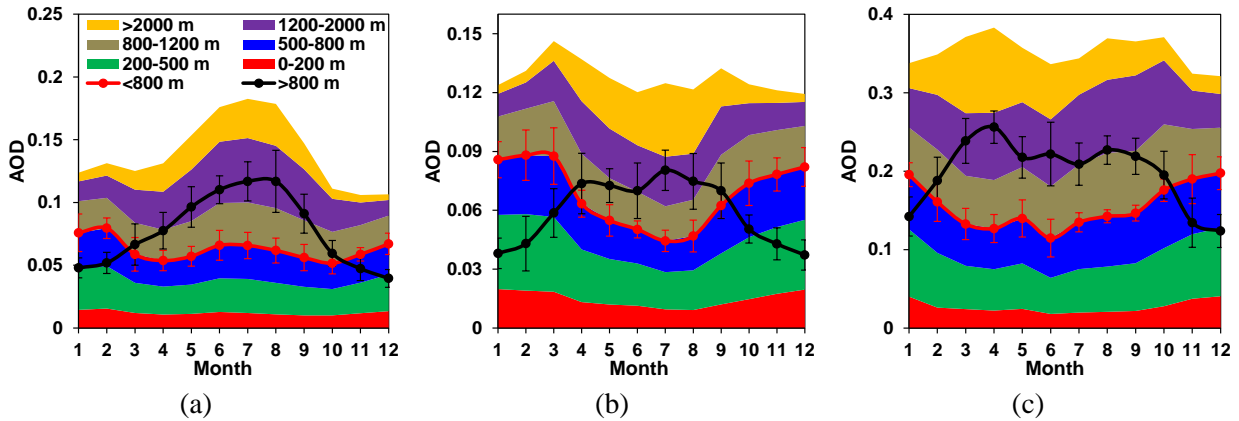

726 **Figure 2.** Monthly mean AOD observed by MISR, MODIS/Terra, MODIS/Aqua, and CALIPSO
727 during 2007-2016 in (a) EUS, (b) WEU, and (c) ECC. For CALIPSO, only clear-sky daytime
728 profiles are averaged in order to be consistent with the MISR and MODIS products.
729 “MODIS/Terra_match MISR” is a sensitivity case in which the monthly mean AOD of MODIS/Terra
730 is calculated using only the days when MISR overpasses, and “MODIS/Aqua_match CALIPSO”
731 is a case in which the monthly mean AOD of MODIS/Aqua is calculated using only the

732 overpassing days of CALIPSO. The error bars denote the standard deviation of the monthly mean
 733 AOD values obtained over all years. Note the different scales on the y-axes of the plots.

734

735 **Figure 3.** Monthly mean AOD observed by satellites and AERONET averaged across the
 736 AERONET sites during 2007-2016 in (a) EUS, (b) WEU, and (c) ECC. The observations from
 737 MISR, MODIS/Terra, MODIS/Aqua, and CALIPSO are averaged over $1^{\circ} \times 1^{\circ}$ grid boxes containing
 738 the AERONET sites. The AERONET data are averaged within a 2 h window centered on satellite
 739 overpass times. The numbers of AERONET sites included in analysis are 28, 54, and 13, in the
 740 EUS, WEU, and ECC regions, respectively. Since the four sensors overpass a site in different
 741 days and different times of day, we separately calculate the AERONET data matched to each
 742 sensor (denoted by “AERONET-xxx”). The AERONET curves matched to different sensors are
 743 close in EUS and WEU, partly because there are plenty of sites in these two regions, and the
 744 discrepancy due to the sampling issue is therefore smoothed out. In contrast, there are only 13
 745 AERONET sites in ECC, so there exists larger discrepancy between the AERONET data matched
 746 to different sensors. Note the different scales on the y-axes of the plots.

747 **Figure 4.** Monthly mean AOD as a function of height above ground level observed by CALIPSO
 748 during 2007-2016 in (a) EUS, (b) WEU, and (c) ECC. Only clear-sky daytime profiles are averaged
 749 in order to be consistent with the products of MISR and MODIS. The range of AOD within a
 750 particular height range is depicted by the colored stacks. The integrated AODs for heights below
 751 and above 800 m are shown as solid lines, for which the error bars are defined in the same way
 752 as in Fig. 2. Note the different scales on the y-axes of the plots.

753 **Figure 5.** Monthly mean surface $PM_{2.5}$ concentrations during 2007-2016 in three target regions.
 754 The numbers of observational sites included in averaging are 225, 52, and 496, in the EUS,
 755 WEU, and ECC regions. Note the different scales on the y-axes for EUS/WEU and ECC.

757 **Figure 6.** Monthly mean AOD of different aerosol types observed by MISR during 2007-2016 in
 758 (a) EUS, (b) WEU, and (c) ECC. The size-resolved AODs are depicted by the colored stacks (left
 759 Y-axis); the integration of the three size ranges yields total column AOD, as represented by the
 760 upper edge of the blue color. The AOD of absorbing aerosols is shown as solid lines (right Y-axis),
 761 for which the error bars are defined in the same way as in Fig. 2. Note the different scales on the
 762 y-axes of the plots.

763 **Figure 7.** Monthly mean AOD of different aerosol types (a-c) below 800 m and (d-f) above 800 m
 764 observed by CALIPSO during 2007-2016 in (a, d) EUS, (b, e) WEU, and (c, f) ECC. Only clear-
 765 sky daytime profiles are used in the averaging to be consistent with the products of MISR and
 766 MODIS. The definition of error bars is the same as in Fig. 2. Note the different scales on the y-
 767 axes of the plots.

768 **Table 1.** Summary of the seasonal variations of the total, height-specific, and type-specific AOD

	EUS	WEU	ECC
Total column AOD	Peak in summer	Peak in summer/late spring	Peak in summer/spring
AOD > 800 m AGL	Peak in summer	Peak in summer/late spring	Peak in summer/spring
AOD < 800 m AGL	Two peaks in winter and summer	Peak in winter	Peak in winter
Small-size	Peak in summer	Peak in summer/late spring	Peak in summer/spring
Medium-size	Peak in summer	Peak in summer/late spring	Peak in summer/spring
Large-size	Rather uniform	Rather uniform	Peak in spring
Absorbing	Peak in summer	Peak in summer/late spring	Two peaks in Mar and Aug
Polluted continental/dust	Similar to height-specific total AOD	Similar to height-specific total AOD	Similar to height-specific total AOD
Dust	No obvious seasonal pattern	Peak in summer	Peak in spring
Clean marine	No obvious seasonal pattern	Peak in winter	Negligible amount
Smoke	Peak in summer	Peak in summer/late spring	Two peaks in Mar and Aug
