Contrasting stable water isotope signals from convective and large-scale precipitation phases of
a heavy precipitation event in Southern Italy during HyMeX IOP 13: a modelling perspective

ABSTRACT

The dynamical context and moisture transport pathways embedded in large scale flow and associated with a heavy precipitation event (HPE) in Southern Italy (SI) are investigated with the help of stable water isotopes (SWIs) based on a purely numerical framework. The event occurred during the intensive observation period (IOP) 13 of the field campaign of the Hydrological Cycle in the Mediterranean Experiment (HyMeX) on 15 and 16 October 2012 and SI experienced intense rainfall of 62.4 mm over 27 h with two precipitation phases during this event. The first one (P1) was induced by convective precipitation ahead of a cold front, while the second one (P2) was mainly associated with precipitation induced by large-scale uplift. The moisture transport and processes responsible for the HPE are analysed using a simulation with the isotope-enabled regional numerical model COSMO_{iso}. The simulation at a horizontal grid spacing of about 7 km over a large domain (about 4,300 km × 3,500 km) allows to distinguish the isotopes signal due to local processes or large-scale advection. Backward trajectory analyses based on this simulation show that the air parcels arriving in SI during P1 originate from the North Atlantic, and descend within an upper-level trough over the north-western Mediterranean. The descending air parcels reach elevations below 1 km over the sea and bring dry and isotopically depleted air (median $\delta^{18}\text{O} \leq -25 \text{ ‰}$, water vapour mixing ratio $q \leq 2 \text{ g kg}^{-1}$) close to the surface,

1 which induces strong surface evaporation. These air parcels are rapidly enriched in SWI ($\delta^{18}\text{O} \geq -14 \text{‰}$) and
2 moistened ($q \geq 8 \text{ g kg}^{-1}$) over the Tyrrhenian Sea by taking up moisture from surface evaporation and
3 potentially from evaporation of frontal precipitation. Thereafter, the SWI-enriched low-level air masses
4 arriving upstream of SI are convectively pumped to higher altitudes, and the SWI-depleted moisture from
5 higher levels is transported towards the surface within the downdrafts ahead of the cold front over SI,
6 producing a large amount of convective precipitation in SI. Most of the moist processes (i.e. evaporation,
7 convective mixing) related to the HPE take place during the 18 hours before P1 over SI. Four hours later,
8 during the second precipitation phase P2, the air parcels arriving over SI mainly originate from North Africa.
9 The strong cyclonic flow around the eastward moving upper-level trough induces the advection of a SWI-
10 enriched African moisture plume towards SI and leads to large-scale uplift of the warm air mass along the cold
11 front. This lifts moist and SWI-enriched air (median $\delta^{18}\text{O} \geq -16 \text{‰}$, median $q \geq 6 \text{ g kg}^{-1}$) and leads to gradual
12 rain out of the air parcels over Italy. Large-scale ascent in the warm sector ahead of the cold front takes place
13 during the 72 hours preceding P2 in SI. This work demonstrates how stable water isotopes can yield additional
14 insights into the variety of thermodynamic mechanisms occurring at the meso- and synoptic scales during the
15 formation of a HPE.

16

17 **1. Introduction**

18 The Mediterranean basin is frequently affected by deep convection resulting in heavy precipitation and
19 potentially leading to devastating flash floods. Deep convection generally results from complex multi-scale
20 interactions between large-scale, mesoscale, and microphysical processes. In the north-western Mediterranean,
21 the large-scale patterns associated with heavy precipitation events (HPEs) have been shown to be connected
22 to upper-level troughs, responsible for generating low-level northward flow of marine air masses characterized
23 by high values of equivalent potential temperature and precipitable water (Lin et al., 2001; Martius et al., 2006;
24 Nuissier et al., 2008, 2011; Ricard et al., 2012; Barthlott and Davolio, 2015). In this favourable large-scale
25 situation, organized deep convection can occur and often produces high-impact events, with rainfall amounts
26 larger than 100 mm in less than 6 hours. The origin of the moisture feeding the convective systems is an
27 important research topic that has been addressed using different techniques and tools, such as trajectory and
28 numerical tracer analyses (e.g. Turato et al. 2004; Winschall et al., 2012; Duffourg and Ducrocq, 2013;
29 Winschall et al., 2014; Röhner et al., 2016; Duffourg et al., 2018; Lee et al., 2018). These studies found

1 substantial contributions of subtropical and tropical moisture coming from various sources such as Africa
2 (latitude $\geq 20^\circ\text{N}$) and the extratropical remnants of Atlantic tropical cyclones, among others. More recent
3 studies (e.g. Lee et al. 2016 and 2017), pointed out a significant moisture contribution, one quarter of the total
4 integrated water vapour, from North Africa in the mid-troposphere (3-5 km above sea level, ASL) feeding the
5 deep convective systems together with the local water vapour sources over the Mediterranean in the lower
6 troposphere (below 2 km ASL). Moreover, the importance of intensified evaporation over the Mediterranean
7 Sea surface for HPE has been studied (Duffourg and Ducrocq, 2013; Winschall et al., 2014). The vertical
8 distribution of moisture in the atmosphere is shaped by source, transport, and sink processes, e.g. evaporation
9 and condensation, horizontal and vertical advection, as well as turbulent and convective mixing.

10 To improve our understanding of the water vapour transport upstream of HPEs and the moisture cycling
11 during such events, humidity observations based on measurements of the most abundant stable water isotope
12 (SWI) H_2^{16}O alone can be limited. In this context, the SWI observation of other, less abundant SWIs, i.e. H_2^{18}O
13 and HD^{16}O can provide relevant additional insights (Noone et al., 2012; Pfahl et al., 2012; Aemisegger et al.
14 2015; Galewsky et al., 2016; Sodemann et al., 2017). Heavy and light isotopes of the water molecule are
15 partitioned in a very specific way during phase transitions, leading to an enrichment of the heavier molecules
16 compared to the lighter ones in the phase with the stronger bonds (liquid or ice) and a depletion in vapour.
17 Therefore, they can provide a record of evaporation and condensation cycles along the pathway of air parcels.
18 Moreover SWI are a powerful indicator of phase change conditions in the atmosphere that occur during the
19 transport of air parcels at various scales, evidencing processes such as mixing, evaporation, and condensation,
20 since the fractionation degree follows the meteorological conditions, e.g. temperature and level of saturation
21 (e.g., Sodemann et al., 2017). For instance, low $\delta^2\text{H}$ (typical range between -160 and -180 ‰) or $\delta^{18}\text{O}$ (i.e.
22 range between -20 and -30 ‰) values in atmospheric water vapour at the surface indicate low air mass
23 temperatures and strong rainout of air parcels (e.g. Jacob and Sonntag, 1991; Yoshimura et al., 2010), whereas
24 high $\delta^2\text{H}$ (typical range between -120 and -100 ‰) or $\delta^{18}\text{O}$ (range between -18 and -14 ‰) indicate high air
25 mass temperatures and recent admixture of fresh ocean evaporate. The δ notation describes the concentrations
26 of the heavy isotopes relative to the isotope ratio of the Vienna Standard Mean Ocean Water–RVSMOW, by
27 for instance, $\delta^{18}\text{O} = (\text{Rs}/\text{RVSMOW} - 1) \times 1000$, where $\text{Rs} = [\text{H}_2^{18}\text{O}]/[\text{H}_2^{16}\text{O}]$ is the isotope ratio of a water
28 sample.

29 In the past, some of the most prominent applications of SWIs have been in a paleoclimate context to

1 infer past temperatures and moisture sources from natural archives, for groundwater studies, and in studies
2 investigating the water vapour budget in the stratosphere (Sherwood and Dessler, 2000; Vimeux et al., 2001;
3 Dessler and Sherwood, 2003; Jouzel et al., 2005). The process-based insight provided by the isotope
4 composition of atmospheric water have more recently been extended to synoptic and sub-diurnal timescales
5 and to the lower troposphere, where most atmospheric water vapour resides. Thanks to a tremendous expansion
6 in the number of datasets of water vapour isotopic composition and a substantially improved set of theories
7 and models for interpreting them, the related studies have been expanded during the past several years (*e.g.*
8 Pfahl et al. 2008; Steen-Larsen et al. 2014; Bonne et al. 2014; Aemisegger et al. 2015; Dütsch et al., 2017;
9 Lacour et al., 2017; Christner et al., 2018).

10 Recent studies have shown the unique information about meteorological processes registered in SWI
11 data. For instance, using ground-based SWI measurements and numerical simulations, Pfahl et al. (2012) and
12 Aemisegger et al. (2015) investigated the mixing processes of different air masses, as well as isotope
13 fractionation and equilibration in relationship with precipitation evaporation during the passage of cold fronts.
14 Aemisegger and Papritz (2018) and Aemisegger and Sjolte (2018) showed that the important moisture uptake
15 by cold and dry airstreams during events of strong large-scale ocean evaporation carries a distinct SWI-
16 signature in water vapour. Recent studies (Schneider et al. 2016; Lacour et al. 2017) analysed the influence of
17 the Saharan heat low on the isotopic budget of offshore of West Africa on various temporal and spatial scales,
18 highlighting the importance of the Saharan heat low dynamics on the moistening and the SWI enrichment of
19 air parcels in the free troposphere over the North Atlantic. In addition, Risi et al. (2008) used stable isotopic
20 signals to better understand convective precipitation processes. These previous studies evidenced the
21 usefulness of water vapour isotope data to better understand meteorological processes and moisture transport.
22 Nevertheless, there are still very few studies (Risi et al., 2008 and 2010; Tremoy et al., 2014) focusing on the
23 application of water vapour isotopes to investigate moist processes associated with HPEs at the mesoscale,
24 particularly in the extratropics.

25 SWI measurements are mainly obtained from space-borne retrievals (*e.g.* Schneider et al., 2016; Lacour
26 et al., 2017) and ground-based in-situ laser spectroscopy (*e.g.* Aemisegger et al., 2012). The space-borne
27 measurements provide continuous datasets in space at the global scale with coarse vertical resolution and
28 limited precision. On the other hand, ground-based measurements with high temporal resolution are only
29 available from a few locations and from dedicated field campaigns. In particular, the data availability for the

1 Mediterranean region is very limited. A notable exception is the airborne dataset acquired around Corsica
2 (Sodemann et al., 2017) during the first Special Observing Period of the Hydrological cycle in the
3 Mediterranean Experiment (HyMeX SOP-1, Ducrocq et al., 2014). However, it does not include SWI
4 observations for the days under scrutiny in this paper. Due to these limitations we use a model to demonstrate
5 the usefulness of SWI data for understanding moist processes associated with a Mediterranean HPE.

6 Our study focuses on the transport of moisture associated with a HPE that occurred over southern Italy
7 (SI) on 15–16 October 2012 and produced precipitation over land exceeding 60 mm in 27 h (Fig. 1a). The
8 HPE consists of two precipitation peaks, the first peak in the late afternoon of 15 October and the second peak
9 around midnight on that day. The target HPE occurred during the Intensive Observation Period 13 (IOP 13) of
10 the HyMeX SOP-1. Using a combination of ground-based, airborne and space-borne observations and
11 numerical simulations of this HPE, Lee et al. (2016) investigated the detailed dynamic and thermodynamic
12 environments of the two precipitation phases of the HPE. During Phase 1 (P1), rainfall was connected to
13 convection triggered by local low-level convergence ahead of a cold front and was favoured by moist
14 conditions in the lower troposphere over the Tyrrhenian Sea. Heavy precipitation during Phase 2 (P2) first
15 occurred over Algeria and was favoured by the southerly flow ahead of the upper-level trough and high low-
16 level moisture content and high sea surface temperatures in the Strait of Sicily. The penetration of the mistral
17 over the Mediterranean and SI at the end of 15 October terminated the convective activity. Thanks to the
18 unprecedented data acquired offshore and inland during IOP 13, the detailed moisture structure upstream of
19 the HPE was investigated by Lee et al. (2016). However, the origin and transport pathways of moisture have
20 not been studied to date.

21 Here we investigate these moisture transport processes using trajectory calculations and SWI data
22 obtained from a COSMOiso numerical simulation with 7-km horizontal resolution with parameterized
23 convection. This setup results from a trade-off between having high enough resolution for including detailed
24 dynamics of the mesoscale systems and being able to run efficiently over a large domain that includes the
25 moisture transport from Africa. More importantly, it allows addressing the question we are interested in,
26 namely: which isotope signals are due to local processes, and which are due to large-scale advection? A
27 detailed description of the data and methodology is presented in section 2. Section 3 provides an overview of
28 the meteorological conditions during the two precipitation peaks related to the HPE during IOP 13. Section 4
29 discusses the isotope signals and relates them to the moisture transport history. A summary and a discussion

1 of the findings of the present study are given in section 5.

2

3 **2. Data and method**

4 *2.1. COSMOiso model configuration and simulation*

5 The COSMO model (Steppeler et al., 2003) is a non-hydrostatic, limited-area numerical weather and climate
6 prediction model and is operationally used by several European weather services. The isotope implementation
7 (COSMOiso; Pfahl et al., 2012) is similar to other Eulerian isotope models (e.g. Joussaume et al., 1984; Sturm
8 et al., 2005; Blossey et al., 2010). COSMOiso has already shown its capability to simulate the variations of
9 stable water isotopes at the event-timescale (Pfahl et al., 2012; Aemisegger et al. 2015) as well as in a
10 climatological context (Christner et al. 2018; Dütsch et al. 2018). It includes two additional parallel water
11 cycles for each of the heavy isotopes (H_2^{18}O , HD^{16}O), which are applied only diagnostically and do not
12 influence other components. All prognostic moisture fields, which are simulated by the model in terms of
13 specific humidities, are duplicated twice, representing the specific humidities of H_2^{18}O and HD^{16}O ,
14 respectively. From the prognostic specific humidity fields, the isotope ratios in usual δ -notation can be
15 calculated. Except during phase transition during which isotopic fractionation takes place, the heavy and light
16 isotopes undergo identical processes. A one-moment microphysics scheme is employed while deep convection
17 is parameterised following Tiedtke (1989). In the microphysical scheme, transfer rates between the different
18 water species during the formation of clouds and precipitation are specified. The heavy isotopes are affected
19 by equilibrium fractionation during the formation of liquid clouds, and both non-equilibrium and equilibrium
20 fractionation during the formation of ice clouds (using the predicted super-saturation) as well as the re-
21 evaporation of rain drops. For the parameterisation of moist convection, all physical processes during
22 simulated convective up- and downdrafts affect the heavy isotopes in a similar way as the standard light
23 humidity, again taking into account equilibrium and non-equilibrium fractionation when appropriate. For more
24 details about the physics and isotope parameterisations, the reader is referred to Doms et al. (2011) and Pfahl
25 et al. (2012), respectively.

26 In this study, a horizontal grid spacing of 0.0625° (in a rotated grid), corresponding to about 7 km is
27 used with 40 hybrid vertical levels. The model domain covers the northwestern Mediterranean, the east
28 Atlantic, and the northern African regions (longitude ranging from -16.3 to 22.8°E and latitude ranging from

1 17.3 to 49.2°N, *i.e.* about 4,300 km × 3,500 km). The simulation starts at 00 UTC on 12 October 2012, and
2 runs for 5 days producing output fields every hour. The initial and boundary conditions for the standard
3 variables are provided by the operational analysis data from the European Centre for Medium-Range Weather
4 Forecasts (ECMWF). For the period in October 2012, these data are interpolated to the COSMO grid with a
5 spectral resolution of T1279 and 91 vertical levels. The model boundaries are updated with inputs of the
6 analysis data every six hour, using a relaxation scheme (Davies, 1976). For the water isotopes, initial and
7 boundary data are taken from a historical isotope global circulation model IsoGSM (which is based on the
8 Scripps Experimental Climate Prediction Center’s GSM that was used operationally for medium range
9 forecasts at NCEP) simulation by Yoshimura et al. (2008), who performed these simulations using a nudging
10 technique (see also Pfahl et al., 2012). The Scripps Experimental Climate Prediction Center’s GSM was based
11 on the medium range forecast model used at NCEP for making operational analysis and predictions.

12

13 *2.2. Trajectory calculation*

14 Air parcel backward trajectories (Wernli and Davies, 1997; Sprenger and Wernli, 2015) are calculated using
15 the three-dimensional wind fields from the COSMOiso simulation. In total 1440 trajectories per hourly time
16 step are started from 60 grid points within a box over SI (bounded by 15.2°W, 16.6°W, 39.6°N, 41.3°N; Fig.
17 1) and 24 different vertical levels between 1000 and 400 hPa. The trajectories are computed five days back in
18 time. Note that generally the COSMO trajectories move out of the regional model domain after 3 days. The
19 air parcel position as well as the interpolated conditions ($\delta^{18}\text{O}$, water vapour mixing ratio $-q$, surface
20 evaporation) along the trajectories are written out every hour. In this study, two series of trajectories, starting
21 at the times of the two precipitation peaks (20 UTC on 15 October 2012 and 00 UTC on 16 October 2012;
22 lines in Fig. 2) over SI are discussed.

23

24 *2.3. q - δ analysis*

25 As variations in δ are tied to those in specific humidity q , the q - δ space is often used for the interpretation of
26 the information contained in δ . The theoretical framework for understanding q - δ data is from a series of simple
27 models that describe the mixing and condensation environments (Noone, 2012). A Rayleigh distillation model
28 expressed as $\delta = (\alpha - 1) \ln (q/q_0) + \delta_0$, in which α is the coefficient of fractionation while q_0 and δ_0 are the
29 humidity and the isotopic composition of the water vapour source, is used to described to the isotopic depletion

1 of water vapour that experiences condensation an equilibrium. In this study, q_0 and δ_0 are set to 15 g kg^{-1} and
2 -10 ‰ , respectively. The mixing model is $\delta = q_0 (\delta_0 - \delta_F) 1/q + \delta_F$, in which the subscript F denotes the flux
3 into the volume of interest, here set to -12 ‰ .

4 Mixing and distillation of water vapour with various origins can take place over a wide range of
5 combinations and generate q - δ pairs in between the boundaries of two models. A tropical water vapour source
6 can be used to identify the lower limit of the domain of q - δ pairs in a Rayleigh model. A mixing model,
7 accounting for mixing between upper tropospheric depleted and dry air masses and the tropical boundary layer
8 enriched and humid air masses can be used to define the upper limit of the domain. The large-scale distribution
9 of water vapour isotope ratios results from a balance between the condensation-related depleting effects
10 (linked to Rayleigh processes), mixing of air masses with different isotopic composition during large-scale
11 transport, and the boundary layer source effects leading to an enrichment of air masses by a (Noone 2008;
12 Galewsky and Hurley 2010). Also note that raindrop re-evaporation can lead to q - δ pairs below the Rayleigh
13 distillation model (Worden et al., 2007).

14

15 **3. Overview of meteorological conditions**

16 *3.1 One HPE with two precipitation phases over southern Italy*

17 From 00 UTC on 15 October to 03 UTC on 16 October 2012, the SI area (box marked by ‘SI’ in Figure 1) was
18 affected by a HPE, with two phases of precipitation. The large amount of maximum precipitation (in total 62.4
19 mm over 27 h) recorded by the rain gauge network (Fig.1a) is realistically reproduced by COSMOiso
20 simulation (maximum precipitation of 59 mm, Fig. 1b) both in terms of amplitude and spatial distribution. The
21 temporal evolution of the COSMOiso domain-averaged total precipitation within the SI area (bars in Figure 2)
22 shows precipitation in excess of 10 mm within the SI region between 19 UTC on 15 October and 01 UTC on
23 16 October. The period has two distinct precipitation phases: 1) a convective precipitation phase (**P1**) in the
24 late afternoon (19–21 UTC) on 15 October (dashed line in Fig. 2), and 2) a large-scale precipitation phase (**P2**)
25 just before midnight (22–00 UTC) on that day (solid line). The precipitation associated with P1 is delayed by
26 4 hours in the COSMOiso simulation compared to the precipitation recorded by the rain gauge network, which
27 shows a peak at 16–18 UTC (grey line with dot in Fig. 2), while the precipitation during P2 phase is closely
28 reproduced by the simulation with a good timing (~1 hour early, with the measured peak occurring at 23–01
29 UTC). P1 is related to rain from the convection parameterization, and P2 is related to rain associated with

1 large-scale vertical motion. The model, in contrast to the observations, does not produce two peaks in the total
2 precipitation. These peaks can be seen by looking at the two precipitation types separately. In the following,
3 20 UTC on 15 October and 00 UTC on 16 October are considered as times representative of P1 and P2,
4 respectively, while 16 UTC on 15 October is considered as representative of the pre-HPE conditions.

5

6 *3.2 Distribution of SWI over the Mediterranean*

7 The moisture structure upstream of the HPE studied by Lee et al. (2016) has been further analysed. Three
8 features are highlighted below: 1) the presence of an African moisture plume favouring the efficiency of the
9 convection to produce more precipitation, 2) the significance of the southerly flow from the warmer
10 Mediterranean Sea to the south of Sicily in strengthening the convergence ahead of the cold front, and 3) the
11 role of the extended upper-level trough over southern France and the western Mediterranean in enhancing
12 convection at the leading edge of the surface front. At 16 UTC on 15 October 2012, an upper-level trough,
13 located over south-eastern France, extends to northern Algeria. Sea-level pressure values lower than 1006 hPa
14 can be observed over south-eastern France extending to northern Italy (Fig. 3a) with the associated cyclonic
15 flow seen at 850 hPa. Strong northerly mistral and tramontane winds associated with cold and dry air with
16 $\delta^{18}\text{O}_v$ less than -16‰ and q less than 2 g kg^{-1} (Fig. 4a, b), and low potential temperature θ are located over the
17 Gulf of Lion ($\leq 300 \text{ K}$, dark-blue area in Fig. 3b). Fig. 4a shows two bands of large q values in excess of 6
18 g kg^{-1} at 850 hPa upstream of the HPE, one over the Tyrrhenian Sea ('TY' box in Fig. 3b) where a cold front
19 is located (large gradient of θ in range of $315\text{--}330 \text{ K}$, dashed line in Fig. 3b), and another one across north
20 Africa extending towards SI with south to south-westerly winds where the African moisture plume with the
21 values of $\theta \geq 330 \text{ K}$ is located ahead of the trough (red area in Fig. 3b), ahead of trough. At 600 hPa (Fig. 4c),
22 $\delta^{18}\text{O}_v$ in excess of -25‰ can be seen at the southern edge of the surface cold front. This signature can be
23 explained by the transport of water vapour to higher levels by updrafts along the front. Comparing the maps
24 of q and $\delta^{18}\text{O}_v$ (crescent closed by a dashed line in Fig. 4a–b) reveals an additional band of enriched water
25 vapour ($\delta^{18}\text{O}_v \geq -18 \text{‰}$, Fig. 4b) is found at the southern boundary of the mistral (and the tramontane), in a
26 region of still relatively low q ($\leq 5 \text{ g kg}^{-1}$, Fig. 4a). This SWI-enriched band reflects the moisture brought to
27 higher levels by convective updrafts that develop within the strong mistral outflow over the warm sea surface,
28 typical of cold-air outbreaks. In this region, a band of moderate brightness temperature at $10.8 \mu\text{m}$ ($230\text{--}240$
29 K , altitudes about $5\text{--}6 \text{ km}$) is measured by the Spinning Enhanced Visible and Infrared Imager on board the

1 geostationary Meteosat Second Generation satellite (not shown, see Fig. 4 of Lee et al., 2016). In the
2 simulation, weak precipitation is also produced in this region from clouds located mostly below 5 km above
3 sea level (ASL) (not shown).

4 The hourly evolution of the moist and SWI-enriched air mass over the TY during the period 16–20 UTC
5 can also be seen in Fig. 5, which shows the average $\delta^{18}\text{O}_v$ in 1-km deep layers spanning from 1 to 7 km ASL
6 in the TY region from 09 UTC on 15 October to 09 UTC on 16 October together with the average θ values at
7 850 hPa within TY. From 09 UTC to 19 UTC on 15 October, while the average θ at 850 hPa is consistently
8 high at 322 K, $\delta^{18}\text{O}_v$ between 1 and 5 km ASL increase slightly but $\delta^{18}\text{O}_v$ between 5 and 7 km ASL gradually
9 decrease revealing the arrival of the upper-level trough (Figure 5a).

10 At 20 UTC (Fig. 3c, d), southerly winds ($10\text{--}15\text{ m s}^{-1}$) transport the warm and moist air mass with high
11 θ ($\geq 325\text{ K}$) from the Strait of Sicily to SI, and the convection occurred in the high θ region at the southern
12 edge of the front (dashed line in Fig. 3d). The frontal wind convergence of south-westerly and southerly winds
13 ($10\text{--}15\text{ m s}^{-1}$) can be seen upstream of the HPE at 850-hPa. Meanwhile, the African moisture plume including
14 the SWI-enriched air mass ($q \geq 10\text{ g kg}^{-1}$ and $\delta^{18}\text{O}_v \geq -16\text{‰}$ in Fig. 4d–f) continues to advect toward SI.

15 At 00 UTC, when the trough is located in the southern Tyrrhenian Sea with the low-level mistral air
16 mass ($q \leq 3\text{ g kg}^{-1}$ and $\delta^{18}\text{O}_v \leq -24\text{‰}$ in Fig. 4g–h), strong cyclonic flow can be identified over the SI region
17 while the warm and moist air mass ($\theta \geq 325\text{ K}$) over the Strait of Sicily is continuously advected towards SI
18 (Fig. 3f). Higher up, at 600 hPa, the trough-related, strongly SWI-depleted air masses descending from higher
19 altitudes show $\delta^{18}\text{O}_v$ lower than -45‰ (Fig. 4i). In contrast to the trough, the African moisture plume is
20 associated with large q in excess of 10 g kg^{-1} at 850 hPa level extending to the SI region (Fig. 4g).

21 During the two precipitation phases at 20 UTC and 00 UTC, both θ and $\delta^{18}\text{O}_v$ drop dramatically in the
22 TY region with arrival of the upper-level trough and cold front (Fig. 5a), while the warm and moist air mass
23 with large q and large $\delta^{18}\text{O}_v$, coming from tropical Africa persists upstream of SI (Fig. 5b). As θ decreases from
24 322 to 300 K in TY (Fig. 5a), the $\delta^{18}\text{O}_v$ drops more rapidly at altitudes above 3 km compared to the $\delta^{18}\text{O}_v$ drop
25 seen in lower altitudes, where the trough-related dry airstreams are moistened by SWI-enriched fresh ocean
26 evaporate. The minimum $\delta^{18}\text{O}_v$ increases lowering the altitudes to near surface, for instance, the minimum
27 $\delta^{18}\text{O}_v$ of -23 and -36‰ are seen at 1–2 and 2–3 km ASL respectively, while values lower than -47‰ occur
28 at altitudes above 3 km ASL. The hourly evolution of average $\delta^{18}\text{O}_v$ in the TY region shows the propagation
29 of the surface front and upper-level trough at altitudes of 1–7 km ASL, and the associated subsidence of dry

1 and cold air. It is worth noting that the arrival timing of cold and dry air subsidence in TY, 19–20 UTC, (Fig.
2 5a) corresponds to the onset of precipitation in SI at 19 UTC (vertical bars, Fig. 2). Overall the synoptic
3 evolution simulated by COSMOiso is similar to the one analysed using an observational dataset by Lee et al.
4 (2016).

5

6 **4. SWI distribution during the two precipitation phases**

7 The temporal evolution of the domain-averaged $\delta^{18}\text{O}_v$ in water vapour and q within the SI area at the first
8 model level (approximately 20 m ASL) (Fig. 6) shows the different behaviour during IOP 13. While q increases
9 gradually to 13.5 g kg^{-1} until 19 UTC, just before P1, $\delta^{18}\text{O}_v$ maximizes to -13.6 ‰ at 16 UTC and then
10 decreases during P1 to -15 ‰ . During P2, $\delta^{18}\text{O}_v$ increases shortly to -14.6 ‰ whereas q continues to decrease
11 to 8 g kg^{-1} . The detailed 3-D history and structure of $\delta^{18}\text{O}$ and q of the air parcels associated with P1 and P2
12 over SI will be shown in the following section.

13

14 *4.1. Phase one: the convective phase*

15 *4.1.1. History of air parcels and related SWI evolution*

16 This section aims to investigate the history of the air masses involved in the convective precipitation phase P1.
17 Figure 7 displays the history of air parcel arriving at SI in the layer 800–700 hPa at 20 UTC on 15 October
18 2012. The 3-day backward trajectories in Fig. 7 indicate that the air parcels arriving at SI in the 800–700 hPa
19 layer originated over the North Atlantic. These air parcels remain dry ($q \leq 5 \text{ g kg}^{-1}$) along the track during the
20 3 days except for the last 18 hours before their arrival in SI (Fig. 7a). In the period between 48 and 18 hours
21 before their arrival in SI, the air parcels descend from altitudes of 3–5 km to below 1 km ASL over the
22 Tyrrhenian Sea, and below 2.5 km ASL over the Strait of Sicily (Fig. 7d). This penetration of dry air from
23 upper-levels to the surface enhances surface evaporation, leading to a sharp increase of q and $\delta^{18}\text{O}_v$ (Fig. 7a–c).
24 When the air parcels travel over the sea, e.g. during 24–18 hours, or 18–6 hours before their arrival in SI, the
25 surface evaporation instantly increases. For instance, between 18 and 6 hours before arrival in SI, the median
26 surface evaporation rate along the trajectories doubles from 0.15 to 0.32 mm h^{-1} with a peak 12 hour before
27 the arrival in SI. A few air parcels travel over the Strait of Sicily towards SI where they mix with the moist and
28 SWI-enriched moisture plume from North Africa (Fig. 4d–f). The median of q along the trajectories increases
29 by a factor of 2.5 from 3.8 to 8.4 g kg^{-1} with the peak 10 hour before arrival in SI, whereas the median $\delta^{18}\text{O}_v$

1 value increases from -27 to -18 ‰ (not shown).

2 Figure 8 displays the $q-\delta^{18}\text{O}_v$ scatter diagram along the entire trajectories seen in Fig. 7 at different times
3 before their arrival, showing that q and $\delta^{18}\text{O}_v$ increase rapidly in the last 12 hours before the parcels arrive over
4 SI. Between 60 and 12 hours before their arrival (Fig. 8a, b), q and $\delta^{18}\text{O}_v$ are still relatively small, at around
5 $2-6$ g kg^{-1} and between -25 and -19 ‰, respectively. During the last 12 hours (black star, Fig. 8b), q is about
6 9 g kg^{-1} on average, and the average $\delta^{18}\text{O}_v$ is about -17 ‰. During this time, the $q-\delta^{18}\text{O}_v$ evolution follows a
7 curve that lies close to a typical Rayleigh line for conditions in the Mediterranean (SST of 26°C , dashed line),
8 indicating the onset of precipitation. Several points fall substantially below this Rayleigh distillation line (solid
9 line, Fig. 8b), suggesting a precipitation recycling by partial re-evaporation of rain drops (Worden et al., 2007).

10 Between 6 and 3 hours before their arrival in SI, the upper to low-level trajectories (green to purple dots
11 in Fig. 9a, b) follow a mixing line (dashed line) during their descent while the lowermost trajectories (black
12 and grey dots) are distributed over wider domain and do not follow exactly a Rayleigh distillation line (solid
13 line). This shows that the descending dry air parcels mix with the warm and moist air parcels from lower
14 altitudes, which also increases surface evaporation. During P1 (Fig. 9c), the $q-\delta^{18}\text{O}_v$ evolution at all levels lies
15 on and below the Rayleigh line, suggesting that air parcels are representative of the convective updraft after
16 condensation of the rain drops ($q-\delta^{18}\text{O}_v$ along the Rayleigh curve) and that some air parcels took up the
17 evaporated moisture from falling precipitation.

18

19 *4.1.2. Horizontal SWI distribution*

20 At 20 UTC, the precipitation over SI is associated with multiple a convective line, which extends from SI to
21 the Strait of Sicily (area closed by dashed line in Fig. 10a) and is located ahead of the surface cold front.
22 Westerly and north-westerly winds prevail at 542 m ASL (Fig. 10b) while south-westerly wind is dominant at
23 2455 m ASL (Fig. 10d). Within the precipitation area, lower $\delta^{18}\text{O}_v$ values (≤ -16 ‰) than in the vicinity are
24 found at 542 m ASL while locally higher $\delta^{18}\text{O}_v$ values are found at 2455 m and 5565 m ASL (Fig. 10d, f),
25 indicating the presence of strong and deep convective mixing. This convection causes the vertical transport of
26 SWI-depleted moisture towards the surface within the downdrafts and SWI-enriched moisture is pumped to
27 higher altitudes within the updrafts. This signature is consistent with the temporal evolution of average $\delta^{18}\text{O}_v$
28 in SI. Figure 5b shows a larger $\delta^{18}\text{O}_v$ increase at high altitudes of 4–7 km ASL (green to purple lines in Fig.
29 5b) than at lower altitudes of 1–3 km ASL (black to yellow lines) from 19 to 22 UTC. The SWI-enriched air

1 masses with high $\delta^{18}\text{O}_r$ in rain (≥ -10 ‰), are distributed over the TY region (Fig. 10e) and SWI-enriched air
2 masses with high $\delta^{18}\text{O}_s$ in snow (≥ -16 ‰), are aligned ahead of the cold front over Sicily (Fig 10g). The
3 depletion of water vapour and the enrichment of rain water and snow over the TY indicate the uptaking by the
4 air mass of evaporated moisture from falling hydrometeors.

5 At the same time, the African moisture plume is associated with SWI-enriched vapour with $\delta^{18}\text{O}_v$ in
6 excess of -22 ‰ and SWI-enriched snow with $\delta^{18}\text{O}_s$ larger than -12 ‰ around the southern tip of the
7 precipitating area at 5565 m (Fig. 10f, g), indicating the continuous supply of the enriched moisture plume
8 from North Africa to SI. We can see this constantly large $\delta^{18}\text{O}_v$ values in SI at all altitudes between 1 and 7 km
9 during IOP13 in Fig. 5b. The dry pocket of the upper-level trough is distinguished by SWI-depleted vapour air
10 masses with low $\delta^{18}\text{O}_v \leq -36$ ‰ at 2455 m and 5565 m ASL over Sardinia and Corsica (Fig. 10d, f).

11 The Lagrangian analysis indicates that most processes inducing precipitation during P1 take place during
12 the last 18 hours over the Tyrrhenian Sea and the Strait of Sicily. The descending air parcels from the mid
13 troposphere reach altitudes below 1 km ASL along the cold front and take up large amounts of evaporated
14 moisture near the warm sea surface of the Tyrrhenian Sea. Additional moisture is then taken up at altitudes
15 below 2 km ASL from mixing with the African moisture plume that extends from the African continent to the
16 Strait of Sicily. During the period from 18 to 6 hours before the precipitation peak P1, q and $\delta^{18}\text{O}_v$ increase
17 strongly. At the time of precipitation, strong convective mixing injects SWI-enriched moisture into higher
18 altitudes and depleted moisture to near surface over SI.

19

20 *4.2. Phase two: the large-scale phase*

21 *4.2.1. History of air parcel and related SWI evolution*

22 The 3-day backward trajectories in Fig. 11 evidence that the air parcels arriving at SI in the layer between 800
23 and 700 hPa at 00 UTC on 16 October come from North Africa and partly from the southern Iberian Plateau.
24 The air parcels are consistently moist along the tracks (Fig. 11a), with average q value mostly ≥ 5 g kg⁻¹ along
25 the track, in contrast to the air parcels involved in the P1 phase (see section 4.1.1). During the 3 days prior to
26 their arrival in SI, the air parcels are enriched with SWI, showing large $\delta^{18}\text{O}_v$ in excess of -24 ‰, and the air
27 parcels are located at low altitudes, mostly below 2 km ASL (Fig. 11b, d). They continuously take up water
28 vapour in the Strait of Sicily (Fig. 11a–b). The median of q increases from 6.5 to 9 g kg⁻¹ and the median $\delta^{18}\text{O}_v$
29 increases from -18 to -16 ‰ in the period from 72 to 10 hours before the onset of precipitation. The air parcels

1 arriving at SI at 00 UTC at higher levels between 700 and 500 hPa are also moist and SWI-enriched, originate
2 from North Africa (not shown).

3 These moist and SWI-enriched air parcels are also evident from the scatter diagram of q and $\delta^{18}\text{O}_v$.
4 Figure 12 shows the relatively large q and $\delta^{18}\text{O}_v$ values during the 3 days prior to their arrival in SI, i.e. q of
5 $5\text{--}16\text{ g kg}^{-1}$ (average of $8\text{--}10\text{ g kg}^{-1}$), and $\delta^{18}\text{O}_v$ between -12 and -25 ‰ (average in -16 and -18 ‰). During
6 this period, the minimum $\delta^{18}\text{O}_v$ of the air parcels gradually increases from -33 to -27 ‰ . In particular, the
7 moist branch of this $q\text{--}\delta^{18}\text{O}_v$ distribution lies close to Rayleigh distillation curve (solid line, Fig. 12a–c) for all
8 3 days, indicating sustained cloud and precipitation formation. As above, values below this Rayleigh curve
9 point to the importance of precipitation recycling, which also occurs repeatedly during the 3-day period.

10

11 4.2.2. Horizontal SWI distribution

12 At 00 UTC on 16 Oct. during P2, stronger precipitation than that of P1 is produced, and the precipitation
13 system is located mainly over SI (marked area closed by dashed line in Fig. 13a). In the vicinity of the
14 precipitating region, strong cyclonic south-westerly flow $\geq 25\text{ m s}^{-1}$ is dominant at 2455 m and 5565 m ASL
15 (Fig. 13d, f). Within the precipitating area, water vapour is gradually depleted and $\delta^{18}\text{O}_v$ are relatively low from
16 near the surface (between -22 and -26 ‰ , 542 m ASL) to mid altitudes of 5565 m ASL (between -30 and
17 -36 ‰) (Fig. 13b, d, and f). A strong depletion of isotopes in rain water is seen at 2455 m ASL (Fig. 13e). This
18 is due to the steady large-scale ascent of air parcels in front of the trough that lead to cloud formation and rain
19 out. The strong depletion of vapour in lower to mid altitudes is also evident from Fig. 5b, which shows
20 decreasing $\delta^{18}\text{O}_v$ from 23 to 01 UTC (red to purple lines). It is worth noting that θ increases continuously until
21 23 UTC and reaches 327 K in SI (thin line with white circles in Fig. 5b), while θ is rather constant before the
22 arrival of the front and trough and the peak value is about 5 K lower in TY compared to SI (thin line with white
23 circles in Fig. 5a, b). This reflects the influence of the African moisture plume including high $\delta^{18}\text{O}_v$ of vapour
24 in excess of -22 ‰ which is advected by the strong south-westerly flow from the Strait of Sicily to SI (Fig.
25 13d). This is consistent with the rapid re-enrichment of vapour in SI after the precipitation (Fig. 5b). Then after
26 04 UTC, with the arrival of the front and upper-level trough, the vapour decreases at all levels (Fig. 5b).

27 The Lagrangian analysis indicates that the moistures which feeds the convection during P2 is related to
28 large scale ascent from North Africa and the air parcels take up additional moisture ($2\text{--}3\text{ g kg}^{-1}$) over the
29 Mediterranean. These air parcels carry moist and SWI-enriched air at layers below 2 km ASL. With the arrival

1 of the upper-level trough over the southern Tyrrhenian Sea, strong cyclonic flow leads to the mixing of air
2 from the African moisture plume to SI. During P2, the gradual depletion of water vapour takes a place at SI at
3 all levels.

4

5 **5. Conclusion**

6 On 15 to 16 October 2012, SI experiences a HPE (total precipitation of 62.4 mm) with two phases of
7 precipitation. The first one (P1) is induced by moist convection, while the second one (P2) is mainly associated
8 with large-scale uplift along a front. The moisture transport and processes responsible for the HPEs that
9 occurred over the SI area during IOP 13 have been analysed here using SWI data obtained from a numerical
10 simulation with COSMO_{iso} at 7-km horizontal resolution. The main findings are summarized in two schematic
11 illustrations (Fig. 14).

12 The 3-day backward trajectory analysis shows that the air parcels arriving in SI during P1 originate from
13 the North Atlantic and descend within the upper-level trough over the north-western Mediterranean Sea. The
14 SWI-depleted air mass within the descending air parcels rapidly take up a large amount of water vapour from
15 ocean evaporation (green encapsulated area in Fig. 14a) over the Tyrrhenian Sea and also from evaporated
16 moisture from falling precipitation. Additional moisture is taken up over the Strait of Sicily from mixing with
17 the enriched African moisture plume. The SWI-enriched low-level air masses arriving upstream of SI are
18 convectively pumped to higher altitudes, producing precipitation, and the SWI-depleted moisture is transported
19 towards the surface within the downdrafts ahead of the cold front (red and blue arrows, Fig. 14a).

20 During P2 (Fig. 14b), just a few hours after P1, the origin of the air parcels arriving at SI is distinct, i.e.
21 mostly from North Africa. The air parcels are moist and associated with large $\delta^{18}\text{O}_v$ (bottom most arrow). With
22 the arrival of the upper-level trough and mistral over the southern Tyrrhenian Sea, the strong cyclonic flow
23 around the trough (grey dashed line in Fig. 14b) induces the advection of the African moisture plume towards
24 SI and leads to large-scale uplift of the warm and moist air mass along the cold front. The existence of an
25 African moisture plume is often associated with the presence of a deepening, north-south oriented upper-level
26 trough over the western Mediterranean (Chazette et al., 2015; Lee et al., 2016 and 2017). It brings moisture
27 and leads to gradual rain out of the air parcels over Italy. For the convective precipitation phase (P1), most of
28 the moisture processes producing the HPE take place during the last 18 hours before the arrival over SI, while
29 the large-scale advection of SWI-enriched air mass in the African moisture plume by strong cyclonic flow lasts

1 about 72 hours during the large-scale precipitation phase (P2). In both phases, the air parcels take up substantial
2 amount of water vapour over the Mediterranean.

3 Using the hourly 3-D water vapour isotope data, we highlight the large variety of moisture sources and
4 transport pathways that induced the two phases of the HPE in South Italy during IOP13, and the isotopic
5 characteristics of various air masses associated with the upper-level trough, cold front, mistral, and African
6 moisture plume, that were involved in convection development. We also highlight the role of the upper-level
7 trough over the south Tyrrhenian Sea in driving the advection of the SWI-enriched plume from North Africa
8 into the region of the deep convective system resulting in heavy precipitation over SI. Moreover, we
9 demonstrate the importance of various moist processes such as mixing, condensation, and re-evaporation along
10 the pathway based on the q - δ analysis using 3D SWI fields. Although our study is entirely based on a model
11 simulation, the results suggest that the information on mesoscale moist dynamical processes and moisture
12 transport that is contained in SWI, when combined with SWI observations, can provide very useful constraints
13 on the representation of such processes in numerical models.

14 Our study is the first study to investigate the potential benefit of SWI in the context of a HPE in the
15 Mediterranean. As such, our study provides a proof of concept of the usefulness of SWI data to understand the
16 variety of origins and moist processes associated with air masses feeding the convection over SI. This will be
17 further investigated in future research using SWI measurements obtained from various platforms, e.g. ground-
18 based, near surface, airborne (Sodemann et al., 2017), and space-borne. Our modelling study will also allow
19 designing forthcoming tailored field campaigns in the Mediterranean region. To further study the details of the
20 fractionation processes in and around deep convective systems, complementary investigations will be
21 conducted using higher resolution convection-permitting simulation with a 2 km grid to shed a light on cloud
22 microphysical processes inside deep convection.

23

24 **Author contribution**

25 KOL, FA, SP and CF planned the manuscript and analyses. SP and KOL designed the numerical simulation
26 and SP performed it. JLL and JPC contributed to the discussion of the results. KOL prepared the manuscript
27 with contributions from all co-authors.

Figure 1. Accumulated precipitation during IOP 13 from 00 UTC on 15 October 2012 to 03 UTC on 16 October 2012 obtained from (a) rain gauge network, and (b) COSMOiso simulation.

8

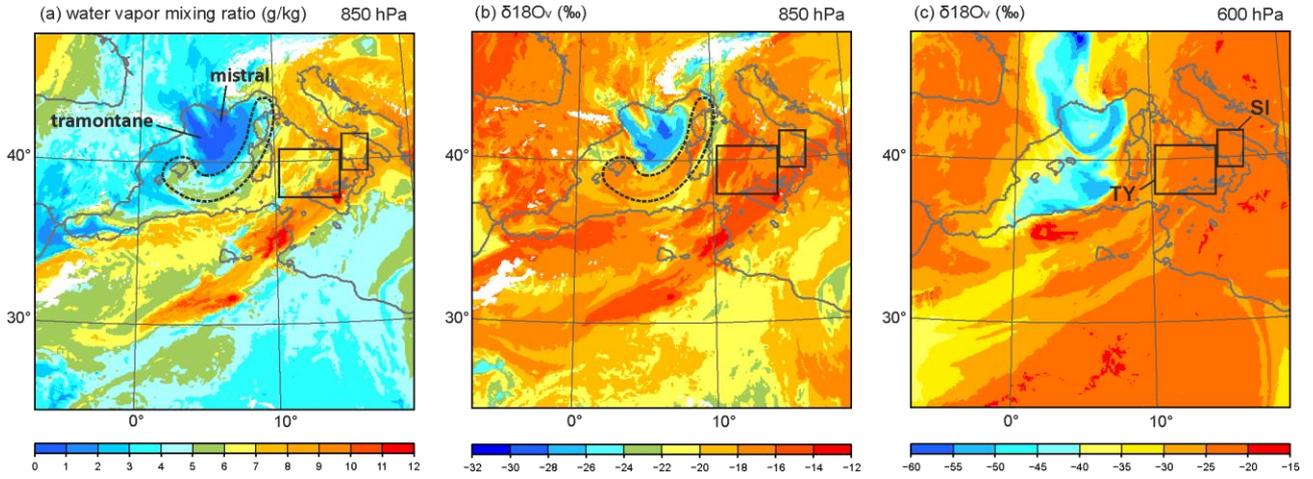

Figure 2. COSMOiso-produced domain-averaged total precipitation (bar), synoptic precipitation (black solid line), and convective precipitation (dashed line) in domain of South Italy (SI) over the land during IOP 13. Temporal evolution of observed maximum rainfall within the SI domain is shown by a line with dot. The location of domain SI is depicted by the box in Figure 1.

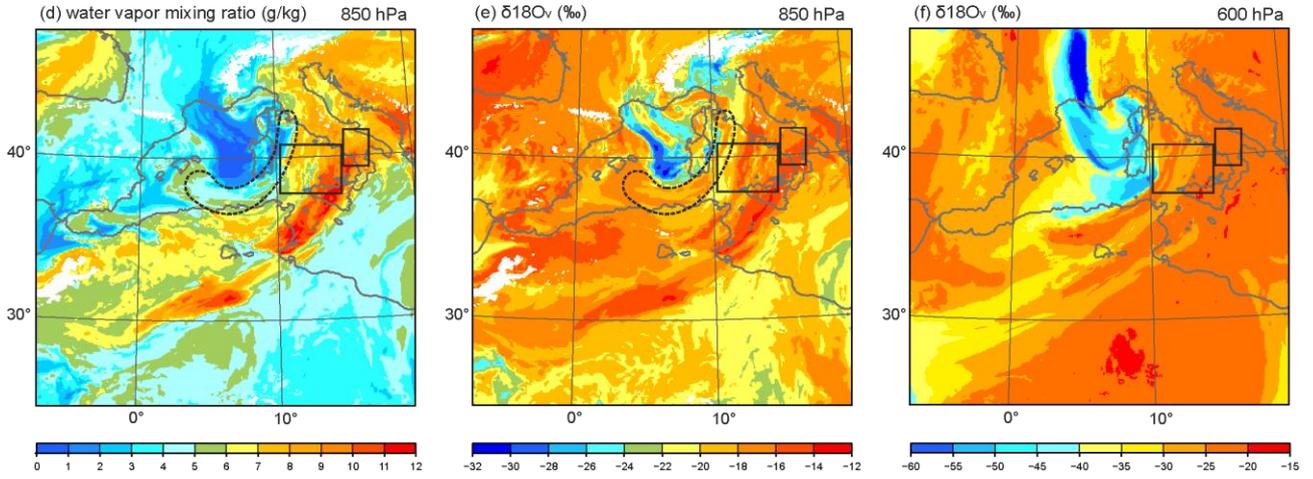

1

2 **Figure 3.** Horizontal distributions of sea level pressure (shades) and geopotential height at 500 hPa (contour) (left), and
 3 potential temperature, θ (shades), and wind (black and white arrows) at 850 hPa (right) at 16 UTC (top) and at 20 UTC
 4 (middle) 15 October 2012, and 00 UTC on 16 October 2012 (bottom) produced by the COSMOiso simulation. Coastal
 5 line is depicted by black line. The location of cold front is depicted by a dashed line in right panels.

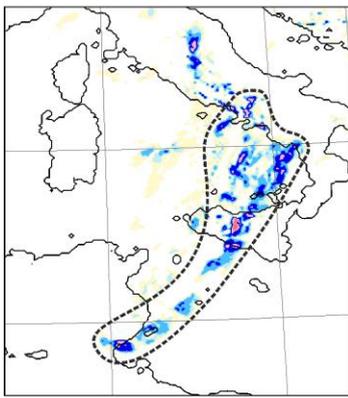

Figure 8. Scatter diagram of q and $\delta^{18}\text{O}_v$ along the backward trajectories of Figure 7 during (a) the times between -72 and -48 h, and (b) times between -48 and 0 h every 12 hours from 20 UTC on 15 October 2012. The colour of dot changes every 12 h. The mixing and Rayleigh lines are indicated in each panel by dashed and solid line, respectively. The averaged q and $\delta^{18}\text{O}_v$ every 12 hours is displayed in the bottom right corner of each panel.

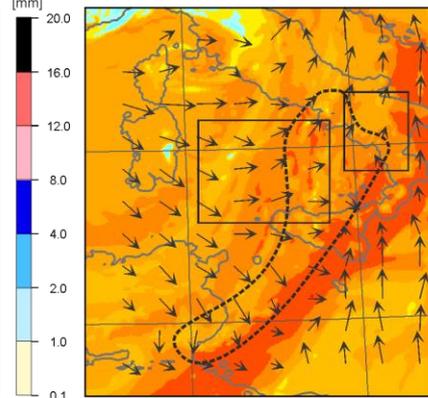

1
 2 **Figure 9.** Scatter diagram of q and $\delta^{18}O_v$ along the backward trajectories of Figure 7 but for all altitudes of 1–2 km (black
 3 dots), 2–3 km (red dots), 3–4 km (yellow dots), 4–5 km (green dots), 5–6 km (blue dots), and 6–7 km (purple dots) at (a)
 4 –6 h, (b) –3 h, and (c) 0 h from 20 UTC on 15 October 2012. The mixing and Rayleigh lines are indicated in each panel
 5 by dashed and solid line, respectively.

20 UTC 15/10/2012

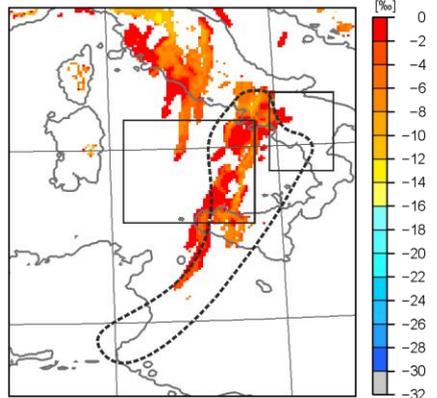

(a) Hourly precipitation

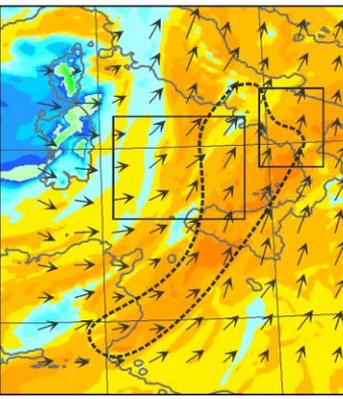

(b) $\delta^{18}O_v$ z = 542 m

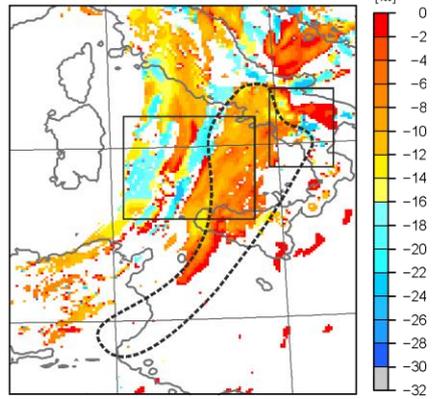

(c) $\delta^{18}O_r$ z = 542 m

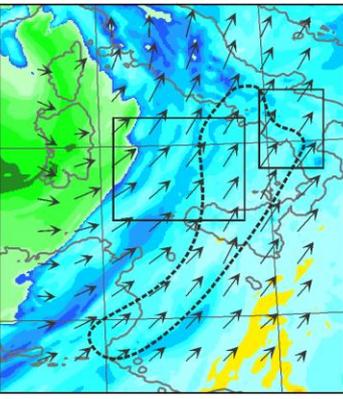

(d) $\delta^{18}O_v$ z = 2455 m

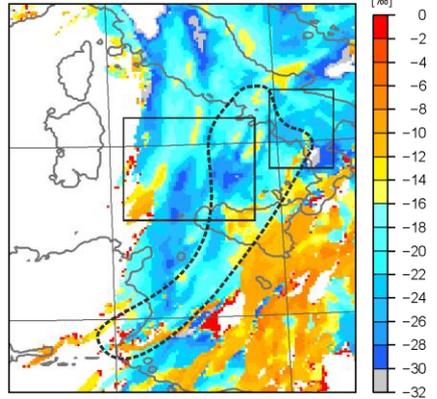

(e) $\delta^{18}O_r$ z = 2455 m

(f) $\delta^{18}O_v$ z = 5565 m

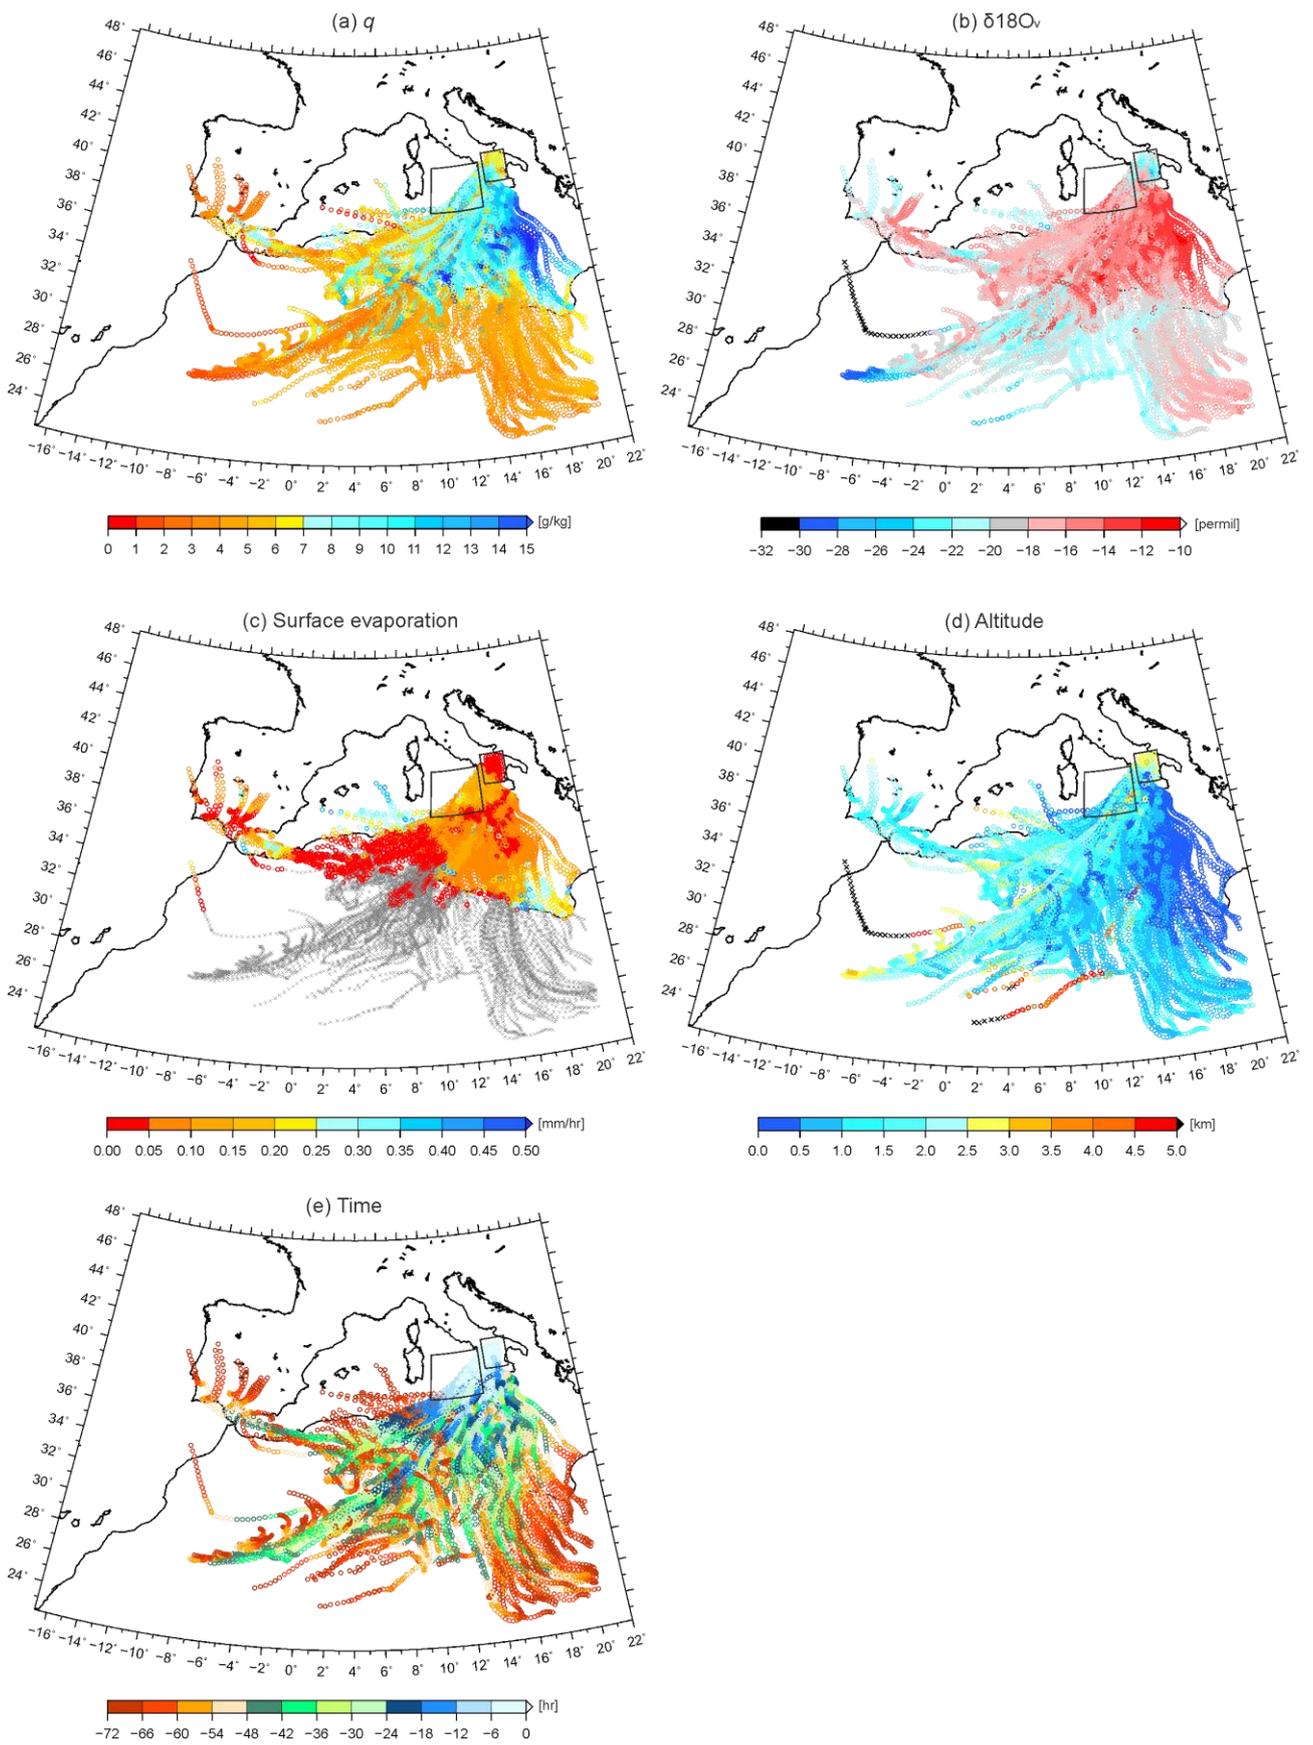

(g) $\delta^{18}O_s$ z = 5565 m

1

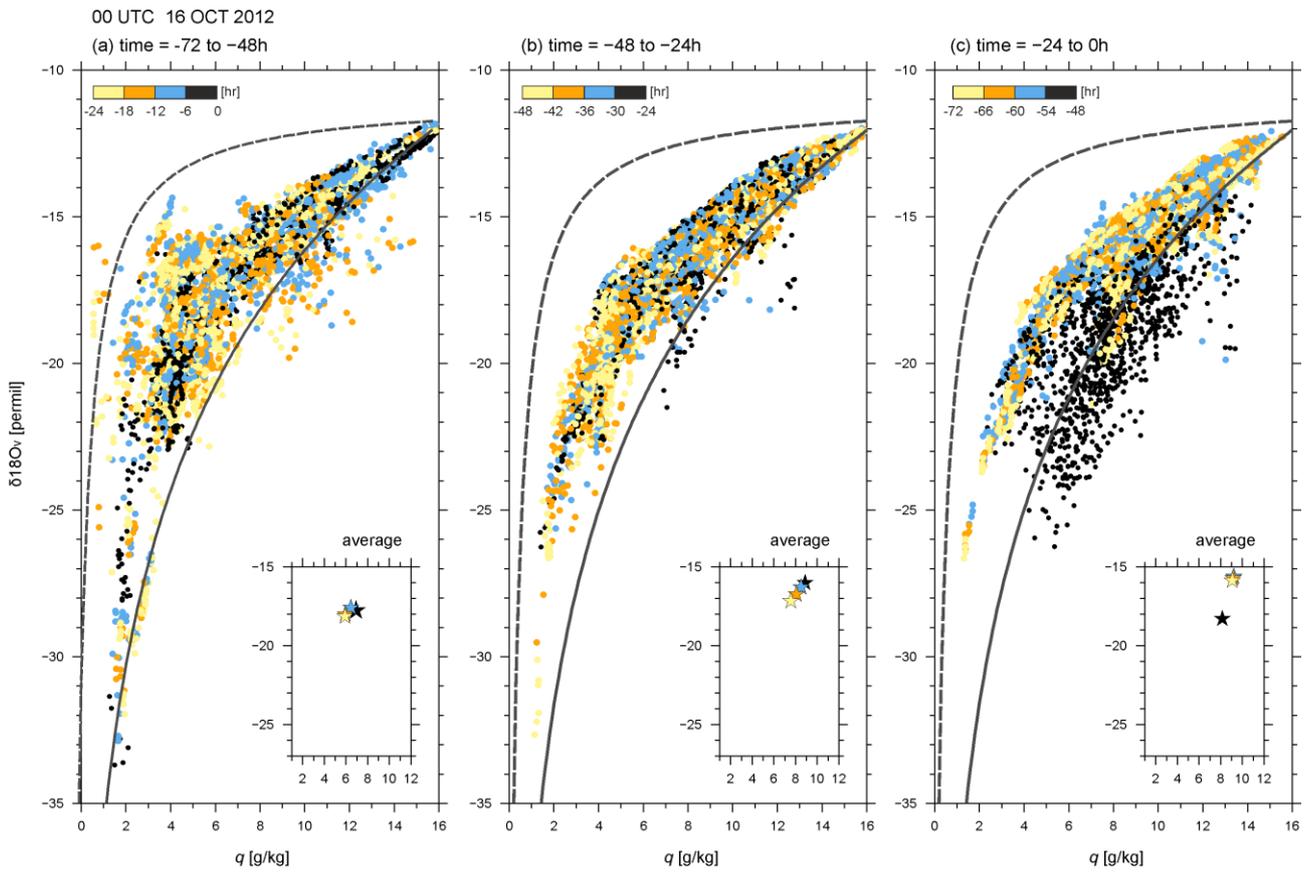

2 **Figure 10.** Horizontal distributions of (a) surface hourly precipitation (mm), $\delta^{18}O_v$ (‰) at (b) model level 8 (about 542 m
3 ASL), (c) model level 16 (about 2455 m ASL), and (d) model level 23 (about 5565 m ASL, $\delta^{18}O_r$ (‰) at (e) 542 m ASL
4 and (f) 2455 m ASL, and $\delta^{18}O_s$ (‰) at 5565 m ASL at 20 UTC on 15 October 2012. Note that due to the terrain-following
5 coordinates, the SWI values are partly depleted over the topography, e.g. in central Italy. The precipitating area is marked
6 by the area enclosed by the dashed line.

7

1

2 **Figure 11.** Same as Figure 7 but for the air parcel arriving at SI in layer of 800–700 hPa at 00 UTC on 16 October 2012.

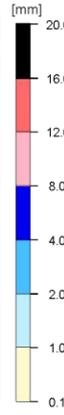

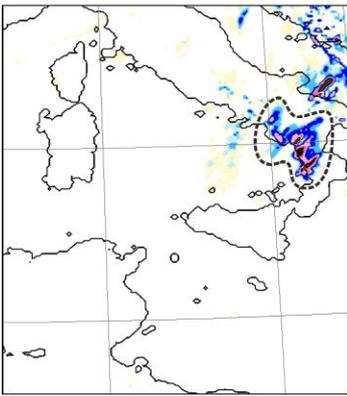

1

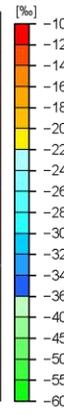

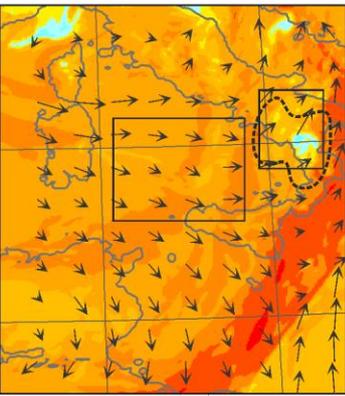

2 **Figure 12.** Scatter diagram of q and $\delta^{18}\text{O}_v$ along the backward trajectories of Figure 11 during (a) the times between -72
 3 and -48 h, (b) times between -48 h and -24 h, and (c) times between -24 h and 0 h from 00 UTC on 16 October 2012
 4 every 6 hours. The colour of dot changes every 6 h. The mixing and Rayleigh lines are indicated by dashed and solid line,
 5 respectively. The averaged q and $\delta^{18}\text{O}_v$ every 6 hours is displayed in the bottom right corner of each panel.

00 UTC 16/10/2012

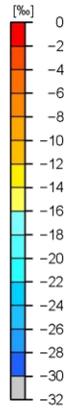

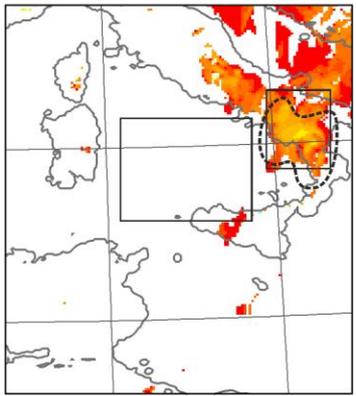

(a) Hourly precipitation

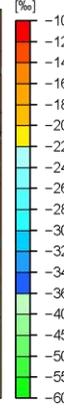

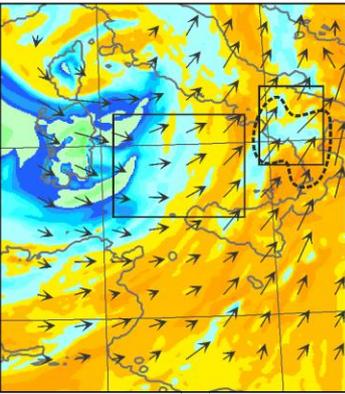

(b) $\delta^{18}O_v$ $z = 542$ m

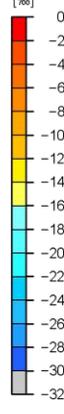

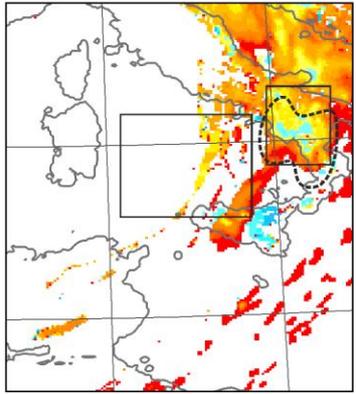

(c) $\delta^{18}O_r$ $z = 542$ m

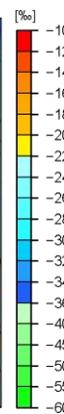

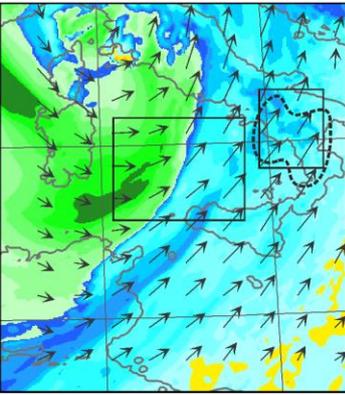

(d) $\delta^{18}O_v$ $z = 2455$ m

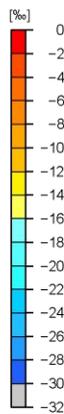

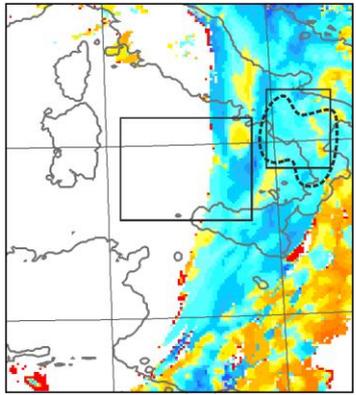

(e) $\delta^{18}O_r$ $z = 2455$ m

(f) $\delta^{18}O_v$ $z = 5565$ m

(g) $\delta^{18}O_s$ $z = 5565$ m

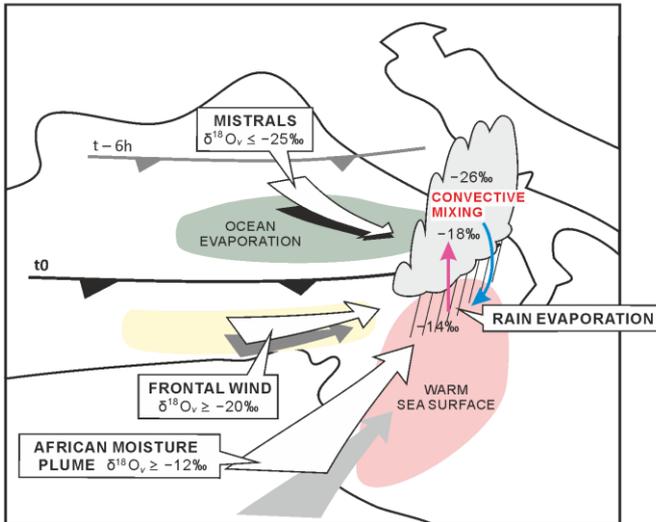

1

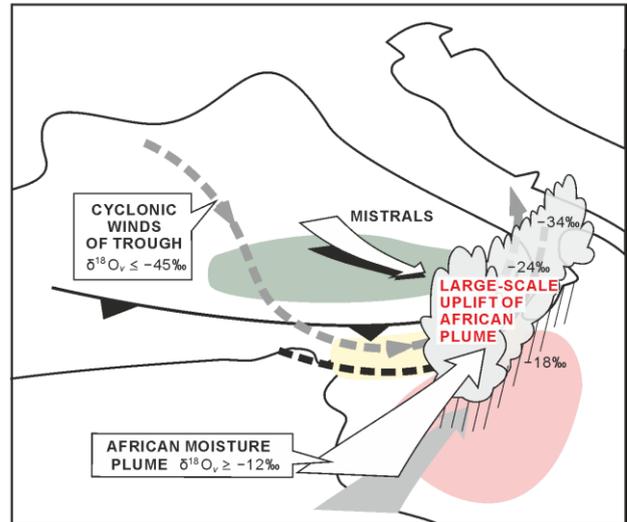

2 **Figure 13.** Same as Figure 10 but for 00 UTC on 16 October 2012.

3

(a) Convective precipitation phase

(b) Large-scale precipitation phase

1

2 **Figure 14.** Schematics summarizing the main features of water vapour isotopologues and processes for deep convection
3 upstream of SI and leading to the Phase 1 (a) and Phase 2 (b) of the HPE. In (a) and (b), white descending arrow indicate
4 the mistral wind behind the edge of the cold front (thick black line). The white arrow in the yellow-shading encapsulated
5 area illustrates the frontal wind at 850 hPa, and white arrow in the red-shading encapsulated area (warm sea surface)
6 indicates the elevated African moisture plume. In (a), convective ascent and precipitating downdraft is depicted by red
7 and blue arrows, respectively. In (b), the southern edge of upper trough is indicated by black dashed line and the cyclonic
8 flow of the trough is indicated by grey dashed line.
