Interactive comment on "New particle formation events observed at King Sejong Station, Antarctic Peninsula – Part 1: Physical characteristics and contribution to cloud condensation nuclei" by Jaeseok Kim et al.

Anonymous Referee #1

Received and published: 18 December 2018

We thank Referee 1 for providing insightful suggestions that have considerably improved the readability of the revised manuscript. Our responses to general and specific comments raised by Referee 1 are stated below. The revised manuscript was uploaded in the form of a supplement

General comments:
The manuscript at hand characterizes new particle formation (NPF) events observed at the Korean Antarctic Station King Sejong. As the authors state, this is the first NPF investigation from the Antarctic Peninsula. To my knowledge it is based on the longest observation period actually measured in Antarctica regarding this topic. In addition, the authors discussed in particular NPF events along with cloud condensation nuclei (CCN) data. The article is written in a straight and concise way and presents invaluable results to elucidate NPF and its impact on CCN availability at this site and (coastal) Antarctica in general. However, the article in the present appearance has some weak points. Especially the regrettably scarce discussion in general is not commensurate with the unquestionable valuable data set. In addition, description of the used instruments and data evaluation procedures are often insufficient (see specific comments below). I think this outstanding data set is worth the effort addressing this weakness and considering a more in-depth discussion. Notwithstanding, I am confident that the data and their evaluation presented here are of high quality and on the whole, the subject is appropriate to ACP. Hence, I recommend accepting the paper after revisions according to my specified suggestions from above and listed below.

Specific comments:
1. The authors should provide specification and operation details for the SMPS and CCN instruments even though they were comparable to Kim et al. (2017). Furthermore, I miss an adequate presentation of the SMPS results! In any case, it would be advisable to show some figures (e.g. the typical Dp vs. time contour plots), at least for the two case "A" NPF events.

Authors' response: We have described the specification and operation details for the SMPS and CCN system in our previous paper (Kim et al., 2017). Following referee's advice, in the revised manuscript, we modified the paragraph on Page 4 Line 5 to clarify the specification and operation details for the SMPS and CCN instruments.

"The aerosol size distributions of particles ranging from 10 to 300 nm were measured every 3 minutes with a scanning mobility particle sizer (SMPS) consisting of a differential mobility analyzer (DMA; HCT Inc., LDMA 4210) and a CPC (TSI 3772). The flow rate of sheath air and aerosol flow of DMA were 10 L min^{-1} and 1 L min^{-1}, respectively. The CCN concentrations were simultaneously measured by using a CCN counter (DMT CCN-100) with five different supersaturation values (i.e. 0.2, 0.4, 0.6, 0.8 and 1.0%). The sampling duration was set to be 5 minutes for each supersaturation value (except for 0.2%). For the 0.2% supersaturation value, the CCN concentration was measured for 10 min because of stability after measurements at 1% supersaturation value. In the present work, only results of CCN concentration for a 0.4% supersaturation value were used."

We also added following contour figures in the revised manuscript.

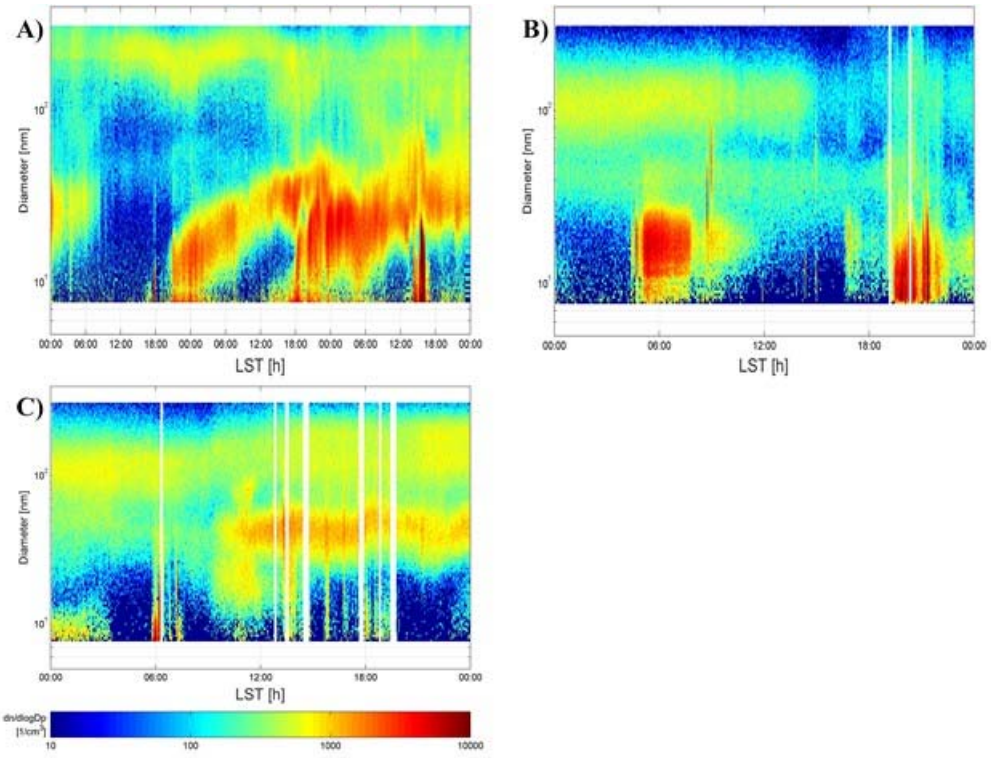

Figure 1. Example of types of the NPF based on the SMPS data. (a) type A (18 January 2011-20 January 2011), (b) type B (13 January 2015) and (c) type C (9 January 2015). Type A is days when the formation and growth of nanoparticles should be clear. Type B is days when the formation occurred but growth was not clear. Type C is days when it cannot be said whether there is an event or not.

2. Another concern is the lack of an appropriate CCN data presentation. For instance, the authors showed no figures regarding the CCN spectrum. I would appreciate a thorough description of the performed data analysis.

Authors' response: CCN data were obtained at five different supersaturation ratio values (0.2, 0.4, 0.6, 0.8 and 1.0%) using commercial CCNC (DMT CCN-100). The sampling time was set at 5 min including stability duration for each supersaturation value except for 0.2% supersaturation value. For 0.2% supersaturation value, the CCN data was collected for 10 min because the additional time was needed to achieve stability after measurements at 1.0% supersaturation value. Based on previous study (Anttila et al., 2012) which compared relationship between CCN concentration and cloud droplet number concentration, in this study, hourly mean CCN data at 0.4% supersaturation value were used. Based on this results, we compared variation in normalized values of $CN_{2.5-10}$ and CCN concentrations during NPF period as shown in Figure 2.

To explain method for CCN data analysis, we added the following sentence in Page 4 Line 8:

"The CCN concentrations were simultaneously measured by using a CCN counter (DMT CCN-100) with five different supersaturation values (i.e. 0.2, 0.4, 0.6, 0.8 and 1.0%). The sampling duration was set to be 5 minutes for each supersaturation value (except for 0.2%). For the 0.2% supersaturation value, the CCN concentration was measured for 10 min because of stability after measurements at 1% supersaturation value. In the present work, only results of CCN concentration for a 0.4% supersaturation value were used."

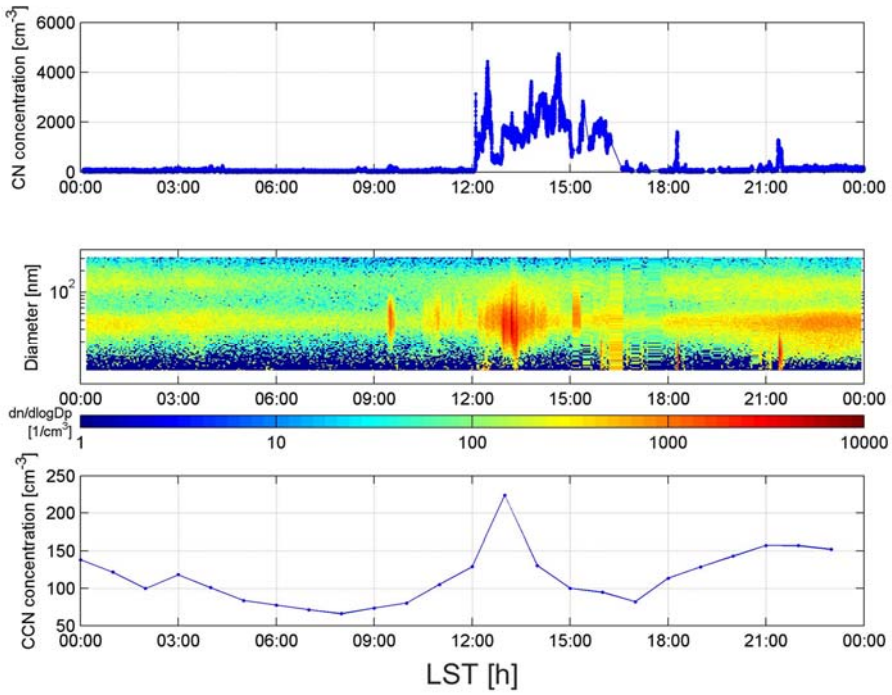

Figure 2. Example of comparison among CN concentrations from CPC data (upper panel), size distribution from SMPS data (middle panel) and hourly mean CCN concentration (bottom panel) at 0.4% supersaturation value as a function of time on 30 March 2009.

Chapters 2.2.1. and 2.2.2: The authors based their definition and classification of NPF events on the criteria compiled by Dal Maso et al. (2005) and Yli-Juuti et al. (2009), which are widely accepted by the community. According to these previous studies, an NPF event must show signs of growth (see Dal Maso et al., 2005, p. 326). Therefore, NPF events can only be identified by size distribution (here SMPS) data, but clearly not by sole CN2.5 minus CN10 data. The latter just indicate a potential NPF, which may be better termed as particle burst.

Authors' response: According to previous study (Dal Maso et al., 2005), an NPF event must show signs of growth. Authors acknowledge and agree that the SMPS data are widely used for identification and classification of the NPF events. However, in this study, because the availability of SMPS data set was lower than that of CPC data set, CN2.5 and CN10 data were used to define NPF events and SMPS data used to classify types of the NPF events. For identification of the NPF events, $CN_{2.5-10}$ data, $CN_{2.5-10}/CN_{10}$ data and the duration time data were used as mentioned at Section 2.2.1. In particular, $CN_{2.5-10}/CN_{10}$ values can be used to distinguish newly formed particles to background particles (Warren and Seinfeld, 1985; Covert et al., 1992; Humphries et al., 2015). Since we used strict category to define the burst of nanoparticles, this supports the widely-used definition of the NPF events. Authors think the definition of the NPF event is feasible in this study.

Chapters 2.2.3: I guess that CN and especially CN2.5 – CN10 concentration data based on 1 s resolution are highly fluctuating, making the FR evaluation somewhat arbitrary. Please specify in more detail the way you extract dNnuc/dt from the data (maybe by showing a representative figure?).

Authors' response: Authors appreciate the issue raised by the referee. Because CN data with 1 s time resolution are highly fluctuating, FR was estimated using an one-minute averaged CN concentration. To calculate the FR values, we first checked $CN_{2.5-10}/CN_{10}$ values. The $CN_{2.5-10}/CN_{10}$ values can be used to distinguish between newly formed particles and background particles events (Warren and Seinfeld, 1985; Covert et al., 1992; Humphries et al., 2015). As shown in Figure 3, when $CN_{2.5-10}/CN_{10}$ values were higher than 10, we considered

as NPF events as mentioned Sec 2.2.1. Time variation (dt) was estimated from the time it starts to increase of $CN_{2.5-10}/CN_{10}$ to the time it was highest values. Variation of CN2.5-10 concentration (dN_{nuc}) was calculated at that time.

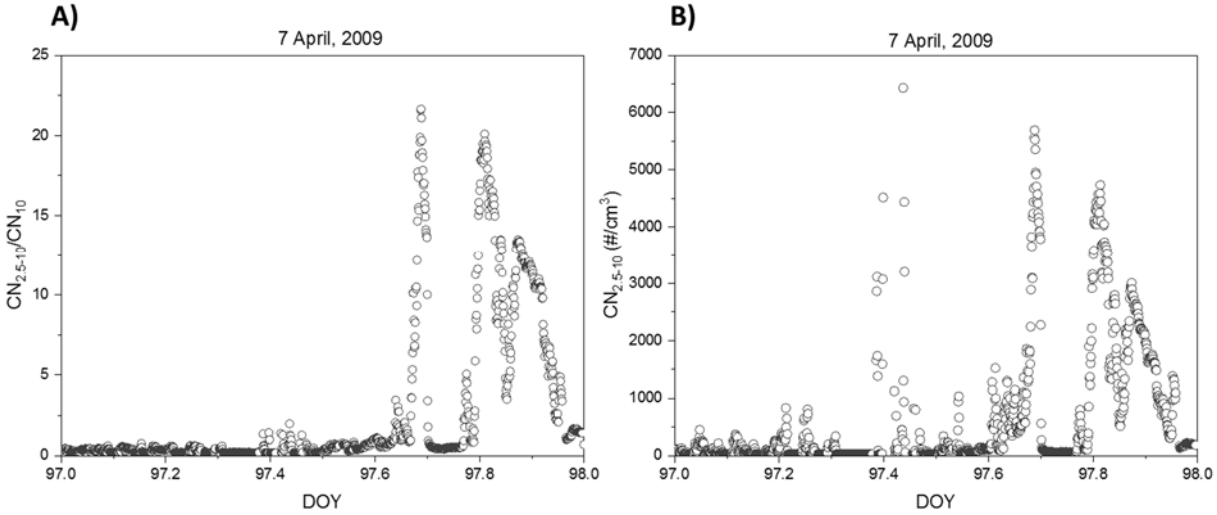

Figure 3. Example for estimation of the formation rate during NPF event on 7 April 2009: (a) $CN_{2.5-10}/CN_{10}$ and (b) $CN_{2.5-10}$ concentration with 1 min time resolution.

To clarify we modified sentence to following text on Page 6 Line 2:
"On the basis of the average number concentration data with 1 min time resolution, the FR was calculated for cases in which $CN_{2.5-10}/CN_{10}$ values and $CN_{2.5-10}$ concentrations sharply increased (Fig. S1 in the Supplement)."

Chapters 2.3: Please specify, in which way/procedure you have characterized air masses (by cluster analysis or just "manually")?

Authors' response: Air mass backward trajectory analysis during the NPF event periods was conducted by using the HYSPLIT model (http://www.arl.noaa.gov/HYSPLIR.php). The origin of air masses arriving at the observation site during the NPF events (a total of 101 event days) was manually categorized into four cases by analyzing 48-h backward trajectory data ending at height of 100m, 500m and 1500 m above the ground level. For instance, if time of the NPF events was from 13:00 to 17:00, we run the 48-h air mass backward trajectory for each hour. The results with similar air mass origins and pathways during the NPF event periods at three different heights were used for the analysis in this study.

To clarify we modified paragraph to following text on Page 8 Line 1:
"The origin of air masses arriving at the observation site during the NPF events (a total of 101 event days) was manually categorized into four cases by analyzing 48-h backward trajectory data ending at height of 100, 500 and 1500 m above the ground level. The results with similar air mass origins and pathways during the NPF event periods at three different heights were used for the analysis in this study, as shown in Fig. 2"

Results and Discussion chapter and Tables 4 and 5: The authors observed just two type "A" NPF events, from which growth can be determined with confidence according to Dal Maso et al. (2005). For type "B" events, the authors state that growth was not clear (see caption of table 4). I am confused about this: Does this mean the bottom line is that the reported growth rates were based on merely two events? Please clarify this point!

Authors' response: Aerosol size distribution data were used for classification of the NPF events. Based on the contour plots of aerosol size distribution, type of the NPF events was classified. For the calculation of growth rates, hourly mean aerosol size distribution data was used for all types of NPF. The geometric mean dimeter (GMD) of particles which is limited to the size range of 10-25 nm was used. According to these method, growth

rate of particles ranging from 10 to 25 nm was estimated regardless of type of the NPF events as shown in Figure 4.

To clarify we modified paragraph to following text on Page 6 Line 16:
"Based on the hourly mean aerosol size distribution data, the geometric mean dimeter (GMD) of particles which is limited to the size range of 10-25 nm was used. Here, the GMD was calculated from log-normal fitting analysis. According to these method, growth rate of particles ranging from 10-25 nm was estimated regardless of the NPF event types (Fig. S2 in the Supplement)"

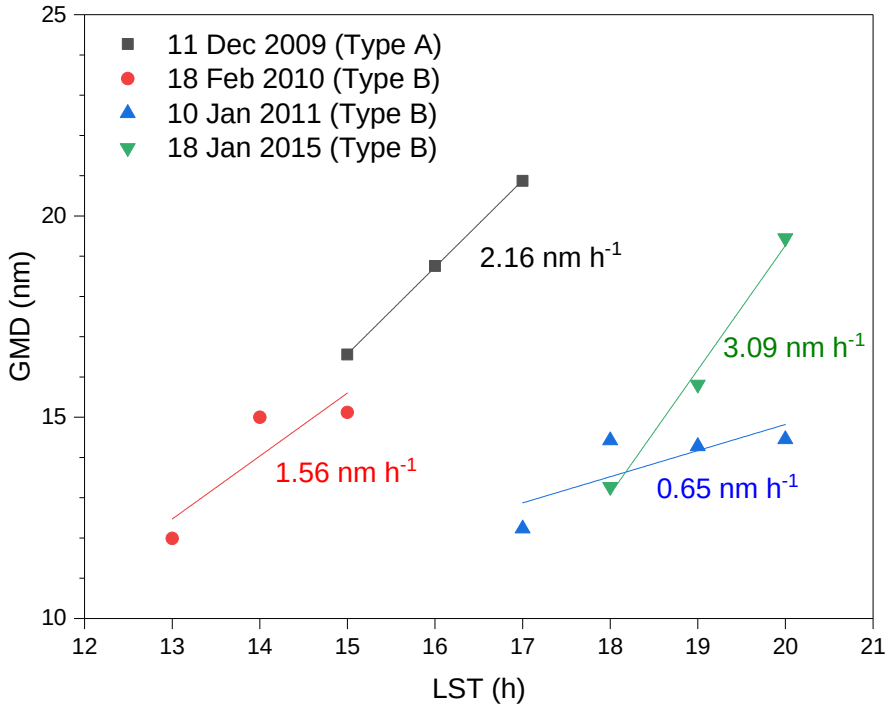

Figure 4. Geometric mean diameter (GMD) of particles ranging from 10 nm to 25 nm as a function of the time: the growth rate (nm h-1) was calculated as the regression slope. The LST means local standard time.

Chapter 3.3: From my point of view the presented discussion is inadequate. Evaluation of the CCNC data demands a more detailed description and discussion. Especially: A systematic analysis along with SMPS data would be crucial and should be presented. Are your CCNC results consistent with SMPS data?

Authors' response: As described in section 3.3, according to previous studies (Pierce et al., 2014; Shen et al., 2016; Rose et al., 2017), in order to understand relationship between NPF event and CCN concentration, it was suggested that number concentrations of particles larger than 50, 80 and 100 nm estimated by SMPS data are compared with aerosol size distribution data. While, in this study, CCN concentration measured directly by CCN counter were compared concentration of newly formed particles ($CN_{2.5-10}$) as the function of time during NPF event periods. Since it was very rare when the all 3 instruments – CPCs, SMPS, and CCN counter – are running together with the very best condition during the particle burst event, authors decide to choose the best way available, comparing CPC data with CCN during the 34 days with two dataset are available. In this manuscript, authors want to show the results that the CCN concentration increase are noticed for a couple of hours following NPF event under clean Antarctic environment, and this results are derived directly from in-situ CCN measurements.

Chapter 3.4, lines 12 through 14: The authors argue that higher GR observed in air masses emerging from the Bellinghausen Sea area are due to higher source rates of condensable vapour. Unless I am very much mistaken, this is a typical case of circular reasoning, because regarding eqs. (4) and (5), the source rate Q is linearly

dependent on the GR, isn't it!

Authors' response: The referee pointed out correctly. To clarify we modified sentence to following text on Page 12 Line 20:

"However, in case of the air mass originating from the Bellingshausen Sea (Case IV), the GR was relatively higher than the values of air masses originated from other region."

Technical corrections:

Abstract

The physical characteristics of aerosol particles during particle bursts observed at King Sejong Station in Antarctic Peninsula from March 2009 to December 2016 were analyzed. This study focuses on the seasonal variation in parameters related to particle formation such as the occurrence, formation rate (FR) and growth rate (GR), condensation sink (CS), and source rate of condensable vapor. The number concentrations during new particle formation (NPF) events varied from 1707 cm^{-3} to 83120 cm^{-3}, with an average of 20649 ± 9290 cm^{-3}, and the duration of the NPF events ranged from 0.6 h to 14.4 h, with a mean of 4.6 ± 1.5 h. The NPF event dominantly occurred during austral summer period (~72%). The measured mean values of FR and GR of the aerosol particles were 2.79 ± 1.05 cm^{-3} s^{-1} and 0.68 ± 0.27 nm h^{-1}, respectively showing enhanced rates in the summer season. The mean value of FR at King Sejong Station was higher than that at other sites in Antarctica, at 0.002-0.3 cm^{-3} s^{-1}, while those of growth rates was relatively similar results observed by precious studies, at 0.4~4.3 nm h^{-1}. The derived average values of CS and source rate of condensable vapor were (6.04 ± 2.74) × 10^{-3} s^{-1} and (5.19 ± 3.51) × 10^{4} cm^{-3} s^{-1}, respectively. The contribution of particle formation to cloud

condensation nuclei (CCN) concentration was also investigated. The CCN concentration during the NPF period increased approximately 9% compared with the background concentration. In addition, the effects of the origin and pathway of air masses on the characteristics of aerosol particles during a NPF event were determined. The FRs were similar regardless of the origin and pathway, whereas the GRs of particles originating from the Antarctic Peninsula and the Bellingshausen Sea, at 0.77 ± 0.25 nm h^{-1} and 0.76 ± 0.30 nm h^{-1}, respectively, were higher than those of particles originating from the Weddell Sea (0.41 ± 0.15 nm h^{-1}).

1. Introduction

Understanding the effect of atmospheric aerosol particles on climate change is an important issue in atmospheric science. These particles are highly significant substances in the radiation transfer process in the atmosphere, with direct effects through scattering and absorption of solar radiation and indirect effects by acting as cloud condensation nuclei (CCN) for cloud droplets (Anttila et al., 2012). These particles also influence the properties and life time of clouds (Twomey, 1977; Albrecht, 1989). Although aerosol particles play an important role in global and regional climates, large uncertainties remain owing to a lack of knowledge on their formation and physicochemical characteristics (Carslaw et al., 2013; IPCC, 2013).

New particle formation (NPF) frequently occurs in the atmosphere and leads to enhancement of the total number concentrations of aerosol particles due to high numbers of nucleation mode particles (Spracklen et al., 2006; Dall'Osto et al., 2017). The modeling study of Pierce and Adams (2007) indicates that ultrafine particles of <100 nm can contribute to maximum CCN generations of 40% and 90% at the boundary layer and in the remote free troposphere, respectively. In order to understand the characteristics of the NPF, studies have been conducted in various regions including coastal, forest, mountainous, rural and urban sites (O'Dowd et al., 2002; Komppula et al., 2003; Kulmala et al., 2004; Yoon et al., 2006; Park et al., 2009; Kim et al., 2011; Rose et al., 2015; Bianchi et al., 2016; Kontkanen

et al., 2017). In addition, studies on the NPF phenomenon have recently been conducted at various sites in the polar regions (Asmi et al., 2010; Järvinen et al., 2013; Kyrö et al., 2013; Park et al., 2004; Weller et al., 2015; Humphries et al., 2016; Nguyen et al., 2016; Willis et al., 2016; Barbaro et al., 2017; Dall'Osto et al., 2017). A NPF event occurring in the period between December 1998 and December 2000 at the South Pole was reported by Park et al. (2004). Kyrö et al. (2013) showed that oxidized organics derived from the oxidation of biogenic precursors originating from local melting ponds might have contributed to particle growth at the Finnish research station Aboa (73.50°S, 13.42°W). Although CCN concentrations were indirectly estimated at Aboa, Asmi et al. (2010) also showed and discussed hygroscopic growth factor and CCN activity. In addition, studies on the NPF were conducted at the Concordia station, Dome C (75.10°S, 123.38°E; Järvinen et al., 2013) and at the coastal Antarctic station Neumayer (70.65°S, 8.25°W; Weller et al., 2015). Although studies on NPF events have been conducted at various stations in the Antarctica, no results are available for the station in the Antarctic Peninsula. Also, the contribution of NPF to CCN concentration is not well understood in this area. Furthermore, results of the general long-term characteristics of aerosol particles during the period of NPF observation in Antarctica are rare compared with those in other continents.

In the present study, the frequency of NPF events was determined on the basis of total aerosol number concentration. We investigated the physical characteristics such as formation rate (FR) and growth rate (GR), condensation sink (CS) and source of condensation vapor as well as the seasonality of atmospheric aerosols during NPF events at King Sejong Station in the Antarctic Peninsula. The effect of particle formation on CCN concentrations was also examined. Furthermore, the air mass back trajectories were analyzed by using the Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model to understand physical properties of NPF events depending on the origins and pathway of the air masses.

2. Methods

2.1. Site description and instrumentation

The data analyzed in this study were obtained from March 2009 to December 2012 at the King Sejong station in the Antarctic Peninsula (62.22°S, 58.78°W). Further details on the sampling site as well as the instrumental specification and operation were introduced in the previous study (Kim et al., 2017). In brief, two condensation particle counters (CPCs; TSI 3776 and TSI 3772) were used to measure the total particle number concentrations. The aerosol size distributions of particles ranging from 10 to 300 nm were measured every 3 minutes with a scanning mobility particle sizer (SMPS) consisting of a differential mobility analyzer (DMA; HCT Inc., LDMA 4210) and a CPC (TSI 3772). The flow rate of sheath air and aerosol flow of DMA were 10 L min^{-1} and 1 L min^{-1}, respectively. The CCN concentrations were simultaneously measured by using a CCN counter (DMT CCN-100) with five different supersaturation values (i.e. 0.2, 0.4, 0.6, 0.8 and 1.0%). The sampling duration was set to be 5 minutes for each supersaturation value (except for 0.2%). For the 0.2% supersaturation value, the CCN concentration was measured for 10 min because of stability after measurements at 1% supersaturation value. In the present work, only results of CCN concentration for a 0.4% supersaturation value were used. In addition, meteorological parameters including temperature, relative humidity, wind speed, wind direction, pressure, and solar radiation intensity were continuously monitored by using an automatic weather station (AWS; Vaisala HMP45 for measuring temperature and relative humidity, WeatherTronics 2102 for measuring wind speed and direction, WeatherTronics 7100 for measuring pressure and Eppley Precision Spectral Pyranometer PSP for measuring solar radiation intensity) system.

2.2. Data analysis

To ensure data quality, raw data measured during the following conditions were discarded: (i) wind direction between 355° and 55° (local pollution sector) (ii) concentration of black carbon higher than 100 ng m^{-3}, (iii) wind speed less than 2 m s^{-1} and (iv) instrument malfunction based on the log-book.

If valid data for one day were less than 50% after discarding the raw data, such days were excluded. The acquisition rate for each instrument is summarized in Table 1. Here, the acquisition rate indicates the value of the analyzed days divided by the total measurement days. Because the acquisition rate from the SMPS was lower than that of the CPC in this study, the value difference between the concentrations of particles larger than 2.5 nm ($CN_{2.5}$) and 10 nm (CN_{10}) observed from two CPCs was used to identify the NPF events.

2.2.1. Definition of NPF events

As mentioned in the previous section, the difference between $CN_{2.5}$ and CN_{10} concentrations were used to define days for NPF events or non-NPF events (Yoon et al., 2006). The $CN_{2.5\text{-}10}$ represents the number concentrations of newly formed particles produced from gas-to-particle conversion. The NPF days were defined in this study according to the following conditions: (i) The $CN_{2.5\text{-}10}$ is higher than 500 cm^{-3} (ii) the $CN_{2.5\text{-}10}/CN_{10}$ ratio is higher than 10 and (iii) the NPF duration is longer than 30 min. The $CN_{2.5\text{-}10}/CN_{10}$ ratio is the parameter used to distinguish between particles newly formed from gas-to-particle conversion and background particles (Warren and Seinfeld, 1985; Humphries et al., 2015). Humphries et al. (2016) also used the $CN_{2.5\text{-}10}/CN_{10}$ ratio to distinguish the NPF days during a 52 days' voyage in the East Antarctic sea ice region because the number concentration data were more reliable than the size distribution data.

2.2.2. Classification of NPF events using SMPS data

After identification of the NPF event days, classification of the NPF events was conducted by using size distributions from a SMPS. The NPF events were classified into three types of A, B and C according to the classification by Dal Maso et al. (2005) and Yli-Juuti et al. (2009) as shown in Fig. 1. Type A describes days in which the formation and growth of particles were clear. Type B describes days in which the formation occurred but growth was not clear. Type C describes days in which the event occurrence was not distinct.

2.2.3. Estimation of parameters for NPF characteristics

On the basis of the average number concentration data with 1 min time resolution, the FR was calculated for cases in which $CN_{2.5\text{-}10}/CN_{10}$ values and $CN_{2.5\text{-}10}$ concentrations sharply increased (Fig. S1 in the Supplement). The FR of new particles ranging from 2.5 nm to 10 nm was determined according to variation in the number concentrations of $CN_{2.5\text{-}10}$ based on the following equation (Dal Maso et al., 2005):

$$FR = \frac{dN_{nuc}}{dt} + F_{coag} + F_{growth} \quad (1)$$

Here, N_{nuc} is the particle number concentrations of nucleation mode. In this study, the $CN_{2.5\text{-}10}$ concentrations obtained by two particle counters were used for the term N_{nuc}. F_{coag} is the particle loss in accordance with coagulation, and F_{growth} represents the flux of particles growing from the nucleation mode. Because the $CN_{2.5\text{-}10}$ concentrations were predominant in the total number concentration and the particles rarely grew over the nucleation mode during the formation period, the F_{coag} and F_{growth} terms in Eq. 1 were neglected in this study (Dal Maso et al., 2005; Shen et al., 2016).

The GRs were calculated by using the size distributions measured by a SMPS. Based on the hourly mean aerosol size distribution data, the geometric mean dimeter (GMD) of particles which is limited to the size range of 10-25 nm was used. Here, the GMD was calculated from log-normal fitting analysis. According to these method, growth rate of particles ranging from 10-25 nm was estimated regardless of the NPF event types (Fig. S2 in the Supplement). The GR was determined by rate of change in the GMD by using the following equation (Kulmala et al., 2004; Dal Maso et al., 2005):

$$GR = \frac{dD_p}{dt} \quad (2)$$

The CS is an important parameter governing the NPF because it indicates the loss rate in which gaseous molecules condense onto pre-existing aerosols. It can be estimated from the size distribution data according to the following equation (Dal Maso et al., 2005; Kulmala et al., 2005; Shen et al., 2016):

$$CS = 2\pi D \sum_{dp} \beta_m d_p N_{dp} \quad (3)$$

where D is the diffusion coefficient of the condensable vapor, β is the transitional regime correction factor from Fuchs and Sutugin (1970), and d_p and N_{dp} are the particle size and number concentration, respectively. It is assumed that condensable vapor is gaseous sulfuric acid which has been reported to play an important role in the nucleation process (Dal Maso et al., 2005).

According to the GR and the CS, it is possible to estimate condensable vapor concentration, C_v (unit: molecules cm^{-3}) and its source rate, Q (unit: molecules cm^{-3} s^{-1}; Kulmala et al., 2001; Dal Maso, 2002), assuming that the particle growth is caused by condensation of a low volatile vapor to the particle surface. In the nucleation mode, the relationship between C_v and GR is estimated by the following equation:

$$C_v = A \times GR \quad (4)$$

where A is a constant, specifically 1.37×10^7 h cm^{-3} for a vapor with the molecular properties of sulfuric acid. It assumed that C_v is constant during the growth process.

Assuming no other sink terms for the condensing vapor, source rate of condensable vapor is estimated under the steady-state condition:

$$Q = CS \times C_v \quad (5)$$

2.3. Backward trajectory analysis

To understand characteristics of NPF events depending on the origin and pathway of air masses, air mass backward trajectory analysis was performed by using the HYSPLIT model (Stein et al., 2015; http://www.arl.noaa.gov/HYSPLIR.php). The origin of air masses arriving at the observation site during the NPF events (a total of 101 event days) was manually categorized into four cases by analyzing 48-h backward trajectory data ending at height of 100, 500 and 1500 m above the ground level. The results with similar air mass origins and pathways during the NPF event periods at three different heights were used for the analysis in this study, as shown in Fig. 2. Accordingly, the air mass was categorized into four cases according to its origin and pathway: two affected continents including South America (Case I) and the Antarctic Peninsula (Case III) and two affected marine cases including the Weddell (Case II) and Bellingshausen Sea (Case IV).

3. Results and discussion

3.1 Characteristics of the NPF events

3.1.1 Occurrence frequency and FR of NPF events

After data screening as mentioned in the previous section, 1655-days of data recorded during the observation periods from March 2009 to December 2016 were analyzed. The data including valid data were classified into two groups, NPF event days and non-event days, by using $CN_{2.5\text{-}10}$ concentrations measured by two CPCs. The duration of the NPF ranged from 0.6 to 14.4 h, with a mean of 4.6 ± 1.5 h. Only 6.1% (101 days) of the results were defined as NPF events, whereas 93.9% (1554 days) were classified as the non-NPF events (Table 2). This NPF frequency at King Sejong Station in the Antarctic Peninsula is quite low compared with those in previous studies at other mid-latitude sites (Kulmala et al., 2004; Dal Maso et al., 2005; Pierce et al., 2014; Rose et al., 2015); comparison with other sites in the Antarctic is difficult owing to the lack of long-term observed results. In addition, the monthly variation of the NPF frequency was compared as shown in Fig. 3. It is clear that the NPF number was highest during the austral summer, from December to February, whereas non-events were observed in

the austral winter period from June to August. Approximately 72% of the NPF occurred during the summer period, showing the highest value of 38% in January. The clear difference in the frequency of the NPF events in austral summer and winter periods indicates that solar intensity and temperature play important roles in the formation and growth of aerosol particles, along with precursor vapors derived from marine biota activities in the Antarctica (Virkkula et al., 2009; Weller et al., 2015; Jang et al., 2018).

The FR of particles ranging from 2.5 nm to 10 nm varied from 0.16 to 9.88 cm^{-3} s^{-1}, with an average of 2.79 ± 1.05 cm^{-3} s^{-1}. Fig.4(a) shows the monthly variations in the FR over whole observation periods. The seasonal trend in the FR shows a pattern similar to that of the NPF events frequency. The FRs were the highest during the austral summer (December-February, 3.20 ± 1.09 cm^{-3} s^{-1}). Those in the austral autumn period (March-May, 1.71 ± 0.56 cm^{-3} s^{-1}) were similar to those of the spring period (September-November, 1.71 ± 0.79 cm^{-3} s^{-1}). Although the FR was 0.20 cm^{-3} s^{-1} and air masses were originated from South America (Case I) in May, only one NPF event occurred. In particular, the monthly maximum FR in December and the minimum in October were 3.52 cm^{-3} s^{-1} and 0.84 cm^{-3} s^{-1}, respectively. The FR measured at various stations in the Antarctic and other continents are summarized in Table 3. The average level of the FR observed in this study was more than 10 times higher than that of other stations in Antarctica. Although it is difficult to directly explain the causes of the higher FR, it is likely that the method used in this study to derive the FR influenced the results. The FRs were estimated in the previous studies on the basis of the size distribution data with few minute time resolution, whereas the FR in this study was calculated by using the variation in total number concentration ($CN_{2.5-10}$) data with a time resolution of 1 s. Another possible reason is the location. As shown in Table 3, the FR at a coastal region, specifically Mace Head located approximately 500 m from the coast, is higher than that reported at other sites due to the high biological activity of marine algae, which produce gaseous precursors from tidal zone and open oceans. Previous modeling research showed that the dimethyl sulfide emission in the Antarctic Peninsula during the

astral summer period is higher than that in other regions in Antarctica (Yu and Luo, 2010). Thus, the characteristics of the sampling site might have caused the FR to be higher than that at other site in Antarctica.

3.1.2 Calculation of other parameters based on size distribution data

On the basis of the size distribution results measured with a SMPS, NPF events were categorized into three NPF types, as mentioned as Sect. 2.2.2. Type C was dominant, as shown in Table 4; among all NPF event days, only two days (2.0%) were considered as Type A events. The GRs of nucleation mode particles ranged between 0.02 nm h^{-1} and 3.09 nm h^{-1}, with a mean of 0.68 ± 0.27 nm h^{-1}. Fig. 4(b) presents the monthly variation in the GR from March 2009 to December 2016. A seasonal trend in the GR is apparent, in which the maximum occurred in the summer. The GR gradually began to decrease in February and increase again in November, as shown in Fig. 4(b). The GR in January was 0.76 ± 0.26 nm h^{-1}, whereas that in November was 0.40 ± 0.15 nm h^{-1}. The GRs in September and October were not shown due to mechanical trouble of the instruments. The GR in this study is similar to the values reported in previous studies conducted in Antarctica. For instance, Weller et al. (2015) reported that the GR at the Neumayer station varied between 0.4 and 1.9 nm h^{-1}, with an average of 0.90±0.46 nm h^{-1}. However, our results are lower than those reported by Järvinen et al. (2013), who studied NPF events at Concordia station, Dome C from December 2007 to November 2009 and showed a GR of 4.3 nm h^{-1}. This discrepancy is likely attributed to the number of analyzed days. In the present study, we analyzed 86 of 101 NPF days, whereas the previous study analyzed 15 NPF days.

Fig. 4(c) shows a monthly variation in CS during NPF events. The CS varied from 0.02 × 10^{-3} s^{-1} to 25.66 ×10^{-3} s^{-1}, with an average of (6.04 ± 2.74) × 10^{-3} s^{-1}. The value was high in February ((8.17 ± 3.55) × 10^{-3} s^{-1}) and a low in April ((2.44 ± 0.70) × 10^{-3} s^{-1}), as shown in Fig. 4(c). The CS measured in this study was approximately 5-10 times higher than that observed at the other Antarctic station. Weller et al. (2015), who estimated the CS using light scattering data measured from Neumayer station,

indicated a CS value of about 10^{-3} s^{-1}. A median CS value of 4.0×10^{-4} s^{-1} in a 47-day observation period at Aboa station was reported by Kyrö et al. (2013). Järvinen et al. (2013) also showed a CS value of 1.8×10^{-4} s^{-1} using data of 15 days.

The monthly variation in the condensable vapor source rate during an NPF event is displayed in Fig. 4(d). The source rates derived were between 0.03×10^{3} and 3.74×10^{5} cm^{-3} s^{-1}, with a mean source rate of $(5.19 \pm 3.51) \times 10^{4}$ cm^{-3} s^{-1}. The source rate of condensable vapor was maximum during the austral summer months. In particular, the maximum and minimum average values of the source rate were $(6.40 \pm 3.43) \times 10^{4}$ cm^{-3} s^{-1} in January and $(1.93 \pm 0.92) \times 10^{4}$ cm^{-3} s^{-1} in November, respectively. This source rate was higher than that measured at a coastal Antarctic station. Kulmala et al. (2005) reported that the value of source rate varied from 0.9×10^{3} cm^{-3} s^{-1} to 2.0×10^{4} cm^{-3} s^{-1} at the Aboa station.

3.3 CCN concentration during NPF events

In this section, the contribution of particle formation to the variation in CCN concentration is investigated. Although recent studies reported that number concentrations of climate-relevant particles increased during NPF events (Pierce et al., 2014; Shen et al., 2016; Rose et al., 2017), the contribution of NPF to CCN concentration was estimated by using an indirect method. The number concentrations of particles larger than 50, 80 and 100 nm were estimated by using size distribution data. That value was considered as potential CCN concentration at different supersaturation value. In this study, however, CCN concentrations at a supersaturation value of 0.4% were directly measured by CCN counter. Hourly mean CCN concentrations were compared with CN concentrations and size distribution results (Fig S3 in the Supplement). Data for only 34 days out of 101 NPF days were valid due to the CCN data availability limited by the mechanical malfunctioning of the instrument. Fig. 5 shows variation in normalized values of $CN_{2.5\text{-}10}$ and CCN concentrations as a function of time during the NPF event periods. The normalized value was calculated from $CN_{2.5}$ and the CCN concentration at each time divided by the concentration recorded 1 h prior to the NPF event. The zero in the x-axis

in the figure represents the start time of the NPF event. The $CN_{2.5-10}$ concentrations sharply increased at NPF start time and the peak concentration occurred 2 h afterward, as shown in Fig. 5. Moreover, the CCN concentrations gradually increased for 9 h. Indeed, the maximum CCN concentrations rose from 170.7±38.6cm^{-3} to 185.6±44.6 cm^{-3} during and after the NPF events, respectively, showing an increase of 9%.

3.4 Effects of air mass origin on NPF events

The effects of air mass origin on the NPF characteristics were also investigated by 48-h air mass back trajectory analysis. Each trajectory according to four cases can be shown in Fig. S4 in the Supplement. The frequencies of NPF, FR, GR, CS, and the source rate of condensable vapor over the whole observation period are listed in Table 5. Here, the analysis results of the NPF characteristics of air masses originating from South America (Case I) are not shown owing to low frequencies. The air masses originating from the sea (Case II and IV) were dominant during NPF event at King Sejong Station. The FRs were analogous regardless of the air mass origin and pathway, while the GR of Case III and Case IV was significantly higher than those of Case II. The lower GR should be related to the CS and the source rate of condensable vapor. In the case of the air mass originating from the Weddell Sea (Case II), the CS was higher than that of other cases, whereas the source rate of condensing vapor was lowest. The higher CS and lower source rate might indicate a decline in condensing vapor and hence a decrease in GR. Our results for the source rate of condensable vapor agree with those of a previous study by Yu and Luo (2010), discussing the role of dimethyl sulfide (DMS) emission in the NPF process in remote oceans. In their model study, the concentrations of DMS and sulfuric acid in the Bellingshausen Sea and the Antarctic Peninsula area during the austral summer season were higher than those in Weddell Sea region. In satellite-derived estimates of the biological activities, DMS produced from phytoplankton was found to be more dominant in the Bellingshausen Sea than in the Weddell Sea (Jang et al., 2018). Sulfuric acid is derived from oxidation of DMS emitted from oceans

(Virkkula et al., 2009). In this study, the condensable vapor was assumed to be sulfuric acid in the source rate calculations, as mentioned in Sect. 2.2.3.

Fig. 6 shows a comparison of the NPF characteristics depending on the origin and pathway of the air mass during the summer season. The mean CS value was high. However, in case of the air mass originating from the Bellingshausen Sea (Case IV), the GR was relatively higher than the values of air masses originated from other region. The mean value of this source rate for the air mass originating from the Weddell Sea (Case II) was similar to that from the Antarctic Peninsula (Case III), while the CS mean value was 1.7 times higher. This resulted in a low GR.

For air mass originating from the Bellingshausen Sea (Case IV), the seasonal properties of the parameters related to the NPF events were analyzed. As shown in Fig. 7, the mean values of FR, GR and the source rate of condensable vapor were highest during the austral summer periods. However, mean values of CS were highest during the spring period.

4. Summary

In this study, the characteristics of NPF at King Sejong station in Antarctic Peninsula were investigated using a data set of eight years from March 2009 to December 2016, of total particle number concentrations and particle size distributions. The frequencies of NPF events and FR were obtained by using the data of total number concentrations, whereas GR, CS and the source rate of condensable vapor were calculated from the aerosol size distribution results. A low occurrence frequency of NPF events, at 6%, was observed, and most of the NPF events occurred during the austral summer. No NPF events were observed during the winter due to lower solar radiation and a lack of precursors for particle formation. The mean values of the FR and GR were 2.79 ± 1.05 cm^{-3} s^{-1} and 0.68 ± 0.27 nm h^{-1}, respectively. These results show that the FR at King Sejong Station as higher than that at other Antarctica sites, whereas the GR was relatively similar to values reported in previous studies conducted in the Antarctic. A possible reason for the lower GR can be attributed to the CS,

which was 5-10 times higher than that reported at other stations in Antarctica. This observation suggests that condensable vapor contributed to growth of nucleated nanoparticles and may have condensed onto pre-existing particles, hence decreasing the GR. According to 48-h backward trajectory analysis, air masses originating from oceanic areas were dominant during the NPF events. In order to investigate the contribution of the NPF events to variation in CCN concentrations at a supersaturation value of 0.4%, the CCN concentrations were compared with the $CN_{2.5\text{-}10}$ concentrations as a function of time. The results showed that the CCN concentrations during and after the NPF events increased approximately 9% compared with those measured before the event. This study is the first to report the characteristics of NPF in the Antarctic Peninsula. However, further research is need to understand the chemical characteristics of aerosol particles and the chemical composition of precursors during NPF events to fully understand the NPF for this region.

Author contributions

JK and YJY designed the study, YG, JHC, HJK, KTP, JP, and BYL analysed aerosol data. JK and YJY prepared the manuscript with contributions from all co-authors.

Acknowledgements

We would like to thank the many technicians and scientists of the overwintering crews. This work was supported by the KOPRI project (PE19010) and a Korea Grant from the Korean Government (MSIP) (NRF-2016M1A5A1901769) (KOPRI-PN19081).

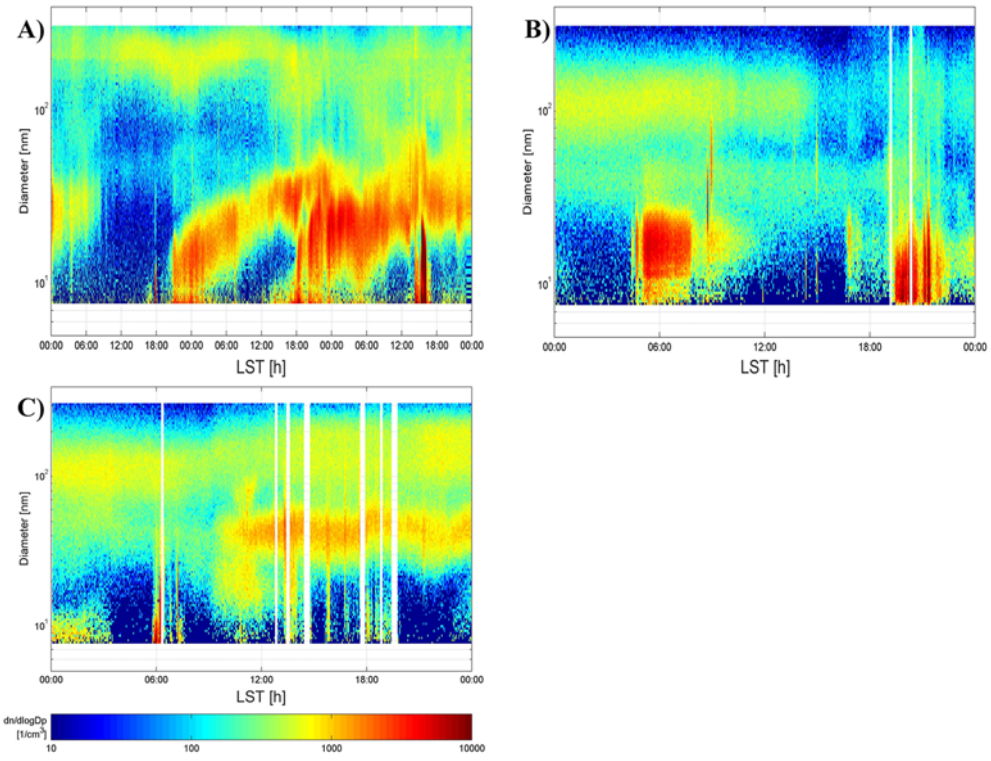

Figure 1. Example of types of the NPF based on the SMPS data. (a) type A (18 January 2011-20 January 2011), (b) type B (13 January 2015) and (c) type C (9 January 2015). Type A is days when the formation and growth of nanoparticles should be clear. Type B is days when the formation occurred but growth was not clear. Type C is days when it cannot be said whether there is an event or not.

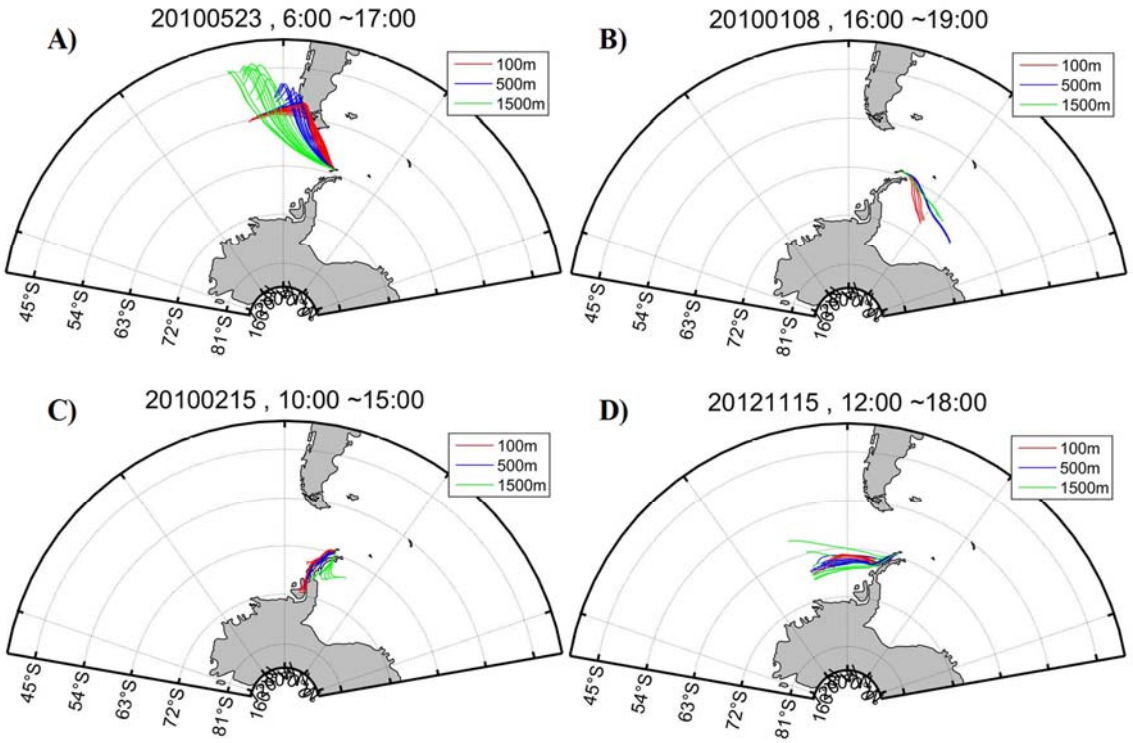

Figure 2. Example of the four cases considering to the air mass origin and pathway: (a) South America, (b) Weddell Sea, (c) Antarctic Peninsula, and (d) Bellingshausen Sea. Typical 48-h air mass backward trajectories were analyzed, ending at heights of 100m (Red line), 500m (Blue line) and 1500m (Green line) above the ground level of the sampling site.

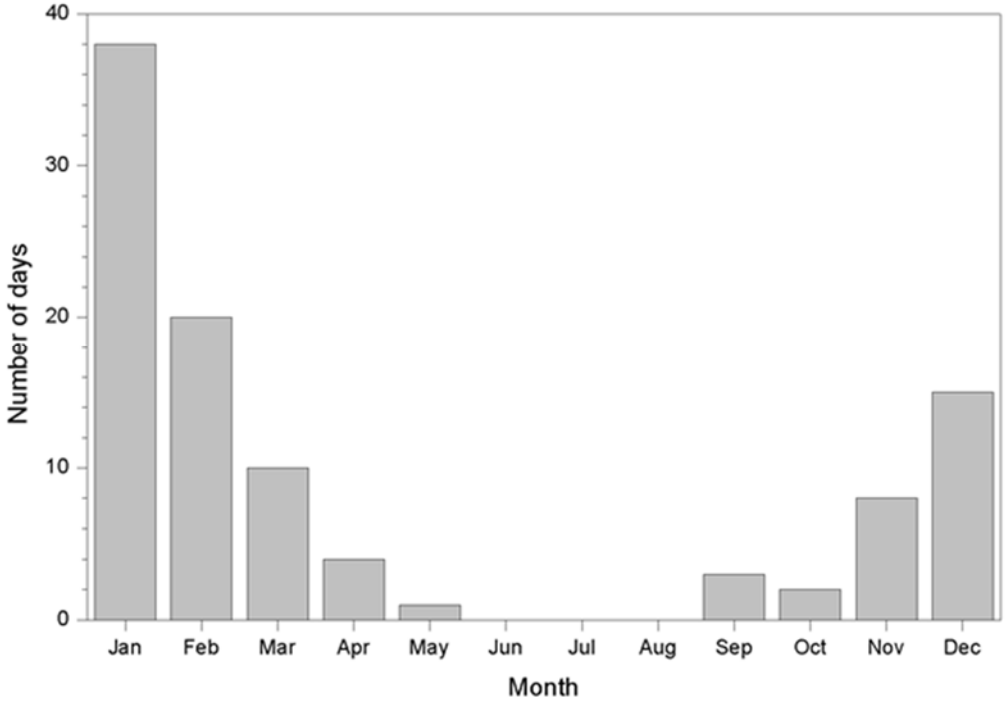

Figure 3. Monthly variation in the number of NPF days between March 2009 and December 2016.

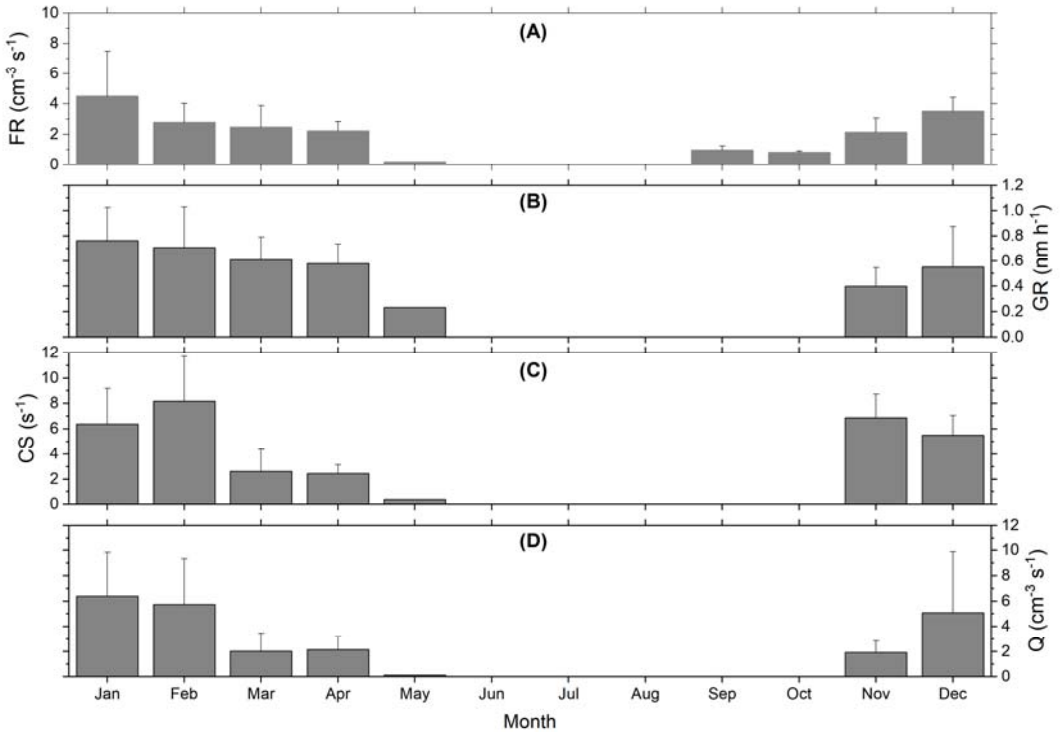

Figure 4. Monthly variations of (a) the formation rates (FR), (b) the growth rates (GR) of nucleation mode particles ranging from 10 nm to 25 nm, (c) the condensation sink (CS), and (d) the source rate of condensable vapor (Q). The error bars represent a standard deviation. The GRs in September and October were not shown due to mechanical trouble of the instruments.

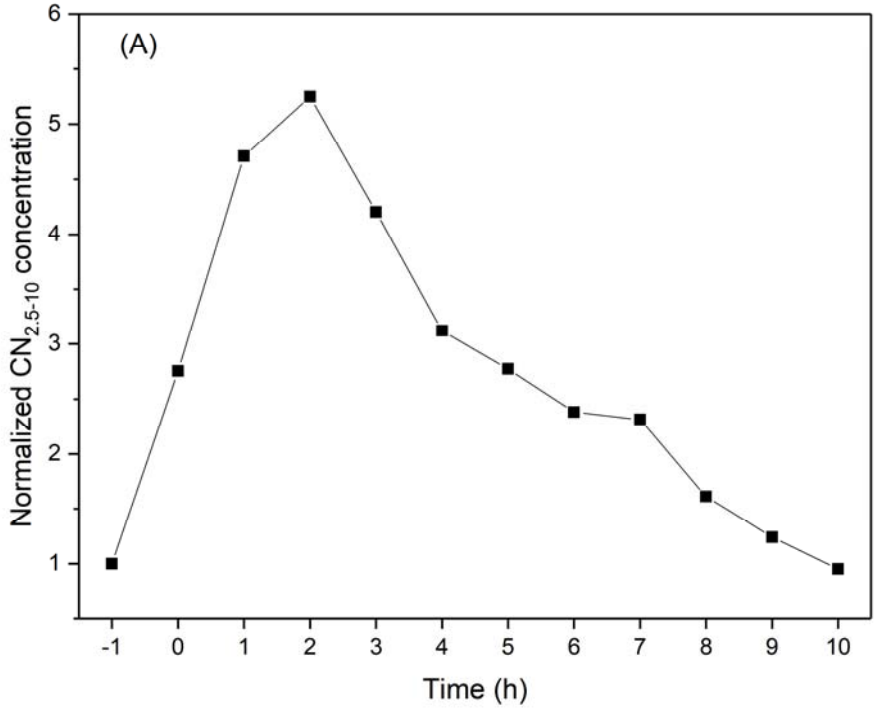

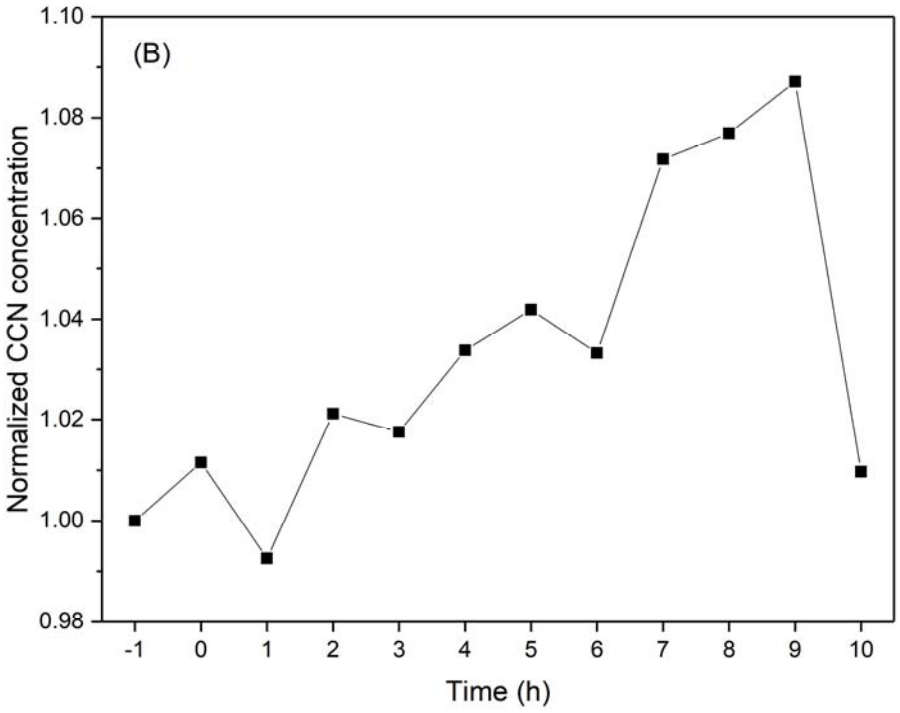

Figure 5. Variation in normalized (a) $CN_{2.5-10}$ and (b) CCN concentration with time. The zero in the x-axis indicates the start time of the NPF events.

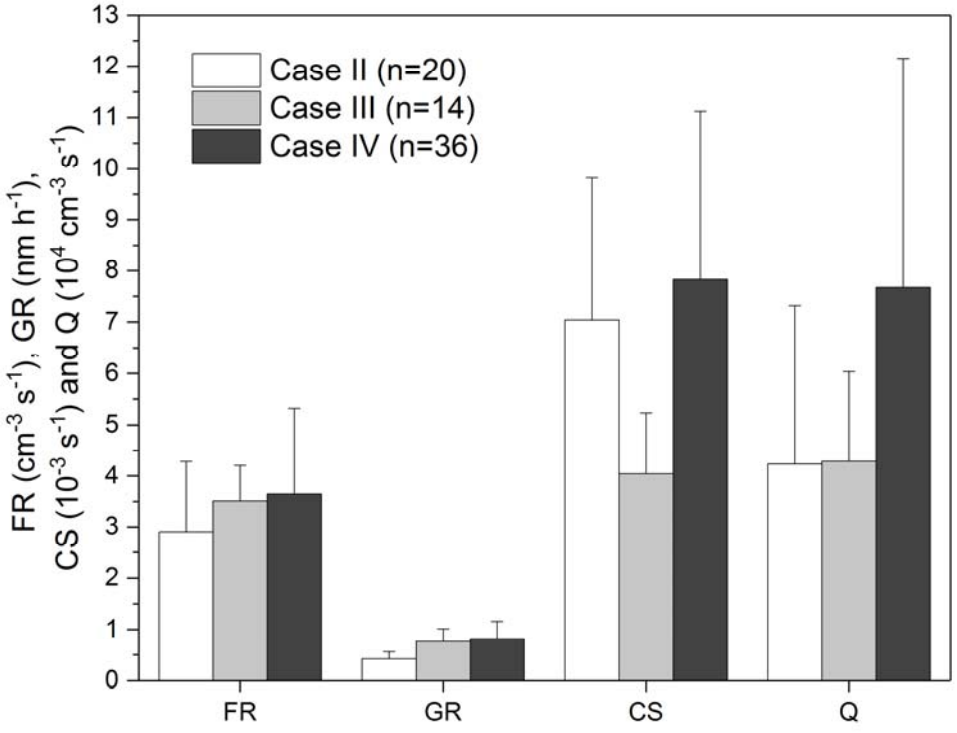

Figure 6. Comparison of NPF characteristics including the formation rate (FR), growth rate (GR), condensation sink (CS) and source rate of condensable vapors (Q) depending on the origins and pathway of air masses during the astral summer period. The error bars represent standard deviation.

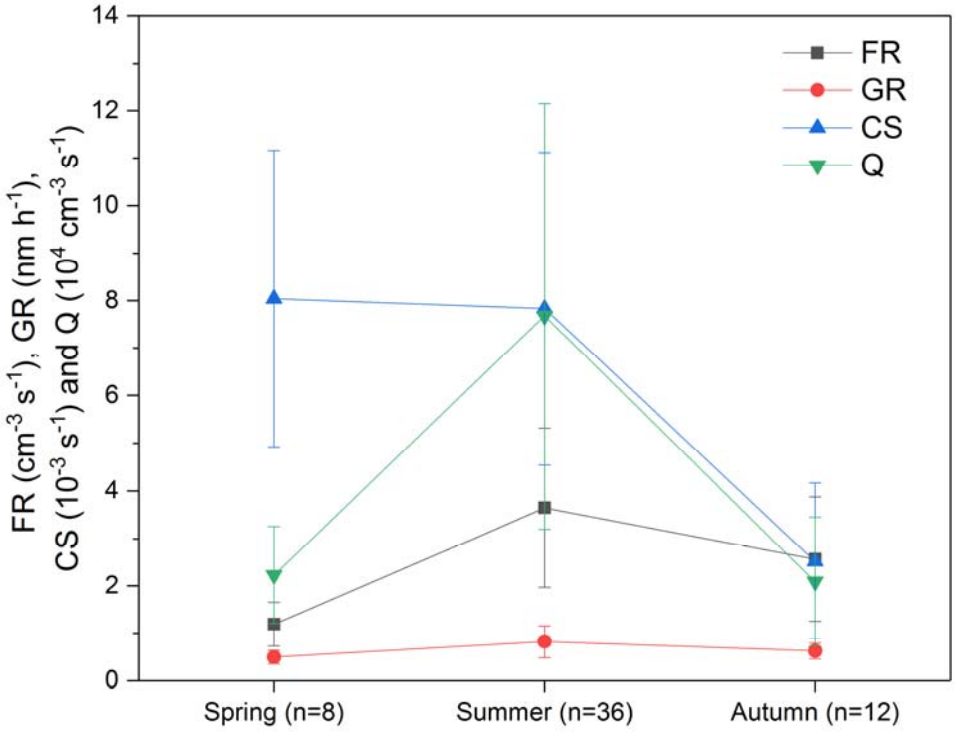

Figure 7. Seasonal characteristics of parameters related to NPF events in which the air masses originated from the Bellingshausen Sea. FR, GR, CS, and Q refer to formation rate, growth rate, condensation sink, and source rate of condensing vapor, respectively. The error bars represent standard deviation.

Table 1. Summary of data acquisition rate for each instrument during the analysis periods

Measurement parameter	Instrument	Data acquisition rate(%)
Number concentration of particle larger than 2.5 nm	CPC (TSI 3776)	80.7
Number concentration of particle larger than 10 nm	CPC (TSI 3772)	79.5
Size distribution	SMPS	40.3
CCN concentrations	CCNC	36.4

Table 2. Event statistics classified by using total concentration data obtained from two CPCs

	Days	Percentage of total days
NPF events	101	6.1
Non events	1554	93.9
Total	1655	

Table 3. Summary of the formation rates observed at different sampling site in Antarctica and in other continents. DMPS, SMPS, and CPC mean differential mobility particle sizer, scanning mobility particle sizer, and condensation particle counter, respectively.

Site	Period	Method	Formation rates (cm^{-3} s^{-1})		References
King Sejong (Antarctic Peninsula)	03/2009 ~ 12/2016	Two CPCs (TSI 3772 & TSI 3776)	$J_{2.5-10}$	2.79	This study

Table 4. NPF event classification statistics using size distribution results. Type A refers to days in which the formation and growth of particles were clear. Type B refer to days in which the formation occurred but the growth was not clear. Type C refers to days in which the event occurrence was unclear.

	Days	Percentage of NPF days
Type A	2	2.0
Type B	37	36.6
Type C	62	61.4
Total	101	

Table 5. Summary of NPF characteristic statics depending on the air mass origin. FR is the formation rate, GR is the growth rate, CS is the condensation sink, and Q is the source rate of condensable vapor. Case I, Case II, Case III, and Case IV refer to the origin and pathway of air masses from South America, the Weddell Sea, the Antarctic Peninsula, and the Bellingshausen Sea, respectively.

	NPF days	FR (cm^{-3} s^{-1})	GR (nm h^{-1})	CS (10^{-3} s^{-1})	Q (10^{4} cm^{-3} s^{-1})
Case I	3				
Case II	24	2.81 ± 1.29	0.41 ± 0.15	6.95 ± 2.65	3.87 ± 2.90
Case III	16	3.10 ± 0.80	0.77 ± 0.25	4.19 ± 1.30	4.29 ± 1.75
Case IV	56	3.08 ± 1.55	0.76 ± 0.30	6.79 ± 3.20	6.20 ± 4.08

Supplement of

New particle formation observed at King Sejong Station, Antarctic Peninsula – Part 1: Physical characteristics and contribution to cloud condensation nuclei

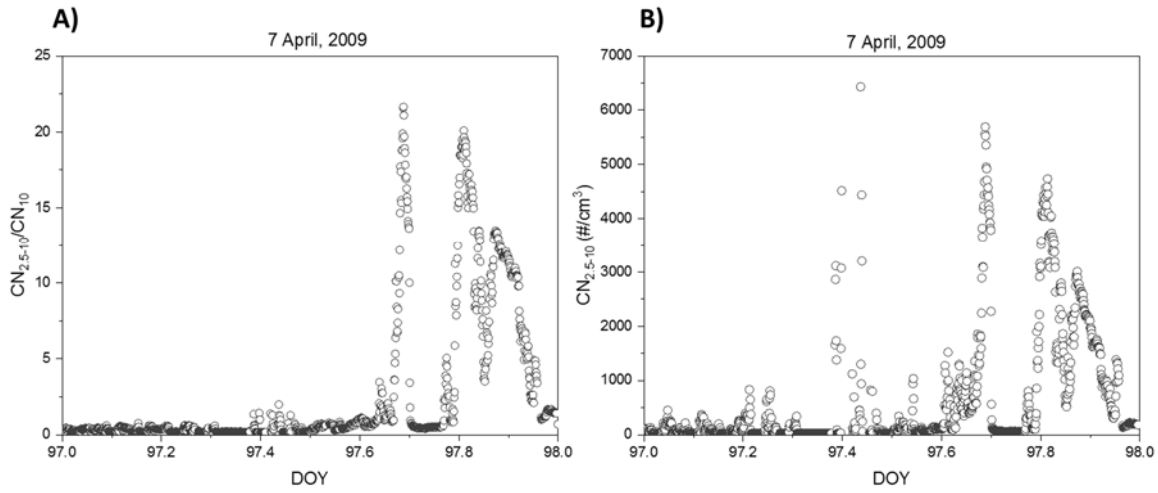

Figure S1. Example for estimation of the formation rate during NPF event on 7 April 2009: (a) $CN_{2.5-10}/CN_{10}$ and (b) $CN_{2.5-10}$ concentration with 1-minute time resolution.

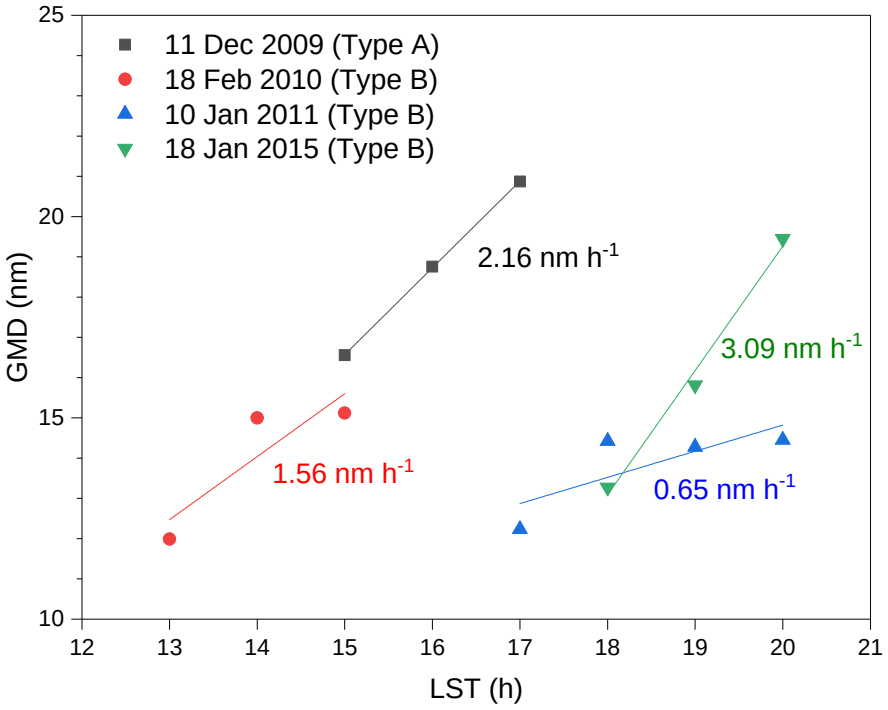

Figure S2. Geometric mean diameter (GMD) of particles ranging from 10 nm to 25 nm as a function of the time: the growth rate (nm h^{-1}) was calculated as the regression slope. The LST means local standard time.

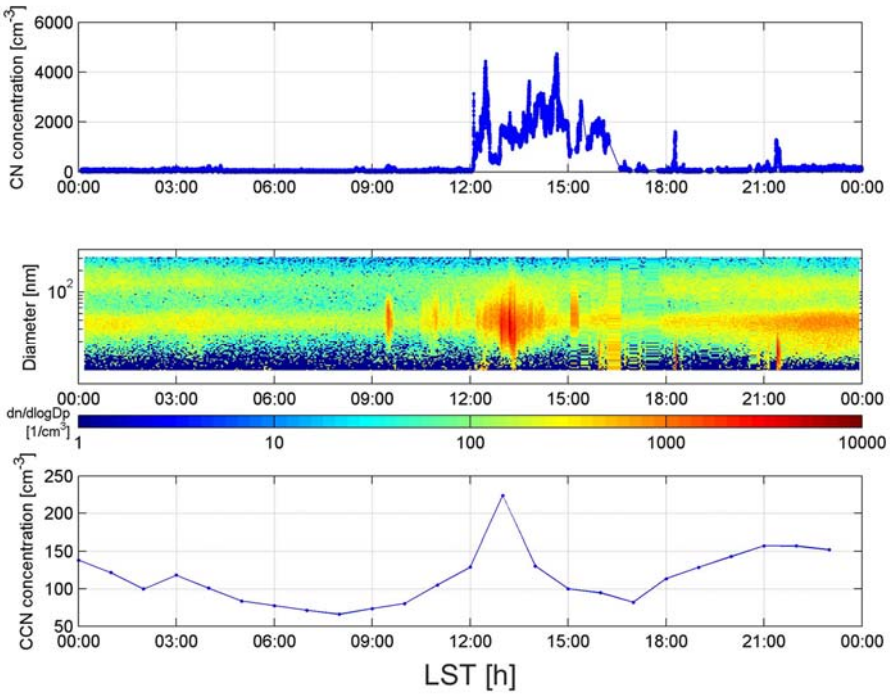

Figure S3. Example of comparison among CN concentrations from CPC data (upper panel), size distribution from SMPS data (middle panel) and hourly mean CCN concentration (bottom panel) at 0.4% supersaturation value as a function of time on 30 March 2009.

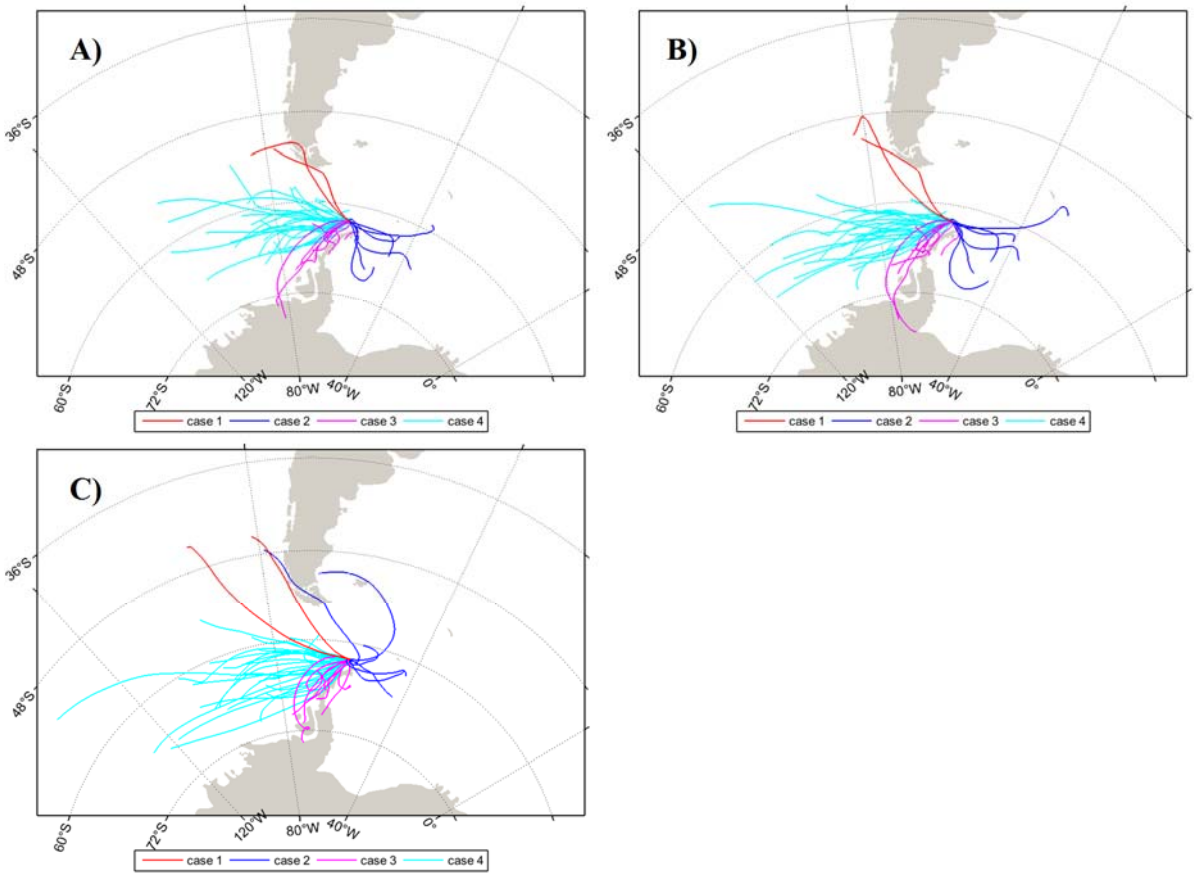

Figure S4. 48-h air mass backward trajectories at height of (a) 100m, (b) 500 m and (c) 1500 m above the ground level of the sampling site. Because 2-day trajectories can't be classified in four cases based on category method in this study, 99-day trajectories were shown. Red, blue, pink and cyan colored line indicate that air masses originated from the South America area (Case I), Weddell Sea (Case II), Antarctic Peninsula area (Case III) and Bellingshausen Sea (Case IV), respectively.
