Abstract

The physical characteristics of aerosol particles during particle bursts observed at King Sejong Station in Antarctic Peninsula from March 2009 to December 2016 were analyzed. This study focuses on the seasonal variation in parameters related to particle formation such as the occurrence, formation rate (FR) and growth rate (GR), condensation sink (CS), and source rate of condensable vapor. The number concentrations during new particle formation (NPF) events varied from 1707 cm⁻³ to 83120 cm⁻³, with an average of 20649 ± 9290 cm⁻³, and the duration of the NPF events ranged from 0.6 h to 14.4 h, with a mean of 4.6 ± 1.5 h. The NPF event dominantly occurred during austral summer period (~72%). The measured mean values of FR and GR of the aerosol particles were 2.79 ± 1.05 cm⁻³ s⁻¹ and 0.68 ± 0.27 nm h⁻¹, respectively showing enhanced rates in the summer season. The mean value of FR at King Sejong Station was higher than that at other sites in Antarctica, at 0.002-0.3 cm⁻³ s⁻¹, while those of growth rates was relatively similar results observed by precious studies, at 0.4~4.3 nm h⁻¹. The derived average values of CS and source rate of condensable vapor were (6.04 ± 2.74) × 10⁻³ s⁻¹ and (5.19 ± 3.51) × 10⁴ cm⁻³ s⁻¹, respectively. The contribution of particle formation to cloud

1 condensation nuclei (CCN) concentration was also investigated. The CCN concentration during the
2 NPF period increased approximately 11% compared with the background concentration. In addition,
3 the effects of the origin and pathway of air masses on the characteristics of aerosol particles during a
4 NPF event were determined. The FRs were similar regardless of the origin and pathway, whereas the
5 GRs of particles originating from the Antarctic Peninsula and the Bellingshausen Sea, at 0.77 ± 0.25
6 nm h^{-1} and $0.76 \pm 0.30 \text{ nm h}^{-1}$, respectively, were higher than those of particles originating from the
7 Weddell Sea ($0.41 \pm 0.15 \text{ nm h}^{-1}$).

8

9 **1. Introduction**

10 Understanding the effect of atmospheric aerosol particles on climate change is an important issue
11 in atmospheric science. These particles are highly significant substances in the radiation transfer
12 process in the atmosphere, with direct effects through scattering and absorption of solar radiation and
13 indirect effects by acting as cloud condensation nuclei (CCN) for cloud droplets (Anttila et al., 2012).
14 These particles also influence the properties and life time of clouds (Twomey, 1977; Albrecht, 1989).
15 Although aerosol particles play an important role in global and regional climates, large uncertainties
16 remain owing to a lack of knowledge on their formation and physicochemical characteristics (Carslaw
17 et al., 2013; IPCC, 2013).

18 New particle formation (NPF) frequently occurs in the atmosphere and leads to enhancement of the
19 total number concentrations of aerosol particles due to high numbers of nucleation mode particles
20 (Spracklen et al., 2006; Dall'Osto et al., 2017). The modeling study of Pierce and Adams (2007)
21 indicates that ultrafine particles of $<100 \text{ nm}$ in diameter can contribute to maximum CCN generations
22 of 40% and 90% at the boundary layer and in the remote free troposphere, respectively. In order to
23 understand the characteristics of the NPF, studies have been conducted in various regions including
24 coastal, forest, mountainous, rural and urban sites (O'Dowd et al., 2002; Komppula et al., 2003;
25 Kulmala et al., 2004; Yoon et al., 2006; Park et al., 2009; Kim et al., 2011; Rose et al., 2015; Bianchi

1 et al., 2016; Kontkanen et al., 2017). In addition, studies on the NPF phenomenon have recently been
2 conducted at various sites in the polar regions (Asmi et al., 2010; Järvinen et al., 2013; Kyrö et al.,
3 2013; Park et al., 2004; Weller et al., 2015; Humphries et al., 2016; Nguyen et al., 2016; Willis et al.,
4 2016; Barbaro et al., 2017; Dall'Osto et al., 2017). A NPF event occurring in the period between
5 December 1998 and December 2000 at the South Pole was reported by Park et al. (2004). Kyrö et al.
6 (2013) showed that oxidized organics derived from the oxidation of biogenic precursors originating
7 from local melting ponds might have contributed to particle growth at the Finnish research station
8 Aboa (73.50°S, 13.42°W). Although CCN concentrations were indirectly estimated at Aboa, Asmi et
9 al. (2010) also showed and discussed hygroscopic growth factor and CCN activity. In addition, studies
10 on the NPF were conducted at the Concordia station, Dome C (75.10°S, 123.38°E; Järvinen et al.,
11 2013) and at the coastal Antarctic station Neumayer (70.65°S, 8.25°W; Weller et al., 2015). Although
12 studies on NPF events have been conducted at various stations in the Antarctica, no results are available
13 for the station in the Antarctic Peninsula. Also, the contribution of NPF to CCN concentration is not
14 well understood in this area. Furthermore, results of the general long-term characteristics of aerosol
15 particles during the period of NPF observation in Antarctica are rare compared with those in other
16 continents.

17 In the present study, the frequency of NPF events was determined on the basis of total aerosol
18 number concentration. We investigated the physical characteristics such as formation rate (FR) and
19 growth rate (GR), condensation sink (CS) and source of condensation vapor as well as the seasonality
20 of atmospheric aerosols during NPF events at King Sejong Station in the Antarctic Peninsula. The
21 effect of particle formation on CCN concentrations was also examined. Furthermore, the air mass back
22 trajectories were analyzed by using the Hybrid Single Particle Lagrangian Integrated Trajectory
23 (HYSPLIT) model to understand physical properties of NPF events depending on the origins and
24 pathway of the air masses.

25

1 **2. Methods**

2 **2.1. Site description and instrumentation**

3 The data analyzed in this study were obtained from March 2009 to December 2012 at the King
4 Sejong station in the Antarctic Peninsula (62.22°S, 58.78°W). Further details on the sampling site as
5 well as the instrumental specification and operation were introduced in the previous study (Kim et al.,
6 2017). In brief, two condensation particle counters (CPCs; TSI 3776 and TSI 3772) were used to
7 measure the total particle number concentrations. The aerosol size distributions of particles ranging
8 from 10 to 300 nm were measured every 3 minutes with a scanning mobility particle sizer (SMPS)
9 consisting of a differential mobility analyzer (DMA; HCT Inc., LDMA 4210) and a CPC (TSI 3772).
10 The flow rate of sheath air and aerosol flow of DMA were 10 L min⁻¹ and 1 L min⁻¹, respectively. The
11 CCN concentrations were simultaneously measured by using a CCN counter (DMT CCN-100) with
12 five different supersaturation values (i.e. 0.2, 0.4, 0.6, 0.8 and 1.0%). The sampling duration was set
13 to be 5 minutes for each supersaturation value (except for 0.2%). For the 0.2% supersaturation value,
14 the CCN concentration was measured for 10 min because of stability after measurements at 1%
15 supersaturation value. In the present work, only results of CCN concentration for a 0.4%
16 supersaturation value were used. In addition, meteorological parameters including temperature,
17 relative humidity, wind speed, wind direction, pressure, and solar radiation intensity were continuously
18 monitored by using an automatic weather station (AWS; Vaisala HMP45 for measuring temperature
19 and relative humidity, WeatherTronics 2102 for measuring wind speed and direction, WeatherTronics
20 7100 for measuring pressure and Eppley Precision Spectral Pyranometer PSP for measuring solar
21 radiation intensity) system.

22 23 **2.2. Data analysis**

24 To ensure data quality, raw data were discarded if one of the following conditions was satisfied: (i)
25 wind direction between 355° and 55° (local pollution sector) (ii) concentration of black carbon higher

1 than 100 ng m^{-3} , (iii) wind speed less than 2 m s^{-1} and (iv) instrument malfunction based on the log-
2 book. If valid data for one day were less than 50% after discarding the raw data, such days were
3 excluded. The acquisition rate for each instrument is summarized in Table 1. Here, the acquisition rate
4 indicates the value of the analyzed days divided by the total measurement days. Because the acquisition
5 rate from the SMPS was lower than that of the CPC in this study, the value difference between the
6 concentrations of particles larger than 2.5 nm ($\text{CN}_{2.5}$) and 10 nm (CN_{10}) observed from two CPCs was
7 used to identify the NPF events.

8

9 **2.2.1. Definition of NPF events**

10 As mentioned in the previous section, the difference between $\text{CN}_{2.5}$ and CN_{10} concentrations were
11 used to define days for NPF events or non-NPF events (Yoon et al., 2006). The $\text{CN}_{2.5-10}$ represents the
12 number concentrations of newly formed particles produced from gas-to-particle conversion. The NPF
13 days were defined in this study according to the following conditions: (i) The $\text{CN}_{2.5-10}$ is higher than
14 500 cm^{-3} (ii) the $\text{CN}_{2.5-10}/\text{CN}_{10}$ ratio is higher than 10 and (iii) the NPF duration is longer than 30 min.
15 The $\text{CN}_{2.5-10}/\text{CN}_{10}$ ratio is the parameter used to distinguish between particles newly formed from gas-
16 to-particle conversion and background particles (Warren and Seinfeld, 1985; Humphries et al., 2015).
17 Humphries et al. (2016) also used the $\text{CN}_{2.5-10}/\text{CN}_{10}$ ratio to distinguish the NPF days during a 52 days'
18 voyage in the East Antarctic sea ice region because the number concentration data were more reliable
19 than the size distribution data.

20

21 **2.2.2. Classification of NPF events using SMPS data**

22 After identification of the NPF event days, classification of the NPF events was conducted by using
23 size distributions from a SMPS. The NPF events were classified into three types of A, B and C
24 according to the classification by Dal Maso et al. (2005) and Yli-Juuti et al. (2009) as shown in Fig. 1.
25 Type A describes days in which the formation and growth of particles were clear. Type B describes

1 days in which the formation occurred but growth was not clear. Type C describes days in which the
2 event occurrence was not distinct.

3

4 **2.2.3. Estimation of parameters for NPF characteristics**

5 On the basis of the average number concentration data with 1 min time resolution, the FR was
6 calculated for cases in which $CN_{2.5-10}/CN_{10}$ values and $CN_{2.5-10}$ concentrations sharply increased (Fig.
7 S1 in the Supplement). The FR of new particles ranging from 2.5 nm to 10 nm was determined
8 according to variation in the number concentrations of $CN_{2.5-10}$ based on the following equation (Dal
9 Maso et al., 2005):

10

$$11 \quad FR = \frac{dN_{nuc}}{dt} + F_{coag} + F_{growth} \quad (1)$$

12

13 Here, N_{nuc} is the particle number concentrations of nucleation mode. In this study, the $CN_{2.5-10}$
14 concentrations obtained by two particle counters were used for the term N_{nuc} . F_{coag} is the particle loss
15 in accordance with coagulation, and F_{growth} represents the flux of particles growing from the nucleation
16 mode. Because the $CN_{2.5-10}$ concentrations were predominant in the total number concentration and
17 the particles rarely grew over the nucleation mode during the formation period, the F_{coag} and F_{growth}
18 terms in Eq. 1 were neglected in this study (Dal Maso et al., 2005; Shen et al., 2016).

19

20 The GRs were calculated by using the size distributions measured by a SMPS. Based on the hourly
21 mean aerosol size distribution data, the geometric mean diameter (GMD) of particles which is limited
22 to the size range of 10-25 nm was used. Here, the GMD was calculated from log-normal fitting analysis
23 (Hinds, 1999). According to these method, growth rate of particles ranging from 10-25 nm was
24 estimated regardless of the NPF event types (Fig. S2 in the Supplement). The GR was determined by
25 rate of change in the GMD by using the following equation (Kulmala et al., 2004; Dal Maso et al.,
2005):

$$GR = \frac{dD_p}{dt} \quad (2)$$

The CS is an important parameter governing the NPF because it indicates the loss rate in which gaseous molecules condense onto pre-existing aerosols. It can be estimated from the size distribution data according to the following equation (Dal Maso et al., 2005; Kulmala et al., 2005; Shen et al., 2016):

$$CS = 2\pi D \sum_{d_p} \beta_m d_p N_{dp} \quad (3)$$

where D is the diffusion coefficient of the condensable vapor ($0.1 \text{ cm}^2 \text{ s}^{-1}$), β is the transitional regime correction factor from Fuchs and Sutugin (1970), and d_p and N_{dp} are the particle size and number concentration, respectively. It is assumed that condensable vapor is gaseous sulfuric acid which has been reported to play an important role in the nucleation process (Dal Maso et al., 2005).

According to the GR and the CS, it is possible to estimate condensable vapor concentration, C_v (unit: molecules cm^{-3}) and its source rate, Q (unit: molecules $\text{cm}^{-3} \text{ s}^{-1}$; Kulmala et al., 2001; Dal Maso, 2002), assuming that the particle growth is caused by condensation of a low volatile vapor to the particle surface. In the nucleation mode, the relationship between C_v and GR is estimated by the following equation:

$$C_v = A \times GR \quad (4)$$

where A is a constant, specifically $1.37 \times 10^7 \text{ h cm}^{-3}$ for a vapor with the molecular properties of sulfuric acid. It assumed that C_v is constant during the growth process.

Assuming no other sink terms for the condensing vapor, source rate of condensable vapor is estimated under the steady-state condition:

$$Q = CS \times C_v \quad (5)$$

2.3. Backward trajectory analysis

To understand characteristics of NPF events depending on the origin and pathway of air masses, air mass backward trajectory analysis was performed by using the HYSPLIT model (Stein et al., 2015; <http://www.arl.noaa.gov/HYSPLIT.php>). The origin of air masses arriving at the observation site during the NPF events (a total of 101 event days) was manually categorized into four cases by analyzing 48-h backward trajectory data ending at height of 100, 500 and 1500 m above the ground level. The results with similar air mass origins and pathways during the NPF event periods at three different heights were used for the analysis in this study, as shown in Fig. 2. Accordingly, the air mass was categorized into four cases according to its origin and pathway: two affected continents including South America (Case I) and the Antarctic Peninsula (Case III) and two affected marine cases including the Weddell (Case II) and Bellingshausen Sea (Case IV).

3. Results and discussion

3.1 Characteristics of the NPF events

3.1.1 Occurrence frequency and FR of NPF events

After data screening as mentioned in the previous section, 1655-days of data recorded during the observation periods from March 2009 to December 2016 were analyzed. The data including valid data were classified into two groups, NPF event days and non-event days, by using $\text{CN}_{2.5-10}$ concentrations measured by two CPCs. The duration of the NPF ranged from 0.6 to 14.4 h, with a mean of 4.6 ± 1.5 h. Only 6.1% (101 days) of the results were defined as NPF events, whereas 93.9% (1554 days) were classified as the non-NPF events (Table 2). This NPF frequency at King Sejong Station in the Antarctic Peninsula is quite low compared with those in previous studies at other mid-latitude sites (Kulmala et al., 2004; Dal Maso et al., 2005; Pierce et al., 2014; Rose et al., 2015); comparison with other sites in

1 the Antarctic is difficult owing to the lack of long-term observed results. In addition, the monthly
2 variation of the NPF frequency was compared as shown in Fig. 3. It is clear that the NPF number was
3 highest during the austral summer, from December to February, whereas non-events were observed in
4 the austral winter period from June to August. Approximately 72% of the NPF occurred during the
5 summer period, showing the highest value of 38% in January. The clear difference in the frequency of
6 the NPF events in austral summer and winter periods indicates that solar intensity and temperature
7 play important roles in the formation and growth of aerosol particles, along with precursor vapors
8 derived from marine biota activities in the Antarctica (Virkkula et al., 2009; Weller et al., 2015; Jang
9 et al., 2018).

10 The FR of particles ranging from 2.5 nm to 10 nm varied from 0.16 to 9.88 cm⁻³ s⁻¹, with an average
11 of 2.79 ± 1.05 cm⁻³ s⁻¹. Fig.4(a) shows the monthly variations in the FR over whole observation periods.
12 The seasonal trend in the FR shows a pattern similar to that of the NPF events frequency. The FRs
13 were the highest during the austral summer (December-February, 3.20 ± 1.09 cm⁻³ s⁻¹). Those in the
14 austral autumn period (March-May, 1.71 ± 0.56 cm⁻³ s⁻¹) were similar to those of the spring period
15 (September-November, 1.71 ± 0.79 cm⁻³ s⁻¹). Although the FR was 0.20 cm⁻³ s⁻¹ and air masses were
16 originated from South America (Case I) in May, only one NPF event occurred. In particular, the
17 monthly maximum FR in December and the minimum in October were 3.52 cm⁻³ s⁻¹ and 0.84 cm⁻³ s⁻¹,
18 respectively. The FR measured at various stations in the Antarctic and other continents are
19 summarized in Table 3. The average level of the FR observed in this study was more than 10 times
20 higher than that of other stations in Antarctica. Although it is difficult to directly explain the causes of
21 the higher FR, it is likely that the method used in this study to derive the FR influenced the results.
22 The FRs were estimated in the previous studies on the basis of the size distribution data with few
23 minute time resolution, whereas the FR in this study was calculated by using the variation in total
24 number concentration (CN_{2.5-10}) data with a time resolution of 1 s. Another possible reason is the
25 location. As shown in Table 3, the FR at a coastal region, specifically Mace Head located

1 approximately 500 m from the coast, is higher than that reported at other sites due to the high biological
2 activity of marine algae, which produce gaseous precursors from tidal zone and open oceans. Previous
3 modeling research showed that the dimethyl sulfide emission in the Antarctic Peninsula during the
4 austral summer period is higher than that in other regions in Antarctica (Yu and Luo, 2010). Thus, the
5 characteristics of the sampling site might have caused the FR to be higher than that at other site in
6 Antarctica. Besides, human activities should be one of the possible reasons of high aerosol FR and
7 concentrations. Although strict data filtering procedure was applied to the raw data-set to minimize the
8 effect of local contamination as mentioned in Section 2.2, previous study showed that BC
9 concentrations at King Sejong Station were higher than those at other stations in Antarctica (Kim et
10 al., 2017). In fact, other studies (Shirsat and Graf, 2009; Graf et al., 2010) also reported that there were
11 local pollution sources from tourist ships and emissions associated with scientific activities in Antarctic
12 Peninsula, especially during austral summer seasons. These periodic human activities around the
13 Antarctic Peninsula cannot be ruled out to be a potential factor to contribute the higher aerosol FR and
14 concentrations.

15 16 **3.1.2 Calculation of other parameters based on size distribution data**

17 On the basis of the size distribution results measured with a SMPS, NPF events were categorized
18 into three NPF types, as mentioned as Sect. 2.2.2. Type C was dominant, as shown in Table 4; among
19 all NPF event days, only two days (2.0%) were considered as Type A events. The GRs of nucleation
20 mode particles ranged between 0.02 nm h^{-1} and 3.09 nm h^{-1} , with a mean of $0.68 \pm 0.27 \text{ nm h}^{-1}$. Fig.
21 4(b) presents the monthly variation in the GR from March 2009 to December 2016. A seasonal trend
22 in the GR is apparent, in which the maximum occurred in the summer. The GR gradually began to
23 decrease in February and increase again in November, as shown in Fig. 4(b). The GR in January was
24 $0.76 \pm 0.26 \text{ nm h}^{-1}$, whereas that in November was $0.40 \pm 0.15 \text{ nm h}^{-1}$. The GRs in September and
25 October were not shown due to mechanical trouble of the instruments. The GR in this study is similar

1 to the values reported in previous studies conducted in Antarctica. For instance, Weller et al. (2015)
2 reported that the GR at the Neumayer station varied between 0.4 and 1.9 nm h⁻¹, with an average of
3 0.90±0.46 nm h⁻¹. However, our results are lower than those reported by Järvinen et al. (2013), who
4 studied NPF events at Concordia station, Dome C from December 2007 to November 2009 and showed
5 a GR of 4.3 nm h⁻¹. This discrepancy is likely attributed to the number of analyzed days. In the present
6 study, we analyzed 86 of 101 NPF days, whereas the previous study analyzed 15 NPF days.

7 Fig. 4(c) shows a monthly variation in CS during NPF events. The CS varied from $0.02 \times 10^{-3} \text{ s}^{-1}$
8 to $25.66 \times 10^{-3} \text{ s}^{-1}$, with an average of $(6.04 \pm 2.74) \times 10^{-3} \text{ s}^{-1}$. The value was high in February ($(8.17 \pm$
9 $3.55) \times 10^{-3} \text{ s}^{-1}$) and a low in April ($(2.44 \pm 0.70) \times 10^{-3} \text{ s}^{-1}$), as shown in Fig. 4(c). The CS measured
10 in this study was approximately 5-10 times higher than that observed at the other Antarctic station.
11 Weller et al. (2015), who estimated the CS using light scattering data measured from Neumayer station,
12 indicated a CS value of about 10^{-3} s^{-1} . A median CS value of $4.0 \times 10^{-4} \text{ s}^{-1}$ in a 47-day observation period
13 at Aboa station was reported by Kyrö et al. (2013). Järvinen et al. (2013) also showed a CS value of
14 $1.8 \times 10^{-4} \text{ s}^{-1}$ using data of 15 days.

15 The monthly variation in the condensable vapor source rate during an NPF event is displayed in
16 Fig. 4(d). The source rates derived were between 0.03×10^3 and $3.74 \times 10^5 \text{ cm}^{-3} \text{ s}^{-1}$, with a mean source
17 rate of $(5.19 \pm 3.51) \times 10^4 \text{ cm}^{-3} \text{ s}^{-1}$. The source rate of condensable vapor was maximum during the
18 austral summer months. In particular, the maximum and minimum average values of the source rate
19 were $(6.40 \pm 3.43) \times 10^4 \text{ cm}^{-3} \text{ s}^{-1}$ in January and $(1.93 \pm 0.92) \times 10^4 \text{ cm}^{-3} \text{ s}^{-1}$ in November, respectively.
20 This source rate was higher than that measured at a coastal Antarctic station. Kulmala et al. (2005)
21 reported that the value of source rate varied from $0.9 \times 10^3 \text{ cm}^{-3} \text{ s}^{-1}$ to $2.0 \times 10^4 \text{ cm}^{-3} \text{ s}^{-1}$ at the Aboa station.

22 23 **3.3 CCN concentration during NPF events**

24 In this section, the contribution of particle formation to the variation in CCN concentration is
25 investigated. Although recent studies reported that number concentrations of climate-relevant particles

1 increased during NPF events (Pierce et al., 2014; Shen et al., 2016; Rose et al., 2017), the contribution
2 of NPF to CCN concentration was estimated by using an indirect method. The number concentrations
3 of particles larger than 50, 80 and 100 nm were estimated by using size distribution data. That value
4 was considered as potential CCN concentration at different supersaturation value. In the present study,
5 CCN concentrations at a supersaturation value of 0.4% were directly measured using CCN counter.
6 Hourly mean CCN concentrations were compared with CN concentrations measured by CPC and size
7 distribution results measured by SMPS (Fig S3 in the Supplement). Data for only 27 days, when all
8 the three data-set (CPC, CCN counter, and SMPS) were available, were analyzed. Fig. 5 shows
9 variation in $CN_{2.5-10}$ concentrations, CCN concentrations, and number concentrations as a function of
10 time elapsed after the NPF event. The zero in the x-axis means the start time of the NPF event. As
11 shown in Fig. 5a and b, the $CN_{2.5-10}$ concentrations sharply increased at NPF start time and the peak
12 concentration occurred 2 h afterward, whereas the CCN concentrations gradually increased for 8 h.
13 Indeed, the maximum CCN concentrations rose from $191.4 \pm 16.3 \text{ cm}^{-3}$ to $213.2 \pm 17.7 \text{ cm}^{-3}$ before and
14 after the NPF events, respectively, showing an increase of 11%. Fig 5b also shows variation of number
15 concentrations (N_{50} , N_{80} , and N_{100}) of particles larger than 50 nm, 80 nm, and 100 nm, respectively.
16 Number concentrations were calculated from aerosol size distribution data. Variation trends of the
17 number concentrations were similar to those of CCN concentrations, increasing approximately 15%
18 before and after the NPF events.

19

20 **3.4 Effects of air mass origin on NPF events**

21 The effects of air mass origin on the NPF characteristics were also investigated by 48-h air mass
22 back trajectory analysis. Each trajectory according to four cases can be shown in Fig. S4 in the
23 Supplement. The frequencies of NPF, FR, GR, CS, and the source rate of condensable vapor over the
24 whole observation period are listed in Table 5. Here, the analysis results of the NPF characteristics of
25 air masses originating from South America (Case I) are not shown owing to low frequencies. The air

1 masses originating from the sea (Case II and IV) were dominant during NPF event at King Sejong
2 Station. The FRs were analogous regardless of the air mass origin and pathway, while the GR of Case
3 III and Case IV was significantly higher than those of Case II. The lower GR should be related to the
4 CS and the source rate of condensable vapor. In the case of the air mass originating from the Weddell
5 Sea (Case II), the CS was higher than that of other cases, whereas the source rate of condensing vapor
6 was lowest. The higher CS and lower source rate might indicate a decline in condensing vapor and
7 hence a decrease in GR. Our results for the source rate of condensable vapor agree with those of a
8 previous study by Yu and Luo (2010), discussing the role of dimethyl sulfide (DMS) emission in the
9 NPF process in remote oceans. In their model study, the concentrations of DMS and sulfuric acid in
10 the Bellingshausen Sea and the Antarctic Peninsula area during the austral summer season were higher
11 than those in Weddell Sea region. In satellite-derived estimates of the biological activities, DMS
12 produced from phytoplankton was found to be more dominant in the Bellingshausen Sea than in the
13 Weddell Sea (Jang et al., 2018). Sulfuric acid is derived from oxidation of DMS emitted from oceans
14 (Virkkula et al., 2009). In this study, the condensable vapor was assumed to be sulfuric acid in the
15 source rate calculations, as mentioned in Sect. 2.2.3.

16 Fig. 6 shows a comparison of the NPF characteristics depending on the origin and pathway of the
17 air mass during the summer season. The mean CS value was high. However, in case of the air mass
18 originating from the Bellingshausen Sea (Case IV), the GR was relatively higher than the values of air
19 masses originated from other region. The mean value of this source rate for the air mass originating
20 from the Weddell Sea (Case II) was similar to that from the Antarctic Peninsula (Case III), while the
21 CS mean value was 1.7 times higher. This resulted in a low GR.

22 For air mass originating from the Bellingshausen Sea (Case IV), the seasonal properties of the
23 parameters related to the NPF events were analyzed. As shown in Fig. 7, the mean values of FR, GR
24 and the source rate of condensable vapor were highest during the austral summer periods. However,
25 mean values of CS were highest during the spring period.

4. Summary

In this study, the characteristics of NPF at King Sejong station in Antarctic Peninsula were investigated using a data set of eight years from March 2009 to December 2016, of total particle number concentrations and particle size distributions. The frequencies of NPF events and FR were obtained by using the data of total number concentrations, whereas GR, CS and the source rate of condensable vapor were calculated from the aerosol size distribution results. A low occurrence frequency of NPF events, at 6%, was observed, and most of the NPF events occurred during the austral summer. No NPF events were observed during the winter due to lower solar radiation and a lack of precursors for particle formation. The mean values of the FR and GR were $2.79 \pm 1.05 \text{ cm}^{-3} \text{ s}^{-1}$ and $0.68 \pm 0.27 \text{ nm h}^{-1}$, respectively. These results show that the FR at King Sejong Station is higher than that at other Antarctica sites, whereas the GR was relatively similar to values reported in previous studies conducted in the Antarctic. A possible reason for the lower GR can be attributed to the CS, which was 5-10 times higher than that reported at other stations in Antarctica. This observation suggests that condensable vapor contributed to growth of nucleated nanoparticles and may have condensed onto pre-existing particles, hence decreasing the GR. According to 48-h backward trajectory analysis, air masses originating from oceanic areas were dominant during the NPF events. In order to investigate the contribution of the NPF events to variation in CCN concentrations at a supersaturation value of 0.4%, the CCN concentrations were compared with the $\text{CN}_{2.5-10}$ concentrations as a function of time. The results showed that the CCN concentrations during and after the NPF events increased approximately 11% compared with those measured before the event. This study is the first to report the characteristics of NPF in the Antarctic Peninsula. However, further research is needed to understand the chemical characteristics of aerosol particles and the chemical composition of precursors during NPF events to fully understand the NPF for this region including Arctic Permafrost area.

Author contributions

JK and YJY designed the study, YG, JHC, HJK, KTP, JP, and BYL analysed aerosol data. JK and YJY prepared the manuscript with contributions from all co-authors.

Data availability

The data analysed in this publication will be readily provided upon request to the corresponding author (yjyoon@kopri.re.kr).

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

We would like to thank the many technicians and scientists of the overwintering crews. This work was supported by the KOPRI project (PE19010) and a Korea Grant from the Korean Government (MSIT) (NRF-2016M1A5A1901769) (KOPRI-PN19081).

Figure 6. Comparison of NPF characteristics including the formation rate (FR), growth rate (GR), condensation sink (CS) and source rate of condensable vapors (Q) depending on the origins and pathway of air masses during the astral summer period. The error bars represent standard deviation.

Figure 7. Seasonal characteristics of parameters related to NPF events in which the air masses originated from the Bellingshausen Sea. FR, GR, CS, and Q refer to formation rate, growth rate, condensation sink, and source rate of condensing vapor, respectively. The error bars represent standard deviation.

1

2 Table 1. Summary of data acquisition rate for each instrument during the analysis periods

Measurement parameter	Instrument	Data acquisition rate(%)
Number concentration of particle larger than 2.5 nm	CPC (TSI 3776)	80.7
Number concentration of particle larger than 10 nm	CPC (TSI 3772)	79.5
Size distribution	SMPS	40.3
CCN concentrations	CCNC	36.4

5

6 Table 2. Event statistics classified by using total concentration data obtained from two CPCs

	Days	Percentage of total days
NPF events	101	6.1
Non events	1554	93.9
Total	1655	

7

1 Table 3. Summary of the formation rates observed at different sampling site in Antarctica and in other continents. DMPS, SMPS, and CPC mean
 2 differential mobility particle sizer, scanning mobility particle sizer, and condensation particle counter, respectively.

1 Table 4. NPF event classification statistics using size distribution results. Type A refers to days in which
 2 the formation and growth of particles were clear. Type B refer to days in which the formation occurred
 3 but the growth was not clear. Type C refers to days in which the event occurrence was unclear.

	Days	Percentage of NPF days
Type A	2	2.0
Type B	37	36.6
Type C	62	61.4
Total	101

5 Table 5. Summary of NPF characteristic statics depending on the air mass origin. FR is the formation
 6 rate, GR is the growth rate, CS is the condensation sink, and Q is the source rate of condensable vapor.
 7 Case I, Case II, Case III, and Case IV refer to the origin and pathway of air masses from South America,
 8 the Weddell Sea, the Antarctic Peninsula, and the Bellingshausen Sea, respectively.

NPF days		FR ($\text{cm}^{-3} \text{ s}^{-1}$)	GR (nm h^{-1})	CS (10^{-3} s^{-1})	Q ($10^4 \text{ cm}^{-3} \text{ s}^{-1}$)
Case I	3	2.57 ± 1.18	0.88 ± 0.33	4.49 ± 1.79	4.22 ± 2.05
Case II	24	2.81 ± 1.29	0.41 ± 0.15	6.95 ± 2.65	3.87 ± 2.90
Case III	16	3.10 ± 0.80	0.77 ± 0.25	4.19 ± 1.30	4.29 ± 1.75
Case IV	56	3.08 ± 1.55	0.76 ± 0.30	6.79 ± 3.20	6.20 ± 4.08
