- 25 Abstract. Approximately 3 billion people worldwide cook with solid fuels, such as wood, charcoal, and agricultural residues. These fuels, also used for residential heating, are often combusted in inefficient devices, producing carbonaceous emissions. Between 2.6 and 3.8 million premature deaths occur as a result of exposure to fine particulate matter from the resulting household air pollution (Health Effects Institute, 2018a; World Health Organization, 2018). Household air pollution also contributes to ambient air pollution; the magnitude of this
- 30 contribution is uncertain. Here, we simulate the distribution of the two major health-damaging outdoor air pollutants (PM_{2.5} and O₃) using state-of-the-science emissions databases and atmospheric chemical transport models to estimate the impact of household combustion on ambient air quality in India. The present study focuses on New Delhi and the SOMAARTH Demographic, Development, and Environmental Surveillance Site (DDESS) in the Palwal District of Haryana, located about 80 km south of New Delhi. The DDESS covers an approximate population
- 35 of 200,000 within 52 villages. The emissions inventory used in the present study was prepared based on a national inventory in India (Sharma et al., 2015, 2016), an updated residential sector inventory prepared at the University of Illinois, updated cookstove emissions factors from Fleming et al. (2018b), and PM_{2.5} speciation from cooking fires from Jayarathne et al. (2018). Simulation of regional air quality was carried out using the U.S. Environmental Protection Agency Community Multiscale Air Quality modeling system (CMAQ), in conjunction with the Weather
- 40 Research and Forecasting modeling system (WRF) to simulate the meteorological inputs for CMAQ, and the global chemical transport model GEOS-Chem to generate concentrations on the boundary of the computational domain. Comparisons between observed and simulated O₃ and PM_{2.5} levels are carried out to assess overall airborne levels

and to estimate the contribution of household cooking emissions. Observed and predicted ozone levels over New Delhi during September 2015, December 2015, and September 2016 routinely exceeded the 8-hour Indian standard of 100 µg m⁻³, and, on occasion, exceeded 180 µg m⁻³. PM_{2.5} levels are predicted over the SOMAARTH headquarters (September 2015 and September 2016), Bajada Pahari (a village in the surveillance site, September

5 2015, December 2015, and September 2016), and New Delhi (September 2015, December 2015, and September 2016). The predicted fractional impact of residential emissions on anthropogenic PM_{2.5} levels varies from about 0.27 in SOMAARTH HQ and Bajada Pahari to about 0.10 in New Delhi. The predicted secondary organic portion of PM_{2.5} produced by household emissions ranges from 16% to 80%. Predicted levels of secondary organic PM_{2.5} during the periods studied at the four locations averaged about 30 µg m⁻³, representing approximately 30% and 20%

of total PM_{2.5} levels in the rural and urban stations, respectively.

10

1 Introduction

Although outdoor air pollution is widely recognized as a health risk, quantitative understanding remains uncertain on the degree to which household combustion contributes to unhealthy air. Recent studies in China, for example, show that 50-70% of black carbon emissions and 60-90% of organic carbon (OC) emissions can be attributed to residential
coal and biomass burning (Cao et al., 2006; Klimont et al., 2009; Lai et al., 2011). Moreover, existing global emissions inventories show a significant contribution of household sources to primary PM_{2.5} (particulate matter of diameter less than or equal to 2.5 micrometers) emissions. The Indo-Gangetic Plain of Northern India (23-31° N, 68-90° E) has among the world's highest values of PM_{2.5}. In this region, the major sources of emissions of primary PM_{2.5} and of precursors to secondary PM_{2.5} are coal-fired power plants, industries, agricultural biomass burning, transportation, and combustion of biomass fuels for heating and cooking (Reddy and Venkataraman, 2002; Rehman et al., 2011). The southwest monsoon in summer months in India leads to lower pollution levels than in winter months, which are characterized by low wind speeds, shallow boundary layer depths, and high relative humidity (Sen et al., 2017). With the difficulty in determining representative emissions estimates (Jena et al., 2015; Zhong et al., 2016), simulating the extremely high PM_{2.5} observations in the Indo-Gangetic Plain has remained a challenge (Schnell et al., 2018).

25

Approximately 3 billion people worldwide cook with solid fuels, such as wood, charcoal, and agricultural residues (Bonjour et al., 2013; Chafe et al., 2014; Smith et al., 2014; Edwards et al., 2017). Used also for residential heating, such solid fuels are often combusted in inefficient devices, producing black carbon (BC) and organic carbon emissions. Between 2.6 and 3.8 million premature deaths occur as a result to exposure to fine particulate matter from

- 30 household air pollution (Health Effects Institute, 2018a; World Health Organization, 2018). In India, more than 50% of households report use of wood or crop residues, and 8% report use of dung as cooking fuel (Klimont et al., 2009; Census of India, 2011; Pant and Harrison, 2012). Residential biomass burning is one of the largest individual contributors to the burden of disease in India, estimated to be responsible for 780,000 premature deaths in 2016 (Indian Council of Medical Research et al., 2017). The recent GBD MAPS Working Group (Health Effects Institute, 2018b)
- 35 estimated that household emissions in India produce about 24% of ambient air pollution exposure. Coal combustion, roughly evenly divided between industrial sources and thermal power plants, was estimated by this study to be

responsible for 15.3% of exposure in 2015. Open burning of agricultural crop stubble was estimated annually to be responsible for 6.1% nationally, although more important in some areas.

Traditional biomass cookstoves, with characteristic low combustion efficiencies, produce significant gas-and particle-phase emissions. An early study of household air pollution in India found outdoor total suspended particulate matter (TSP) levels in four Gujarati villages well over 2 mg m⁻³ during cooking periods (Smith et al., 1983). Secondary organic aerosol (SOA), produced by gas-phase conversion of volatile organic compounds to the particulate phase, is also important in ambient PM levels, yet there is a dearth of model predictions to which data can be compared. Overall, household cooking in India has been estimated by various groups to produce 22-50% of ambient PM_{2.5}
exposure (Butt et al., 2016; Chafe et al., 2014; Conibear et al., 2018; Health Effects Institute, 2018b; Lelieveld et al., 2015; Silva et al., 2016), and Fleming et al. (2018a,b) report characterization of a wide range of particle-phase compounds emitted by cookstoves. In a multi-model evaluation, Pan et al. (2015) concluded that an underestimation of biomass combustion emissions, especially in winter, was the dominant source of model underestimation. Here, we address both primary and secondary organic particulate matter from household burning of biomass for cooking.

15

Air quality in urban areas in India is determined largely, but not entirely, by anthropogenic fuel combustion. In rural areas, residential combustion of biomass for household uses, such as cooking, also contributes to non-methane volatile organic carbon (NMVOC) and particulate emissions (Sharma et al., 2015, 2018). Average daily PM_{2.5} levels frequently exceed the 24-hour Indian standard of 60 µg m⁻³ and can exceed 150 µg m⁻³, even in rural areas. The local
region on which the present study focuses is the SOMAARTH Demographic, Development, and Environmental Surveillance Site (DDESS) run by the International Clinical Epidemiological Network (INCLEN) in the Palwal District of Haryana (Figure 1). Located about 80 km south of New Delhi, SOMAARTH covers an approximate population of 200,000 in 52 villages. Particular focus in the present study is given to the SOMAARTH Headquarters (HQ) and the village of Bajada Pahari within DDESS, coinciding with the work of Fleming et al. (2018b), who studied cookstove non-methane hydrocarbon (NMHC) emissions and ambient air quality. Demographically, with a coverage of almost 308 sq km, the DDESS has a mix of populations from different religions and socioeconomic and development statuses.

The climate of the region of interest in the present study is primarily influenced by monsoons, with a dry winter and very wet summer. The rainy season, July through September, is characterized by average temperatures around 30 °C and primarily easterly and southeasterly winds. In a study related to the present one, Schnell et al. (2018) used emission datasets developed for the Coupled Model Intercomparison Project Phases 5 (CMIP5) and 6 (CMIP6) to evaluate the impact on predicted PM_{2.5} over Northern India, October-March 2015-2016, with special attention to the effect of meteorology of the region, including relative humidity, boundary layer depth, strength of the temperature inversion, and low level wind speed. In that work, nitrate and organic matter (OM) were predicted to be the dominant components of total PM_{2.5} over most of Northern India.

The goal of the present work is to simulate the distribution of primary and secondary $PM_{2.5}$ and O_3 using recently updated emissions databases and atmospheric chemical transport models to obtain estimates of the total impact on ambient air quality attributable to household combustion. With respect to ozone, the present work follows that of Sharma et al. (2016) who simulated regional and urban ozone concentrations in India using a chemical transport model and included a sensitivity analysis to highlight the effect of changing precursor species on O_3 levels. The present work is based on simulating the levels of both O_3 and $PM_{2.5}$ at the regional level based on recent emissions inventories using state-of-the-science atmospheric chemical transport models.

5

2 Emissions Inventory

2.1 Non-Residential Sectors Emissions

- 10 The present study uses an emissions inventory conglomerated from two primary sources: (1) an India-scale inventory for all non-residential sectors prepared by TERI (Sharma et al., 2015, 2016) and (2) a high-resolution residential sector inventory detailed here. Emissions data from each source were distributed to a 4 km grid for the present study. The TERI national inventory was prepared at a resolution of 36 × 36 km² using the Greenhouse Gas and Air Pollution Interactions and Synergies (GAINS ASIA) emission model (Amann et al., 2011). GAINS ASIA estimated emissions based on energy and non-energy sources using an emission factor approach after taking into account various fuel-
- sector combinations. Following the approach of Kilmont et al. (2002), the emissions were estimated using the basic equation:

$$E_k = \sum_l \sum_m \sum_n A_{k,l,m} e f_{k,l,m} \left(1 - \eta_{l,m,n} \right) \cdot X_{k,l,m,n} \tag{1}$$

where *E* denotes the pollutant emissions (in kt); *k*, *l*, *m*, and *n* are region, sector, fuel or activity type, and control technology, respectively; *A* the activity rate; *ef* the unabated emission factor (kt per unit of activity); η the removal efficiency (%/100); and *X* the application rate of control technology *n* (%/100) where $\sum X = 1$. Energy sources considered include coal, natural gas, petroleum products, biomass fuels, and others and categorized into five sectors – transport, industries, residential, power, and others. The model uses the state-wise energy data and generates emissions of species such as PM, NO_x, SO₂, NMVOCs, NH₃, and CO.

25

30

For activity data of source-sectors, TERI employed published statistics (mainly population, vehicle registration, energy use, and industrial production) where possible. Energy use data for industry and power sectors were compiled based on a bottom-up approach, collected from the Ministry of Petroleum and Natural Gas (MoPNG, 2010), the Central Statistics Office (CSO, 2011), and the Central Electricity Authority (CEA, 2011). Transportation activity data were compiled from information on vehicle registrations (Ministry of Road Transport and Highways, 2011), emission standards (MoPNG, 2001), travel demand (CPCB, 2000), and mileage (TERI, 2002). Emission factors for energy-based sources from the GAINS ASIA database were used. Speciation factors are adopted from sector-specific profiles from Wei et al. (2014), primarily developed for China as there is a lack of information for India. In the transportation sector, the Chinese species profiles are dependent on fuel type but not technology.

The TERI inventory was compiled on a yearly basis, with monthly variations for brick kilns and agricultural burning, at a native resolution of 36×36 km² then equally distributed to grid resolution of 4×4 km² for this study. Emissions for non-residential sectors have no specified diurnal or daily variations; thus, the inventory for non-residential sectors is the same for each simulated day. Transportation sector emissions were estimated using population and vehicle fleet data at the district level and distributed to the grid using the administrative boundaries. Industry,

- 5 and vehicle fleet data at the district level and distributed to the grid using the administrative boundaries. Industry, power, and oil and gas sector emissions were assigned to the grid by their respective locations. Emissions from agriculture were allocated by crop-types produced by state in India. The inventory was vertically distributed to three layers with the lowest layer extending to 30 43 m, the middle layer to 75 100 m and the top layer to 170 225 m layers. VOC emissions were assumed to occur only in the bottom layer. Industry and power emissions were distributed
- 10

based on stack heights and allocated to the second and third layers.

We incorporated biogenic emissions by using daily-averaged emission rates of isoprene (0.8121 moles s⁻¹) and terpenes (0.8067 moles s⁻¹) per 4 km grid cell, predicted by GEOS-Chem for the region of study. The TERI inventory additionally includes isoprene emissions from the residential sector, so isoprene from natural sources was
calculated as the difference of the total rate predicted by GEOS-Chem and the rate of emissions solely from the residential sector. Terpene emissions are assumed to occur only in non-residential source-sectors. Isoprene and terpene emission rates were applied to all computational cells as an hourly average (with no diurnal profile) in the non-residential inventory.

2.2 Residential Sector Emissions

- 20 To examine local and regional impacts of residential sector emissions in greater detail, an update to the TERI inventory was performed using various sources to consider more granular input data specific to the residential sector (Table 1). Bottom-up estimates of delivered energy for cooking, space heating, water heating, and lighting were informed by those used in Pandey et al. (2014) and converted to fuel consumption at the village level using population size and percentage of reported primary cooking and lighting fuels from the 2011 Census of India (Census of India, 2011).
- 25 Urban areas of the domain were assumed to have the average cooking and lighting fuel use profiles of the average urban areas of their district. Fuel consumption was converted to emission rates using fuel-specific emission factors informed by a review of field and laboratory studies, which was used to update the Speciated Pollutant Emissions Wizard (SPEW) inventory (Bond et al., 2004) and to generate summary estimates by fuel type. Hourly emissions were generated using source-specific diurnal emissions profiles (Figure 2). The same diurnal emissions profile is applied to
- 30 all species from a source category and were informed by real-time emissions measurements taken in homes during cooking reported by Fleming et al. (2018a,b). Profiles for fuel-based lighting were informed by real-time measurements of kerosene lamp usage data reported in Lam et al. (2018). The residential sector inventory represents surface emissions with a native spatial resolution of 30-arc seconds (~1 km).
- 35 In deriving summary estimates of emission factors, priority was given to emission factor measurements from field-based studies. Several studies have shown that laboratory-based measurements of stove and lighting emissions

tend to be lower than those of devices measured in actual homes (Roden et al., 2009), perhaps due to higher variation in fuel quality and operator behavior. Field-based emission factors utilized in this study include those for non-methane hydrocarbons, measured from fuels and stoves within the study domain (Fleming et al. 2018a,b). PM_{2.5} speciation from cooking fires was informed by Jayarathne et al. (2018) (Tables 2 and 3). Residential emission rates for PM_{2.5},

5 black carbon (BC), organic carbon (OC), CO, NO_x, CH₄, CO₂, and total non-methane hydrocarbons (NMHC) were generated from SPEW, which estimates emissions from combustion by fuel type. As such, solvent emissions are not included for lack of specific input data. Additionally, while SPEW incorporates temperature-dependent heating combustion activity, the inventory assumes temperatures too high for this activity to take effect. Thus, our inventory has no emissions from heating.

10

15

We employed various methods to account for pollutant species not explicitly reported by SPEW (Tables 1 and 2). Gas-phase SO₂ and NH₃ emissions were informed by existing residential emissions in the TERI inventory (Sharma et al. 2015); NO and NO₂ were estimated from NO_x emissions assuming a NO:NO₂ emission ratio of 10:1. Total NMHC and PM_{2.5} emission factors from SPEW are distributed by fuel type (wood, dung, agriculture residue, or LPG) (Table 2). Given the low PM_{2.5} emission rate of LPG, (Shen et al., 2018), emissions from LPG are assumed to be negligible. To further speciate NMHCs, we employed HC species-specific emission factors (Eleming et al. 2018b).

- be negligible. To further speciate NMHCs, we employed HC species-specific emission factors (Fleming et al. 2018b), differentiated by fuel and stove type (i.e. traditional stove, or *chulha*, with wood or dung, and simmering stove, or *angithi*, with dung). We assume that all NMHC emissions in each computational grid cell are produced by either wood or dung, whichever contributes the greater fraction of total PM_{2.5} emissions in that cell (Figure 3). The NMHC
 20 emission profile of dung was assumed to be the average of measurements from chulha and angithi stoves. The emission profile for agricultural residue is similar to that of wood; therefore, wood speciation profiles are applied in cells where agricultural residue dominates.
- Particle-phase speciation of total PM_{2.5} was based on PM mass emissions from wood- and dung-fueled cooking fires as reported by Jayarathne et al. (2018), and primary cooking fuel type distribution data from the 2011 census (Tables 2 and 3). A single PM_{2.5} speciation profile, defined as the average of that of wood and that of the wood-dung mixture, was applied in all cells for lack of information on pure dung emissions (Table 3). Non-carbon organic particulate matter (PNCOM) and particulate water (PH₂O) were assumed to be negligible owing to lack of information on these species. Emissions of remaining particle-phase species (i.e. Al, Ca, Fe, Mg, Mn, Si, and Ti) are also assumed

to be negligible for lack of information. Unspeciated fine particulate matter (PMothr) is defined in CMAQ as the portion

30

of total PM_{2.5} unassigned to any other species:

$$PM_{othr} = PM_{2.5} - (P_{EC} + P_{OC} + P_{Na} + P_{NH_4} + P_K + P_{Cl} + P_{NO_3} + P_{SO_4})$$
(2)

Tables 4 and 5 summarize emission rates for the study domain.

3 Atmospheric Modeling

35 To study the impact of household emissions on ambient air pollution, we simulated two emission scenarios each for three time periods which coincide with available INCLEN observation data (Tables 6 and 7). A "total" emission

scenario represents the overall atmospheric environment by including emissions from all source-sectors in the inventory. A "non-residential" emission scenario represents zeroing-out or "turning-off" all household emissions. By considering these scenarios independently, we can isolate the effect of the residential sector on the ambient atmosphere. Each scenario was simulated over a region in northern India (Figure 1) for those periods when measurements were carried out in the region of interest. Figure 1 shows the 600 km by 600 km domain with 4 km grid resolution. The domain is centered over the Palwal District and the SOMAARTH DDESS and includes New Delhi and portions of surrounding states.

- Simulation of regional air quality was carried out using the U.S. Environmental Protection Agency Community Multiscale Air Quality modeling system (CMAQ), version 5.2 (Appel et al., 2017; US EPA, 2017). CMAQ is a three-dimensional chemical transport model (CTM) that predicts the dynamic concentrations of airborne species. CMAQ includes modules of radiative processes, aerosol microphysics, cloud processes, wet and dry deposition, and atmospheric transport. Required input to the model includes emissions inventories, initial and boundary conditions, and meteorological fields. The domain-specific, gridded emissions inventory provides hourly-
- 15 resolved total emission rates for each species (not differentiated by source) by cell, timestep, and vertical layer. Initial conditions (ICs) and boundary conditions (BCs) are necessary to define the atmospheric chemical concentrations in the domain at the first time step and at the domain edges, respectively. Simulations operating with nested domains require two groups of initial conditions and boundary conditions. The present study uses the global chemical transport model GEOS-Chem v11-02c (acmg.seas.harvard.edu/geos/index.html) to generate concentrations on the boundary of
- 20 the computational domain and CMAQ to produce initial and boundary conditions for the inner parent domain and nested domain, respectively. Meteorological conditions (including temperature, relative humidity, wind speed and direction and land use and terrain data) drive the atmospheric processes represented in CMAQ. The Weather Research and Forecasting modeling system (WRF) Advanced Research WRF (WRF-ARW, version 3.6.1), was used to simulate the meteorological input for CMAQ (Skamarock et al., 2008).

25 3.1 GEOS-Chem

5

We used GEOS-Chem v11-02c, a global chemical transport model driven by assimilated meteorological observations from the NASA Goddard Earth Observing System -- Fast Processing (GEOS-FP) of the Global Modeling and Assimilation Office (GMAO), to simulate the boundary conditions for the CMAQ modeling. Simulations are performed at 2°x2.5° horizontal resolution with 72 vertical layers, including both the full tropospheric chemistry with

- complex SOA formation (Marais et al., 2016) and UCX stratospheric chemistry (Eastham et al., 2014). Emissions used the standard HEMCO configuration (Keller et al., 2014), including EDGAR v4.2 anthropogenic emissions (http://edgar.jrc.ec.europa.eu/overview.php?v=42), biogenic emissions from the MEGAN v2.1 inventory (Guenther et al., 2012), and GFED biomass burning emissions (http://www.globalfiredata.org). Simulations were run for 1 year, after which hourly time series diagnostics were compiled for the CMAQ modeling period. Using the PseudoNetCDF
 processor, we remapped a subset of the 616 GEOS-Chem-produced species to CMAQ species
- (https://github.com/barronh/pseudonetcdf). The resulting ICs and BCs include 119 gas- and particle-phase species, 80

adapted from GEOS-Chem and the remaining 39 (including OH, HO₂, ROOH, oligomerized secondary aerosols, coarse aerosol, and aerosol number concentration distributions) from the CMAQ default initial and boundary conditions data (which were developed to represent typical clean-air pollutant concentrations in the United States).

3.2 Weather Research and Forecasting (WRF) Model

- 5 Three monthly WRF version 3.6.1 simulations were conducted in the absence of nudging or data assimilation. The large-scale forcing to generate initial and boundary meteorological fields is adopted from the latest version of the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5 released in January 2019. These reanalysis data are on a 31 km grid and resolve the atmosphere using 137 levels from the surface to a height of 80 km. WRF simulations were performed with 4 km horizontal resolution and 24 vertical layers (the lowest layer of about 50 m depth), consistent with the setup of the CMAQ model. No cumulus parameterization was used in the simulations.
- Meteorological outputs from WRF were prepared as inputs to CMAQ by the Meteorology-Chemistry Interface Processor (MCIP) version 4.4 (Otte et al., 2010).

3.3 Community Multiscale Air Quality (CMAQ) Modeling System

- Within the chemical transport portion of CMAQ, there are two primary components: a gas-phase chemistry module
 and an aerosol chemistry, gas-to-particle conversion module. The present study employs a CMAQ-adapted gas-phase chemical mechanism, CB6R3 (derived from the Carbon Bond Mechanism 06) (Yarwood et al., 2010), and the aerosol-phase mechanism, AERO6, which define the gas-phase and aerosol-phase chemical resolution. The present study considers 70 non-methane hydrocarbon (NMHC) compounds lumped into 12 groups of volatile organic compounds (VOCs). The emissions inventory provides emission rates for 28 chemical species, including 18 gas-phase species and 10 particle-phase species. The CB6R3 adaptation describes atmospheric oxidant chemistry with 127 gas-phase species
- and 220 gas-phase reactions, including chlorine and heterogenous reactions. The CMAQ aerosol module (AERO6) describes aerosol chemistry and gas-to-particle conversion with 12 traditional SOA precursor classes, and 10 semi-volatile primary organic aerosol (POA) precursor reactions. The majority of the gas-phase organic species are apportioned to lumped groups by their carbon bond characteristics, such as single bonds, double bonds, ring structure,
 and number of carbons. Some organic compounds are apportioned based on reactivity, and others, like isoprene, ethene, and formaldehyde, are treated explicitly.

The secondary organic aerosol module, AERO6, developed specifically for CMAQ, interfaces with the gas-phase mechanism, predicts microphysical processes of emission, condensation, evaporation, coagulation, new particle
formation, and chemistry, and produces a particle size distribution comprising the sum of the Aitken, Accumulation, and Coarse log-normal modes (Figure 4). AERO6 predicts the formation of SOA from anthropogenic and biogenic volatile organic compound (VOC) precursors (properties of which are shown in Table 8), as well as semi-volatile POA and cloud processes. CB6R3 accounts for the oxidation of the first-generation products of the anthropogenic lumped VOCs: high-yield aromatics, low-yield aromatics, benzene, PAHs, and long-chain alkanes (Pye and Pouliot, 2012).

In addition to SOA formation from traditional precursors, CMAQv5.2 accounts for the semi-volatile partitioning and gas-phase aging of POA using the volatility basis set (VBS) framework independently from the rest of AERO6 (Murphy et. al., 2017). The module distributes directly emitted POA (as the sum of primary organic carbon,

- 5 POC, and noncarbon organic matter, NCOM) from the emissions inventory input into five new emitted species grouped by volatility: LVPO1, SVPO1, SVPO2, and SVPO3, and IVPO1 (where LV is low volatility, SV is semi-volatile, IV is intermediate volatility, and PO is primary organic). POA is apportioned to these lumped vapor species using an emission fraction and are oxidized in CB6R3 by OH to LVOO1, LVOO2, SVOO1, SVOO2, and SVOO3 (where OO denotes oxidized organics) with stoichiometric coefficients derived from the 2D-VBS model. AERO6
- 10 then partitions the semi-volatile primary organics and their oxidation products to the aerosol phase (Figure 4). Thus, the treatment of POA as semi-volatile products leads to an additional twenty species, a particle- and vapor-phase component for each primary organic and oxidation product (Murphy et al., 2017).
- Emissions inventory modifications were required to match the most recent aerosol module, AERO6, in the
 CMAQ model. Initially, the lumped emissions of PAR (a lumped VOC group characterized by alkanes) and XYL (a lumped VOC group characterized by xylene) derived from grouping specific NMHCs, calculated using the University of Illinois estimation and the Fleming et al. (2018a) emission factors, accounted for characteristics of naphthalene (NAPH) and SOA-producing alkanes (SOAALK), which are not individually described by any of the sources used to construct the inventory. Moreover, only a subset of VOCs in the plume could be measured. However, CMAQv5.2
 simulations incorporate a surrogate species, potential secondary organic aerosol from combustion emissions (pcSOA), to address sources of missing SOA, including unspeciated emissions of semivolatile and intermediate volatility organic compounds. AERO6 predicts the formation of SOA from NAPH and SOAALK independently as well as from

XYL and PAR; these secondary aerosol precursor emission rates are calculated with:

XYLMN = 0.998 * XYL(3)

$$NAPH = 0.002 * XYL \tag{4}$$

 $PAR_{CMAQ} = PAR_{calculated} - 0.00001 * NAPH$ (5)

$$SOAALK = 0.108 * PAR_{CMAO}$$
(6)

30 where XYLMN, NAPH, PARCMAQ, and SOAALK are the new inventory species (Pye and Pouliot, 2012). SOA-producing alkanes are treated separately in AERO6.

4 Surface Observational Data

25

35

Gas-phase air quality data analyzed in the present study come from the Central Pollution Control Board (CPCB) of the Ministry of Environment, Forest & Climate Change, Government of India at two sites in New Delhi (one in the west, and one in the south). Particle-phase data analyzed come from the SOMAARTH Demographic, Development,

and Environmental Surveillance Site (Mukhopadhyay et al., 2012; Pillarisetti et al., 2014; Balakrishnan et al., 2015) managed by the International Clinical Epidemiological Network (INCLEN). Palwal District has a population of ~ 1 million over an area of 1400 km². In this district, ~39% of households utilize wood burning as their primary cooking fuel, with dung (~25%) and crop residues (~7%) (Census of India, 2011). Specific sites studied are the SOMAARTH

5

headquarters (HQ) in Aurangabad (15 km south of Palwal) and the village of Bajada Pahari (8 km northwest of SOMAARTH HQ). Ambient measurement sites are shown in Fig. 1, and Table 6 details available data for each location. We used meteorological data (hourly surface temperature and near-surface wind speed and direction) from INCLEN and CPCB at the two rural and two urban sites, respectively, to evaluate the WRF simulations performance.

5 Simulation Results

10 5.1 WRF Evaluation

We evaluated WRF simulated meteorology against the available surface observations at different sites during the same periods. Figure 5 shows that there is generally good agreement of surface temperature between WRF and observations for all three months. The surface wind direction is found consistent between model and observations for each site and each month (Table 9). The simulated near-surface wind speeds are overestimated in WRF, with an averaged mean-

15 bias (MB) of about +1.5 m/s. Such a bias is partly a result of the difference in the definition of "near-surface" between the model and observations.

5.2 Particulate Matter

Figures 6-9 show measured and predicted total $PM_{2.5}$ and the average diurnal profile at each site for the periods with available measurements. The diurnal profile in these figures includes that of both emission scenarios: the total scenario

- with all emissions and the non-residential scenario with zeroed-out residential sector. The simulations capture the general trend well and produce significant diurnal profiles (Table 10). Rural sites show typical PM_{2.5} levels are predicted between 50 µg m⁻³ and 125 µg m⁻³ in December and 25 µg m⁻³ and 75 µg m⁻³ in September months (Figures 6 and 7). On the other hand, typical values at urban sites range from 100 µg m⁻³ to 300 µg m⁻³ in December and 50 µg m⁻³ to 125 µg m⁻³ in September months (Figures 8 and 9). Observations and predictions show higher PM_{2.5} levels in
- 25 December than September, owing to frequent temperature inversions in winter and shallower planetary boundary layers. Two daily peaks and lows of PM_{2.5} compare with ambient observations at Bajada Pahari December 2015 and September 2016, SOMAARTH HQ September 2015 and 2016, West New Delhi December 2015, and South New Delhi December and September 2015. Average daily PM_{2.5} levels regularly exceed the 24-hour Indian standard of 60 µg m⁻³ in each month in both rural and urban locations, surpassing even double the standard in the village of Bajada
- 30 Pahari during mealtimes in December. Afternoon minima tend to be underestimated in September 2015 and December 2015. Diurnal trends of PM_{2.5} were weaker in September 2016 than the other months, with lower predictions but overestimated minima. Urban sites show greater overestimation than rural sites. This is likely due in part to the granularity of the primary emissions inventory datasets. The non-residential sector was prepared from data with a native resolution of 36 km, while the residential sector used data with ~1 km resolution. Underpredictions of peak

 $PM_{2.5}$ concentrations in September could also result because the emission inventory does not account for day-to-day variations, especially in the agricultural burning sector in which emissions can change significantly on a daily basis. Observed and predicted $PM_{2.5}$ levels in New Delhi can exceed 300 µg m⁻³, especially in winter. In this highly populated urban environment, particulate matter levels are more than double those reported in the nearby rural areas. The employed emissions inventory specifies particulate matter surface emissions, which surpass those of Bajada Pahari

- 5 employed emissions inventory specifies particulate matter surface emissions, which surpass those of Bajada Pahari and SOMAARTH HQ more than 30-fold (Table 5). Biogenic emissions are predicted to be of little importance, accounting for less than 10% on average of total PM_{2.5} concentrations for most stations and months (Table 10).
- Figure 10 shows CMAQ predictions of secondary organic PM_{2.5} (SOA). Like PM_{2.5}, SOA is typically
 predicted to be higher in New Delhi than in the rural sites, due to higher PM_{2.5} and precursor VOC emissions and ambient concentrations in urban environments (Tables 5 and 6). Higher levels are similarly attained in December than in September due to longer residence times and more aging during winter. SOA has high day-to-day variability. Values range from below 20 µg m⁻³ to over 200 µg m⁻³ in December, with average peaks up to 55 µg m⁻³ at the rural sites. September months predict lower SOA, ranging from 10 µg m⁻³ to 130 µg m⁻³. Diurnal average SOA maxima in December for the rural stations is nearly double that of September 2016, which can be attributed to temperature inversions and a shallower planetary boundary layer in winter.

The significance of household emissions on outdoor PM_{2.5} concentrations is demonstrated by the diurnal profiles in Figure 11. The top row of plots shows the predicted contribution of the residential sector to anthropogenic
 PM_{2.5}, while the middle row of plots describes the predicted contribution of the residential sector to secondary organic PM_{2.5}, as in Equations 7 and 8 respectively:

$$\frac{\text{Residential Anthropogenic PM}_{2.5}}{\text{Total Anthropogenic PM}_{2.5}}$$
(7)

The bottom row of plots shows the predicted SOA portion of residential PM_{2.5}, as

25

where residential PM is calculated as the difference in predictions from the non-residential and total emission scenario and averaged over simulation durations (Table 7). Importance of household emissions to ambient PM is strongly correlated with mealtimes. Predicted maximum contributions to anthropogenic PM_{2.5} in Bajada Pahari and SOMAARTH HQ are about double that of South and West New Delhi for each month. Household energy-use is estimated to account for up to 27% of anthropogenic PM_{2.5} (at SOMAARTH HQ during September 2016), remaining consistently above 10% for each rural site during all months. Similar behavior is predicted for SOA (middle plots of Fig. 11). An estimated 15% to 34% of secondary organic matter is attributable to residential emissions in September 2016), where there are greater emissions of SOA precursors from other sectors. The diurnal profile of the contribution to SOA is subdued for all sites in December, suggesting that SOA generation is less efficient in winter when radiation

and temperatures are lower. Aging of VOCs is captured by the phase shift of the impact on SOA daily trend, where peaks consistently occur an hour after the residential sector shows greatest importance to anthropogenic $PM_{2.5}$.

5

At each measurement site during all months, SOA is predicted to make up more than 40% of PM_{2.5} produced by the residential sector on average (bottom row of plots of Fig. 11). SOA is least significant to residential PM_{2.5} in the first half of mealtimes (~20% during breakfast and ~40% during dinner) at rural sites, when primary particulate matter is largest. Aging of precursor VOCs from cooking emissions, paired with maximum incoming radiation, lead to maximum $\frac{\text{Residential SOA}}{\text{Residential PM}_{2.5}}$ values in early afternoon, when SOA accounts for more than 75% of residential PM_{2.5} at both rural and urban sites during each simulated month.

The fractional contribution of total SOA to total PM_{2.5} is shown in Fig. 12. While concentrations of SOA depend significantly on the site and time period, their contribution to total PM_{2.5} shows little variation. At all stations, SOA is predicted to make up to 55% of PM_{2.5} in September months and to be most significant around midday. However, diurnal variation of the significance of SOA is greater in New Delhi than in Bajada Pahari or SOMAARTH HQ, owing to greater diversity of energy-use activities and emissions characteristics in the urban environment.

5.3 Ozone

- 15 The 8-hour India Central Pollution Control Board (CPCB) standard for ozone is 100 μg m⁻³ for an 8-hour average. In the alternative unit of ozone mixing ratio, a mass concentration of ozone of 100 μg m⁻³ at a temperature of 298 K at the Earth's surface equates to a mixing ratio of 51 parts-per-billion (ppb). A number of atmospheric modeling studies of ozone over India exist (Kumar et al., 2010; Chatani et al., 2014; Sharma et al., 2016).
- Sharma et al. (2016) carried out baseline CMAQ simulations for 2010 and compared ozone predictions with measurements at six monitoring locations in India (Thumba, Gadanki, Pune, Anantpur, Mt. Abu, and Nainital). Also carried out were sensitivity simulations in which each emissions sector (transport, domestic, industrial, power, etc.) was systematically set to zero. The domestic sector was predicted to contribute ~60% of the non-methane volatile organic carbon emissions, followed by 12% from transportation and 20% from solvent use and the oil and gas sector.
 The overall NO_x-to-VOC mass ratio in the region simulated by Sharma et al. (2016) was 0.55. This exceptionally low NO_x-to-VOC ratio was attributed, in part, to the widespread use of biomass fuel for cooking (leading to high VOC emissions), coupled with relatively low NO_x emissions. (Although vehicle emissions are high in urban areas, overall vehicle ownership is relatively low at the national level. In addition, Euro equivalent norms have led to reduction of NO_x emissions.) Predicted O₃ levels at the six observation sites tended to exceed measured values, with the ratio of
- 30 predicted to observed annual average O_3 being in the range of 1.04–1.37 at the six locations. Moreover, the overall low NO_x-to-VOC ratios in India lead to NO_x-sensitive O_3 formation conditions. Based on emissions inventories, the overall anthropogenic NMVOC/NO_x mass emissions ratio in India in 2010 as computed by Sharma et al. (2016) was 1.82. Considering only ground-level sources, the ratio increases to 3.68.

Ozone surface measurements and predicted mass concentrations based on the CMAQ 4 km resolution simulations at two sites in New Delhi over the periods $\frac{9}{7}2015 - \frac{9}{29}2015$, $\frac{12}{7}2015 - \frac{12}{30}2015$, and $\frac{9}{7}2016$ -9/29/2016 in the present study are shown in the three panels in Fig. 13. The predicted O₃ concentrations are reproduced well at the West New Delhi and South New Delhi stations, especially in September (Table 10). However, 5 when NO concentrations are higher due to meteorological inversion conditions, ozone concentrations are underestimated, as local $NO+O_3$ titration reactions near the monitoring site are not resolved. The performance of the model improves in prediction of higher values of ozone (as in the case of September), which are of greater importance for assessing exposures. High ozone concentrations in September are quite well reproduced by the model. This shows that, on the larger scale, the model captures photochemistry quite well; however, micro-scale titration is not well 10 represented due to the limitations of inventory resolution. This would require further enhancement of emission inventories at even higher resolution. The results of ozone simulations in the present study are generally consistent with those of previous simulations over India. For example, also using WRF-CMAQ, Kota et al. (2018) showed that the relative bias in ozone simulation ranges from -30% to +50% in major cities of India. In South New Delhi, the bias in O₃ predictions in the present study lies between -2.67 and +7.01 µg m⁻³, as compared to the observations of 29.28 15 to $62.76 \,\mu g \, m^{-3}$.

6 Conclusions

Air quality in India is determined by a mixture of industrial and motor vehicle emissions, and anthropogenic fuel combustion, that includes residential burning of biomass for household uses, such as cooking. Average daily PM_{2.5} levels frequently exceed the 24-hour standard of 60 µg m⁻³ and can exceed 200 µg m⁻³, even in rural areas. PM_{2.5} is a mixture of directly-emitted particulate matter and that formed by the atmospheric conversion of volatile organic compounds to secondary organic aerosol. Here, we assess the extent to which observed O₃ and PM_{2.5} levels in India can be predicted using state-of-the-science emissions inventories and atmospheric chemical transport models. We have focused on the 308 sq km of the SOMAARTH Demographic, Development, and Environmental Surveillance Site (DDESS) in the Palwal District of Haryana, India.

25

Atmospheric simulation of particulate matter levels over a complex region like India tends to be demanding, owing to the combination of a wide range of primary particulate emissions and the presence of secondary organic matter from atmospheric gas-phase reactions generating low-volatility gas-phase products that condense into the particulate phase, forming secondary organic aerosol (SOA). Consequently, the main focus of the present work has

- 30 been the evaluation of the extent to which ambient particulate matter levels over the current region of India can be predicted. Simulations capture the general trend of observed daily peaks and lows of particulate matter, with PM_{2.5} reaching values as high as 250 µg m⁻³. Secondary organic matter accounts for 10% to 55% of total PM_{2.5} mass on average. In India, over 50% of households report use of wood, crop residues, or dung as cooking fuel; such fuels produce significant gas- and particle-phase emissions. We evaluated the fractional impact of the residential sector
- 35 emissions on the formation of secondary organic aerosol, as a function of time of day, for New Delhi, SOMAARTH HQ, and Bajada Pahari. The predicted fractional contribution of residential sector emissions to secondary organic

PM_{2.5} in Bajada Pahari and SOMAARTH HQ reaches values as high as 34% and, moreover, displays a distinct diurnal profile, with maxima corresponding to the morning and evening mealtimes. In both rural and urban areas, SOA is predicted to account for more than 40% of residential PM_{2.5}, reaching up to 80% in early afternoon in September months.

5

10

15

Simulations of ozone levels in New Delhi reported here are largely in agreement with ambient monitoring data, although the simulations fail to capture several one- to two-day ozone episodes that exceed predictions by a factor of two or more. The overall agreement between observed and predicted O₃ levels, also demonstrated in the study of Sharma et al. (2016), suggests that gas-phase atmospheric chemistry over India is reasonably well understood. While ozone and particulate matter were simulated for September and December months, we employed a single emissions inventory, regardless of season. Thus, the inventory does not capture December-specific characteristics, including heating combustion. Furthermore, information regarding household solvent use, emissions profiles by fuel type, and speciation of certain emissions (such as semi volatile organic compounds and intermediate volatility organic compounds) is lacking. Variation in the resolution of specific input data additionally contributes to uncertainty.

Air quality studies such as the present one provide a quantification of the elements of atmospheric composition in India, especially that owing to household sources. The importance of replacing traditional household combustion devices with modern technology is evident in studies such as the present one.

20

Author Contributions

BR carried out the simulations, and wrote the paper; RZ, YW and KB assisted with the simulations; AP carried out field measurements; SS, SK, TB, NL, BO LX, and VG helped formulate the emissions inventory; LF, RW, SM, and

25 DB designed and carried out measurements; SN, RE, AY, and NA performed data analysis; KS designed the research; JS designed the research and wrote the paper.

Table 1. Residential Emissions Inventory Sources by Species

¹Bolded species contribute to SOA production via the AERO6 module. ²Total isoprene and terpene emissions from all sectors are taken from GEOS-Chem and were included only in the O₃ simulations. ³PAR_{calculated} and XYL are excluded from CMAQ and replaced with PAR_{CMAQ}, XYLMN, NAPH, and SOAALK.

Emitted Species	Fuel-Specific Data	Use
PM2.5 (Bond et al., 2004)	wood, dung, agricultural residue, LPG	Total PM _{2.5} emission rate distributed by wood, dung, and agricultural residue. LPG emissions assumed negligible.
<i>Speciated PM</i> _{2.5} (Jayarathne et al., 2018)	wood, wood/dung mix	Average profile of wood and wood/dung mix applied to all fuel type emissions.
NMHC (Bond et al., 2004)	wood, dung, agricultural residue, LPG	Total PM _{2.5} emission rate distributed by wood, dung, and agricultural residue. LPG emissions assumed negligible.
<i>Speciated HCs</i> (Fleming et al., 2018a,b)	wood, dung	One profile applied to each cell according to which fuel type dominates emissions in that cell. Where agricultural residue dominates, wood profile is assumed.

Table 2. Residential PM_{2.5} and NMHC Emissions Speciation

Table 8. Properties of anthropogenic traditional semi-volatile SOA precursors in CMAQv5.2

The semi-volatile reaction products of "long alkanes" (SV_ALK1 and SV_ALK2) are parameterized by Presto et al. (2010). Values for "low-yield aromatics" products (SV_XYL1 and SV_XYL2) are based on xylene, with the enthalpy of vaporization (ΔH_{vap}) from studies of m-xylene and 1,3,5-trimethylbenzene. ΔH_{vap} for products of "high-yield aromatics" (SV_TOL1 and SV_TOL2) are based on the higher end of the range for toluene. The products of benzene (SV_BNZ1 and SV_BNZ2) assume the same value for ΔH_{vap} . All semi-volatile aromatic products are assigned stoichiometric yield (α) and effective saturation concentration (C*) values from laboratory measurements by Ng et al. (2007). Remaining parameters for PAH reaction products (SV_PAH1 and SV_PAH2) are taken from Chan et al. (2009). Properties of semi-volatile primary organic aerosol precursors are given in Murphy et al. (2017).

Table 10. CMAQ Model Performance and Summary Statistics.

5

Statistics are calculated for average diurnal profiles of predicted parameters. $PM_{2.5}$, O_3 , and SOA are the mass concentrations in μ g m⁻³ of total fine particulate matter, ozone, and secondary organic matter, respectively. F_{bio} is the fraction of total $PM_{2.5}$ that is produced by biogenic emissions; $F_{SOA,res}$ is the fraction of total secondary organic matter attributable to the residential sector; $F_{an,res}$ is the fraction of total anthropogenic $PM_{2.5}$ attributable to the residential sector; and $F_{res,SOA}$ is the fraction of residential $PM_{2.5}$ attributable to SOA. PRE is mean predictions; OBS is mean observations; MB is mean bias; ME is mean error; and RMSE is root mean square error. Standard deviation of predictions and observations are noted in parentheses.

Figures

Fig. 1. Geographic area of simulation. The left panel shows the entirety of India, and the right panel shows a closeup of the model domain. The domain spans a 600 km by 600 km area with a grid resolution of 4 km (150 cells along each axis) and includes both New Delhi and SOMAARTH DDESS.

5

Fig. 2. Fraction of daily household emissions by quantifiable fuel-use activity. Red, green, blue, and purple indicates cooking, space heating, water heating, and lighting, respectively. This represents the fraction of activity-specific daily emissions at each hour. Each species obeys the same profile. While profiles for heating are shown, the inventory assumes temperatures too high for this activity to take effect.

10

Fig. 3. Fuel type assumed for speciation of household NMHC emissions. Study domain: 600 by 600 km at 4 km resolution. Red indicates cells where dung use dominated emissions and thus was assumed to be the sole fuel type used. Orange indicates cells where wood and agricultural residue use dominated emissions and was thus assumed to be the sole fuel type used.

15

Fig. 4. Treatment of anthropogenic SOA in CMAQv5.2. Predicted aerosol species are included in the black box. Species in white boxes are semi-volatile and species in gray boxes are nonvolatile. Blue indicates species and processes predicted by CB6R3. All other coloring indicates the AERO6 mechanism where green arrows are 2-product volatility distribution, orange arrows are particle- and vapor-phase partitioning, and purple arrows are

20 oligomerization. In AERO6, anthropogenic and biogenic VOC emissions (lumped by category), are oxidized by OH, NO, and HO₂ and OH, O₃, NO, and NO₃ respectively, to semi-volatile products that undergo partitioning to the particle phase (Pye et al., 2015). Semi-volatile primary organic pathways in CMAQv5.2 are described by Murphy et al. (2017).

25 Fig. 5. Evaluation of WRF simulated meteorological fields versus ground observations.

Fig. 6. Measured and predicted PM_{2.5} (left) and average diurnal cycle (right) in Bajada Pahari for 12/20/15 – 12/31/15 (top) and 09/20/16 – 09/30/16 (bottom). Here the yellow lines correspond to CMAQ predictions of the "total" (solid) and "non-residential" (dotted) simulations. The solid black line represents ambient observations.
Standard deviations of the diurnal profiles for observations and predictions are indicated, respectively, by colored shading. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.

Fig. 7. Measured and predicted PM_{2.5} (left) and average diurnal cycle (right) at SOMAARTH HQ for 12/20/15 –
 12/31/15 (top) and 09/20/16 – 09/30/16 (bottom). Here the green lines correspond to CMAQ predictions of the "total" (solid) and "non-residential" (dotted) simulations. The solid black line represents ambient observations. Standard deviations of the diurnal profiles for observations and predictions are indicated, respectively, by colored shading. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.

40

Fig. 8. Measured and predicted $PM_{2.5}$ (left) and average diurnal cycle (right) in West New Delhi for 12/20/15 - 12/31/15 (top) and 09/20/16 - 09/30/16 (bottom). Here the pink lines correspond to CMAQ predictions of the "total" (solid) and "non-residential" (dotted) simulations. The solid black line represents ambient observations. Standard deviations of the diurnal profiles for observations and predictions are indicated, respectively, by colored shading.

45 Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.

Fig. 9. Measured and predicted $PM_{2.5}$ (left) and average diurnal cycle (right) in South New Delhi for 12/20/15 - 12/31/15 (top) and 09/20/16 - 09/30/16 (bottom). Here the blue lines correspond to CMAQ predictions of the "total"

50 (solid) and "non-residential" (dotted) simulations. The solid black line represents ambient observations. Standard deviations of the diurnal profiles for observations and predictions are indicated, respectively, by colored shading. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.

Fig. 10. Predicted secondary organic $PM_{2.5}$ (left) and average diurnal cycle (right) for 12/20/15 - 12/31/15 (top), 09/07/09/30/15 (middle), and 09/20/16 - 09/30/16 (bottom). Bajada Pahari is shown in yellow, SOMAARTH HQ in green, West New Delhi in pink, and South New Delhi in blue. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution. Statistics are shown in Table 10.

20

Fig. 11. Average diurnal $\frac{\text{Residential Anthropogenic PM}_{2.5}}{\text{Total Anthropogenic PM}_{2.5}}$ (top), $\frac{\text{Residential SOA}}{\text{Total SOA}}$ (middle), and $\frac{\text{Residential SOA}}{\text{Residential PM}_{2.5}}$ (bottom). Bajada Pahari is shown in yellow, SOMAARTH HQ in green, West New Delhi in pink, and South New Delhi in blue. Shading indicates mealtimes. Residential PM is calculated as the difference in predictions from the non-residential and total emission scenario and averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution. Statistics are shown in Table 10.

Fig. 12. Predicted $\frac{\text{Total SOA}}{\text{Total PM}_{2.5}}$ (left) and average diurnal cycle (right) for 12/20/15 - 12/31/15 (top), 09/07/09/30/15 (middle), and 09/20/16 - 09/30/16 (bottom). Bajada Pahari is shown in yellow, SOMAARTH HQ in green, West New Delhi in pink, and South New Delhi in blue. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.

Fig. 13. Predicted O₃ (left) and average diurnal cycle (right) for 12/20/15 - 12/31/15 (top), 09/07/09/30/15 (middle), and 09/20/16 - 09/30/16 (bottom) in West New Delhi (pink), and South New Delhi (blue). Standard deviations of the diurnal profiles for observations and predictions are indicated, respectively, by colored shading. Diurnal profiles were averaged over simulation durations (Table 7). Computations were carried out at 4 km resolution.
