Abstract. Nitryl chloride (CINO₂) is a radical reservoir species that releases chlorine radicals upon photolysis. An integrated analysis of the impact of CINO₂ on regional photochemistry in the Seoul Metropolitan Area (SMA) during the Korean-United States-Air Quality (KORUS-AQ) 2016 field campaign is presented. Comprehensive multiplatform observations were conducted aboard the NASA DC-8 and at two ground sites (Olympic Park, OP; Taehwa Research Forest, TRF), representing an urbanized area and a forested region downwind, respectively. Positive correlations between daytime Cl₂ and CINO₂ were observed at both sites, which were dependant on O₃ levels. The possible mechanisms are explored through box model simulations constrained with observations. The overall diurnal variations of CINO₂ at both sites appeared similar but the night time variations were systematically different. For about half of the observation days at the OP site the level of CINO₂ increased at sunset but rapidly decreased at around midnight. On the other hand, high levels were observed throughout the night at the TRF site. Significant levels of CINO₂ were observed at both sites for 4-5 hours after sunrise. Airborne observations, box model calculations, and back trajectory analysis consistently show that these high levels of CINO₂ in the morning are likely due to the transport of air masses within the boundary layer. Box model results show that chlorine radical initiated chemistry can impact the regional photochemistry by elevating net ozone production rates by ~ 25 % in the morning.

1 Introduction

Nitryl chloride (CINO₂) is a night time radical reservoir that generates chlorine radicals (Cl[•]) upon sunrise (R1), with a lifetime (τ_{CINO_2}) of ≈ 30 minutes at midday in the northern hemisphere mid-latitude summer, under clear sky conditions ($J_{CINO_2} \approx 5.47 \times 10^{-04} \text{ s}^{-1}$, (Madronich and Flocke, 1998)). It is produced through heterogeneous reaction of chloride (Cl⁻) containing aerosols and dinitrogen pentoxide (N₂O₅(g)), which is generated from an equilibrium reaction with gas-phase nitrate radical (NO₃) and nitrogen dioxide (NO₂) (R 2-4, (Finlayson-Pitts et al., 1989)). In acidic aerosols ($\approx \text{pH } 1.8$), uptake of N₂O₅ (g) can also produce gas-phase chlorine (Cl₂, R5), resulting from enhanced CINO₂ uptake coefficient of up to 3 - 4 orders of magnitude higher than neutral pH (Roberts et al., 2008). However, this reaction has yet to be proven in ambient conditions.

During the day, N₂O₅ exists at low levels due to its thermal instability (Malko and Troe, 1982) and the short lifetime of NO₃ ($\tau_{NO_3} < 5 \text{ s}$) from photolysis and reaction with NO (Wayne et al., 1991). Particulate Cl⁻ and chlorine containing gas species can come from both natural sources such as sea salt and biomass burning (Blanchard, 1985; Woodcock, 1953), and anthropogenic sources such as steel making, incineration, bleaching processes, and coal-fired power plants (Hov, 1985; Reff et al., 2009; Tanaka et al., 2000; Lee et al., 2018; Fu et al., 2018). The efficiency of CINO₂ production depends on heterogeneous loss of N₂O₅, which is a function of the N₂O₅ aerosol uptake coefficient ($\gamma_{N_2O_5}$), aerosol surface area, and N₂O₅ mean molecular speed, as well as the yield of CINO₂ (ϕ_{CINO_2}) (e.g., Thornton et al. 2003; Schweitzer et al. 1998; Behnke et al. 1997; Hu and Abbatt 1997; Bertram and Thornton 2009). The recommended value of $\gamma_{N_2O_5}$ in a typical continental boundary layer ranges from 0.01 to 0.04. Many recent studies, however, have reported discrepancies between field derived and laboratory parameterized $\gamma_{N_2O_5}$ (e.g., Brown et al. 2009; Chang et al. 2016; Morgan et al. 2015; Phillips et al. 2016; McDuffie et al. 2018b; Tham et al. 2016; Wang et al. 2017a, b, c) and ϕ_{CINO_2} (e.g., McDuffie et al. 2018a; Riedel et al. 2013; Ryder et al. 2015; Tham et al. 2018; Thornton et al. 2010; Wagner et al. 2013; Wang et al. 2017b, c). In a nocturnal boundary layer,

CINO₂ can accumulate to significant levels due to its long lifetime ($\tau_{CINO_2} > 30$ h) with slow loss mechanisms through heterogeneous uptake (Behnke et al., 1997; Frenzel et al., 1998; George et al., 1995). At sunrise, CINO₂ rapidly photolyzes to generate chlorine radicals (Cl[·]), which can react with most volatile organic compounds (VOCs). For alkanes, Cl[·] has up to 1-2 orders of magnitude larger rate constants than hydroxyl radicals (e.g., $k_{OH+n-C_4H_{10}} = 2.4 \times 10^{-12}$, $k_{Cl+n-C_4H_{10}} = 2.2 \times 10^{-10}$ at 298 K) (Atkinson, 1997; Atkinson and Arey, 2003). Therefore, Cl[·] can potentially influence the radical pool (HO_x-RO_x) and ozone (O₃) level, which can also affect the formation of secondary aerosols. This influence can be most prominent in the morning when concentrations of other oxidants are low (i.e., NO₃ and ·OH) (Finlayson-Pitts, 1993; Hov, 1985; Young et al., 2014).

The first ambient measurements of CINO₂ were carried out by Osthoff et al. (2008), from a ship sampling along the southeastern U.S. coast in 2006. In that study, CINO₂ was observed up to ~1 ppbv at night time, particularly during the time period influenced by urban pollution and ship plumes of the Houston ship channel. Since then, a growing number of measurements reported significant levels of CINO₂, especially in polluted coastal regions with sources from natural and anthropogenic chloride and nitrogen oxides. Riedel et al. (2012) measured up to ~2 ppbv of CINO₂ off the coast of Santa Monica Bay, on board the research vessel Atlantis. Recent studies show that high levels of CINO₂ are also present in mid-continental regions. Thornton et al. (2010) measured up to ~400 pptv in Boulder, Colorado, which is ~1,400 km away from the coastline. Mielke et al. (2011) reported up to ~250 pptv in Calgary, Alberta, Canada, during spring, which is ~800 km from the coastline. Back trajectory analysis results showed that the observations were most likely not influenced by marine airmasses. More recently (in the past 5 years), increasing number of CINO₂ observations have been conducted in Asia consistently showing significant levels of CINO₂ present in the boundary layer (e.g., Tham et al. 2018, 2016; Wang et al. 2016, 2017c, 2014; Yun et al. 2018; Liu et al. 2017). CINO₂ observations at semi-rural (Wangdu of Hebei province) and urban (Hong Kong, Jinan) regions in China have measured up to 2 ppbv and 776 pptv respectively (Tham et al., 2016; Wang et al., 2017b). At the mountain top (957 m above sea level) in Hong Kong, up to 4.7 ppbv of CINO₂ was reported (Wang et al., 2016). The high levels of CINO₂ in these studies were mostly correlated with continental pollution in vicinity (e.g., power plant plumes, biomass burning). A recent study by Yun et al. (2018) reported the highest CINO₂ (8.3 ppb), during a severe haze event in a semi-rural site downwind of the Pearl River Delta in the winter. Overall, observations have shown that CINO₂ is ubiquitous in the tropospheric boundary layer.

65 However, measurements are still limited, as discrepancies remain between global chemical transport models and observations. Uncertainties in model simulated ClNO_2 can arise from limited emission inventories, low resolution of the grid, uncertainties in $\gamma_{\text{N}_2\text{O}_5}$ and ϕ_{ClNO_2} parameterization, complexity of the terrain, and meteorological conditions and these have been dealt in previous studies (e.g., Zhang et al. 2017; McDuffie et al. 2018b, a; Lowe et al. 2015; Sarwar et al. 2012, 2014; Sherwen et al. 2017). For instance, smoothing out local ClNO_2 peaks by diluting local NO_x emissions, will result in limited NO_3 and N_2O_5 production. According to Sarwar et al. (2012, 2014), the CMAQ model with a finer grid (i.e. 12 km) simulated ClNO_2 that corresponded better to the observations, compared to the model runs with coarser grid size (i.e., 108 km), embedded with similar chemistry. Another modeling study by Sherwen et al. (2017) compared the ClNO_2 levels between the GEOS-Chem simulations and observations in inland areas (i.e., London, UK and a mountain top near Frankfurt, Germany) during the summer of 2015. Compared to observations, the simulations underestimated the ClNO_2 maxima levels by ~ 7 times in inland areas (Sherwen et al., 2017). Modeling studies have consistently suggested the significance of Cl^- initiated reactions in regional and global O_3 production and in the lifetime of VOCs in the troposphere (Knipping and Dabdub, 2003; Tanaka et al., 2000, 2003; Sarwar et al., 2014; Sherwen et al., 2016; Simon et al., 2009). Sarwar et al. (2014) explored the production of ClNO_2 from sea salt and biomass burning and its impact in the Northern Hemisphere by including ClNO_2 formation chemistry in the Community Multiscale Air Quality (CMAQ v 5.0.2) model. The results showed that, compared to the simulations without ClNO_2 formation, monthly 8 h wintertime maximum O_3 and $\cdot\text{OH}$ increased up to 15 % and 20 %, respectively. The impact was the largest in China and Western Europe. In the Hong Kong-Pearl River Delta (HK-PRD) region, Li et al. (2016) simulated up to ~ 1 ppbv of ClNO_2 originating from sea salt, biomass burning, and anthropogenic emissions (e.g., coal combustion) with the Weather Research and Forecasting coupled with Chemistry (WRF-CHEM) model. This resulted in ~ 16 % O_3 increase in the planetary boundary. Another modeling study of WRF-CHEM embedded with an updated chlorine chemistry, simulated 3-6 % of surface O_3 increase in the North China Plain and Yangtze River Delta during the summer (Zhang et al., 2017).

East Asian countries are of particular interest due to the rapid economic growth in the past decades with high anthropogenic emissions from densely populated megacities (e.g., Shanghai, Guangzhou, Beijing, Tokyo, Seoul). The majority of the world's megacities are situated in coastal regions (Neumann et al., 2015) with high NO_x emissions and abundant sources of chloride from both anthropogenic and natural origin. These regional characteristics likely promote ClNO_2 production. Moreover, considering that nearly half the population in the world lives near the coast, defined as $< 100\text{km}$ from coastline (Hinrichsen, 1998), a careful evaluation of the impact of ClNO_2 on local tropospheric chemistry is crucial. In this study, we present ClNO_2 observation results from the Korean - United States Air Quality (KORUS-AQ) study conducted in the Seoul Metropolitan Area (SMA), South Korea during late Spring (May 2 to June 12, 2016). The field campaign was an international collaboration between the National Institute of Environmental Research (NIER) of South Korea and the National Aeronautics and Space Administration (NASA) of the United States with the aim to better understand the impact of a megacity on regional air quality. A comprehensive suite of measurements were deployed at two super sites (Olympic Park site, OP; Taewha Research Forest, TRF) and aboard the NASA DC-8 to make airborne observations over the South Korean peninsula and the Yellow Sea. We present observational and box model results to evaluate the impact of ClNO_2 towards regional air quality in SMA.

2 Methods

100 2.1 KORUS-AQ 2016 Field Campaign and Observation Sites

We present observations carried out at Olympic Park, (OP; lat:37° 30' 32.904" N, lon:127° 7' 20.136" E), Taehwa Research Forest (TRF; lat: 37° 19' 14.484" N, lon:127° 18' 32.58" E) and on the NASA DC-8. The two ground sites were within the SMA region, which is the second largest metropolitan area in the world with a population of ~ 24 million (Park et al., 2017). As shown in Figure 1(a), the OP site is located in the southern part of Seoul, surrounded by high rise residence buildings and close to major freeways. The TRF site is in the middle of a forested area, ~ 26 km southeast of the OP site. Previous studies have shown that the TRF site is affected by both aged anthropogenic air masses from the city and fresh biogenic emissions from the forest (Kim et al., 2016, 2015). Both sites were ~ 50 km to the east of the nearest coastline. Figure 1(b) shows the flight tracks of the NASA DC-8, during the KORUS-AQ campaign. Spiral patterns were conducted near the TRF site to measure a vertical profile of the troposphere. Airborne observations were carried out during the daytime, between 8:00 and 17:00 local time. A summary of the analytical techniques of the measurements presented in this study are shown in Table 1. Meteorology during the observation period can be classified into dynamic (May 4th - 16th), stagnation (May 17th - 22nd), transport (May 25th - 31st), and blocking period as shown in Figure 3. During the stagnant period, high pressure system was persistent in the Korean peninsula resulting in local air masses to be more dominant within the SMA compared to the dynamic and transport (May 25nd - 31st) periods. Rex block patterns were observed during the blocking period (June 1st - 6th), which also resulted in more local influence.

2.2 Chemical Ionization Mass Spectrometry and Calibration

A THS Instruments LLC Chemical Ionization Mass Spectrometer (CIMS), using iodide (I^-) as the reagent ion was used for measuring Cl_2 and $ClNO_2$ at the two ground supersites and on the NASA DC-8. The system was similar to what is described in Slusher et al. (2004) and Liao et al. (2011), and the inlet configuration during the campaign is shown in Figure S1. Ambient air was sampled through a stainless steel donut shaped inlet at TRF and a Polytetrafluoroethylene (PTFE) tube inlet at OP. The stainless steel donut inlet has been shown to effectively avoid wall loss of reactive halogens during previous campaigns (Liao et al., 2011). However, artifacts of $ClNO_2$ or Cl_2 from interactions on the inlet has been shown to be negligible in various field conditions (Riedel et al., 2012; Thornton et al., 2010; Liao et al., 2014). Therefore, the use of different types of inlets (e.g., the use of the donut), described above, at the two ground sites and on the DC-8 is not expected to be an issue for the quantitative comparisons in this study. The sampled air went through the first 3-way valves to be delivered to an ambient or charcoal scrubber mode for background, alternating every 5 minutes. The second 3-way valve was for heated (150 °C) and unheated cycles. $ClNO_2$ and Cl_2 were only quantified during the unheated cycles to avoid any potential artifacts as described in Liu et al. (2017). Additional flow of 4 standard liters per minute (slpm) was drawn at the end of the inlet to reduce the residence time and 1 slpm was sampled into the CIMS. All the inlet parts, after the blower, including the fittings and tubings, were made of PTFE. In the flow tube, the target compounds form clusters with I^- (R 5-6, (Huey, 2007; Huey et al., 1995; McNeill et al., 2006)), which were generated by flowing 1 slpm N_2 through a methyl iodide (CH_3I) permittube oven maintained at 50 °C . Polonium

(NRD LLC, Static Master, Model: 2U500, Activity: 20 mCi) was used as the radioactive source for ionization. Clusters of Cl₂ isotopes were detected at the mass to charge ratio (*m/z*) of 197 and 199, and ClNO₂ was measured at 208 and 210. The natural abundance of Cl₂ and ClNO₂ isotopes are approximately 9:6:1 (³⁵Cl³⁵Cl : ³⁵Cl³⁷Cl : ³⁷Cl³⁷Cl) and 3:1 (³⁵ClNO₂ : ³⁷ClNO₂) respectively. Mass 201 (³⁷Cl³⁷Cl) was not considered in the data processing due to artifacts.

Calibrations of Cl₂ and ClNO₂ were carried out during and after the campaign. Cl₂ in a cylinder (Airgas, 10 ppm in N₂) was diluted with zero air to be sampled in either ambient or scrubber (charcoal) mode (Figure S1). The Cl₂ in the cylinder was quantified through the method described by Liao et al. (2012) and was 8.84 ± 0.43 ppm. ClNO₂ was synthesized, based on Thaler et al. (2011). Briefly, Cl₂ gas in N₂ was passed through a pyrex reservoir (diameter = 1.3 cm, length = 5.5 cm) containing a bed of NaCl (MACRON) and NaNO₂ (Sigma Aldrich) with a molar ratio of 10 to 1. This slurry mixture contains NO₂⁻ that reacts with the flowing Cl₂ to generate ClNO₂. The output flow was further diluted with 4 L min⁻¹ of zero air in order to sufficiently provide gas flow. The flow containing synthesized ClNO₂ was then analyzed at *m/z* of 208 and 210 with the CIMS. NO₂ and NO-NO_y were simultaneously measured with a Cavity Ring Down Spectroscopy (CRDS, Los Gatos Research, detection limit: 10 pptv, precision: 50 pptv at 1σ, model: 907-0009-0002) and chemiluminescence (CL, Thermo Scientific, detection limit: 50 pptv, model: 42 i) respectively. ClNO₂ is detected as NO_y in the CL through conversion to NO on the heated (325 °C) molybdenum catalytic converter (Williams et al., 1998). The efficiency of the conversion was assumed to be unity. Therefore, ClNO₂ could be determined by comparing the three instruments and subtracting the byproducts (HONO and NO₂) from the total NO_y.

2.3 Modeling

We used Framework for 0-D Atmospheric Modeling (F0AM v3.1) for simulating daytime Cl₂ production (Figure 5), in-situ ClNO₂ production in the morning (Figure 8), and testing the impact of measured ClNO₂ on the regional tropospheric chemistry (Figure 10). F0AM is a MATLAB based open-source box model. Detailed descriptions of the model can be found in Wolfe et al. (2016). Each step of the model was constrained with the averaged meteorology parameters (e.g., pressure, temperature, relative humidity) and trace gases observed in the two ground sites during the campaign. The constrained trace gases include ClNO₂, Cl₂, O₃, NO, NO₂, CO, CH₄, and 20 non-methane hydrocarbons including 8 alkanes (i.e., ethane, propane, iso-butane, n-butane, iso-pentane, n-pentane, n-hexane, and n-heptane), that have relatively high reaction rate constants with Cl·. Photolysis rate constants were derived through the hybrid method (Wolfe et al., 2016) in the F0AM box model. This method uses clear sky solar spectra from the tropospheric ultraviolet and visible radiation model (TUV v 5.2) and cross sections and quantum yields suggested by IUPAC. To capture the effects of pollution on photolysis rates, the ratio of the measured J_{NO2} to the F0AM modeled J_{NO2} was calculated. This ratio was then applied to other photolysis rate constants calculated in the model. Measured J_{NO2} was taken from the DC-8 actinic flux measurements (Charged-coupled device Actinic Flux Spectroradiometer;

CAFS) when flying near SMA at altitudes under 1 km. A diurnal cycle was applied to the DC-8 measurement to determine
165 j-values at other times of day. Photolysis rate constants of ClNO_2 , Cl_2 , and ClONO_2 were not present in the FOAM model
and therefore taken directly from the DC-8 measurements. The Master Chemical Mechanism v3.3.1 (MCM) was taken from
<http://mcm.leeds.ac.uk/MCM> and embedded in the box model. MCM v3.3.1 has a detailed gas photochemistry (i.e., 5832
species and 17224 reactions), including the oxidation of CH_4 and 142 non-methane primary emitted VOCs (Jenkin et al.,
2015). Since MCM v3.3.1 only includes $\text{Cl}\cdot$ reactions with alkane species, additional chlorine chemistry was embedded in the
170 model, similar to what Riedel et al. (2014) reported. This was done by including multiple $\text{Cl}\cdot$ precursors (e.g., Cl_2 , ClNO_2 ,
 HCl , ClONO_2 , HOCl) and $\text{Cl}\cdot$ reactions with non-alkane VOCs, such as alkene, alcohol, aromatics, alkynes, ketones, organic
acids and nitrates. All the reactions embedded in the model can be found in the supplementary of Riedel et al. (2014) and
Wolfe et al. (2016). More details on the setup of the box model are in the supplement material (S3). The FLEXible PARTi-cle
dispersion model (FLEXPART v9.1, <https://www.flexpart.eu>) was used for the air mass source contribution (Figure 3) and
175 backward trajectory analysis (Figure 9). The backward trajectories reported in our study were initialized 9:00 LST at TRF,
following it 24 hours back in time. The trajectories were driven by the National Centers for Environmental Prediction (NCEP)
Global Forecast System (GFS) with a 0.25 degree resolution. Influence of air mass originating from the ocean at TRF and
OP was calculated every 6 hours following an air mass 5 days back in time. Meteorology was driven by WRF with a 5 km
horizontal resolution. Since emissions of CO are very low in the ocean, and assumed to be inert in the model, it was used as a
180 tracer for contribution of air originating from the ocean within a given air mass at each ground site.

3 Results and Discussions

3.1 ClNO_2 Observations

Figure 2 shows the temporal variation of trace gases measured during the campaign at (a) the OP site (May 17th - June 11th)
and (b) the TRF site (May 5th - June 11th). The OP site, which was located near heavy traffic, showed high levels of NO_x
185 throughout the campaign. During most nights (except for May 24th - 26th, 30th - 31st, and June 6th - 7th), O_3 was completely
titrated by NO. On the other hand, at the TRF site, which is a forested region downwind of the urban area, O_3 remained at ~
30 ppbv throughout the night. During the measurement period, measureable amounts of ClNO_2 were observed at both ground
sites (Figure 3). The maximum observed ClNO_2 was ~800 pptv (10 min averaged) and ~2.5 ppbv (5 min averaged) at the OP
and TRF sites, respectively. At both sites, ClNO_2 started accumulating at sunset and rapidly photolyzed upon sunrise, which
190 was ~5:30 local standard time (LST) during the campaign. Nighttime relationship between ClNO_2 and Cl_2 varied day by day
and did not show a clear correlation. This implies that the sources of Cl_2 and ClNO_2 was not consistent at night. This is similar
to Riedel et al. (2012), where they reported a wide range of correlation between Cl_2 and ClNO_2 off the coast of LA.

Daytime (11:00 - 18:00, LST) ClNO_2 was up to ~100 pptv at OP and ~250 pptv at TRF (Figure 4). The level showed
a positive correlation with Cl_2 , especially in relatively high O_3 conditions (> 50 ppbv). When O_3 was relatively low (< 50
195 ppbv), Cl_2 production was suppressed, while ClNO_2 was not necessarily limited. Excluding the days with low O_3 (i.e., May
26th and 29th for OP and May 6th, 29th, and June 4th for TRF), the relationship between daytime ClNO_2 and Cl_2 showed

positive correlation with R^2 of 0.49 and 0.80 for OP and TRF, respectively. This positive correlation is consistent with the results reported by Liu et al. (2017) in the North China Plain. In their study, up to ~ 450 pptv of both Cl_2 and ClONO_2 was measured during the daytime (10:00 - 20:00, LST), with strong correlation of $R^2 = 0.83$. Cl_2 levels were also suppressed in
200 low O_3 and OH conditions during low solar radiation periods. Therefore, the authors suggested that daytime Cl_2 levels could be positively related to photochemical activities. Considering the short lifetime of Cl_2 and ClONO_2 during the day (i.e., 11:00 - 18:00 LST in our study), the levels we observed are likely affected through local production. According to Liu et al. (2017), the air mass showed moderate correlation to SO_2 with possible influences from power plants. However, in this study, the ClONO_2 measured at both the OP and TRF sites was weakly correlated with SO_2 ($R^2 = 0.02$), which implies that the air masses that we
205 sampled are not fresh emissions from power plants.

The first possibility we explored is the direct generation of Cl_2 from reactions in acidic particles. ClONO_2 is very insoluble ($\gamma_{\text{ClONO}_2} \approx 10^{-6}$ (Rossi, 2003)) in near-neutral pH. However, according to Roberts et al. (2008), γ_{ClONO_2} can increase up to 3 orders of magnitude in acidic surfaces ($\sim \text{pH } 1.8$) leading to direct production of gas-phase Cl_2 . Aerosol acidity was mostly below pH 2 during the campaign, based on thermodynamic calculations, constrained with airborne observations (Figure
210 S3). Therefore, the efficiency of this reaction in ambient conditions requires further investigation. Another possibility is the autocatalytic production of Cl_2 from heterogeneous reactions of gas-phase ClONO_2 (i.e., $\text{ClONO}_{2(g)} + \text{Cl}^-_{(aq)} + \text{H}^+_{(aq)} \rightarrow \text{Cl}_{2(g)} + \text{HNO}_3$, (Gebel and Finlayson-Pitts, 2001; Deiber et al., 2004)) and HOCl (i.e., $\text{HOCl}_{(g)} + \text{Cl}^-_{(aq)} + \text{H}^+_{(aq)} \rightarrow \text{Cl}_{2(g)} + \text{H}_2\text{O}$, (Vogt et al., 1996)) on particles. These reactions are also favored as particle acidity increases. In order to further investigate its possibility, daytime Cl_2 was simulated by constraining the box model with measurements of ClONO_2 and other
215 trace gases corresponding to each data point in Figure 4. Based on the availability of parameters, we were able to simulate 1680 and 1229 runs for the OP and TRF, respectively. This corresponds to more than 96 % of the daytime data points shown in Figure 4. γ_{ClONO_2} and γ_{HOCl} were set to 0.06 (Deiber et al., 2004; Hanson et al., 1994; Hanson and Ravishankara, 1994), which is an upper-limit of previous laboratory studies, and the yields were assumed to be unity. HCl generation from hydrogen abstraction of VOCs by Cl^\cdot were included in the mechanisms used in the model runs. The end points of the 72 hour simulation results
220 are presented in Figure 5. As shown in the Figure, the box model simulations were able to reproduce the positive correlation between Cl_2 and ClONO_2 . Moreover, modeled Cl_2 was suppressed in low O_3 conditions, which corresponds to the observations. This can be explained by Cl^\cdot reacting with O_3 , producing ClO^\cdot , leading to gas-phase ClONO_2 and HOCl production. These can react on acidic aerosols to generate Cl_2 . Sources of Cl^\cdot could be from photo-labile gas-phase chlorine compounds (e.g., Cl_2 , ClONO_2 , ClONO_2 , HOCl) or oxidation of gas-phase HCl by OH. Although the reaction between HCl and OH is relative slow
225 ($k = 7.86 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 298K, (Atkinson et al., 2007)), it has been reported to be a significant source of Cl^\cdot in the daytime (Riedel et al., 2012). A sensitivity test was carried out by comparing modeled Cl_2 between runs with and without HCl production from oxidation of VOCs by Cl^\cdot (Figure S4 c,d). The results show that production of Cl_2 was suppressed by 40 - 70 % when HCl was not generated in the model. This significant contribution of gas-phase HCl as a Cl^\cdot source, should be an upper-limit as the deposition of HCl was not considered in the model. Nonetheless, our analysis leads us to conclude that the
230 mechanisms we have explored could be the main contributors of the daytime Cl_2 production during KORUS-AQ.

3.2 Sources of ClNO₂

FLEXPART source contribution analysis shows that the level of ClNO₂ at the ground sites was highly correlated with the origin of the air mass (Figure 3). During the nights shaded in red in Figure 3 (OP: May 20th, 22nd, June 2nd, and 7th; TRF: May 11th, 19th-22nd, June 2nd, and June 6th-7th), there was limited production of ClNO₂ at the surface. These periods mostly corresponded to meteorological conditions of stagnation or blocking events, which both resulted in localized air masses to be more dominant with limited influence from the west coast. Stagnation events can be characterized by low wind speeds and increased atmospheric stability, possibly leading to enhanced levels of pollutants like NO_x. Previous studies have shown that these stagnant conditions can result in enhanced levels of N₂O₅ (Baasandorj et al., 2017) driven by high ozone and NO₂. However, ClNO₂ production was limited during stagnation events in this study. This is likely due to limited availability of chloride as shown in submicron particle measurements of aerosol mass spectrometer (AMS) at the ground site for OP and airborne over TRF (Figure 3). Whether the chloride is from the ocean or anthropogenic emissions is uncertain since large point sources, such as power plants or petrochemical facilities, are also present along the west coast of the SMA. On the nights of May 20th and May 22nd, rapid changes in air quality were observed with fast shifts in O₃, SO₂, and CO. This corresponded with changes in ClNO₂ and Cl₂ (Figure S7). These events suggest the importance of boundary layer advection in controlling the ClNO₂ levels in the region.

Different diurnal variations of ClNO₂ were observed between OP and TRF (Figure 6). The measurements were averaged over selected days (OP: May 18th-20th, 22nd, 23rd, 29th, June 4th; TRF: May 5th, 8th, 9th, 12th, 17th, 18th, 30th, June 8th, 10th) that showed these two distinct profiles at each site. The description on these profiles are further explained in the following sentences. At the TRF site (Figure 6b), far from direct NO emissions, significant levels of ClNO₂ were sustained throughout the night during most of the observation period with rapid photolysis upon sunrise. On the other hand, at OP (Figure 6 (a)), ClNO₂ started to increase upon sunset, followed by a rapid drop at around 22:00 LST. The trend was consistent with slower nitrate radical production rate ($d[\text{NO}_3]/dt = [\text{NO}_2][\text{O}_3]k$, where $k = 3.52 \times 10^{-17}$ at 298 K, (Atkinson et al., 2004)) as O₃ was titrated to zero by NO close to midnight. The wind direction, SO₂, and CO did not correlate. This suppressed ClNO₂ production in urbanized regions with high NO levels, have also been reported by Osthoff et al. (2018). However, significant levels of N₂O₅ and ClNO₂ could have been present in the upper part of the surface layer as shown in previous studies (Baasandorj et al., 2017; Young et al., 2012; Yun et al., 2018). According to Baasandorj et al. (2017), significant levels of N₂O₅ were observed aloft, within the boundary layer, while O₃ was completely titrated near the surface. On the other hand, airborne measurements at the LA basin (Young et al., 2012) showed a relatively uniform ClNO₂ profile throughout the boundary layer as O₃ did not change significantly within the measured altitude. During the 2015 Megacity Air Pollution Study (MAPS, Seoul, 2015), a Cavity Ringdown Spectrometer (CRDS) was installed on top of the Seoul tower in May - June that measured N₂O₅, NO_x, and O₃ (Brown et al., 2017). The elevation of the measurement site was 360 m above sea level (ASL), allowing for sampling further away from direct NO emissions. In their study, the average nighttime O₃ mixing ratio was around 50 ppbv and N₂O₅ was observed most nights, with mixing ratios reaching up to 5 ppbv. Therefore, it is very likely that ClNO₂ levels higher than the surface measurements could have been present at higher elevation during the observation period.

265 At both sites, ClONO₂ levels started to increase or sustained after the first 2-3 hours of rapid net loss upon sunrise. In the morning, ClONO₂ positively correlated to Cl₂ levels, but did not follow the nitrate production rate at the site (Figure S8). Box model simulations, initially constrained with observed ClONO₂ level, showed rapid photolysis upon sunrise (Figure S5, red dashed line). At TRF, this corresponded to the measurements until 7 - 8 am LST, when a second ClONO₂ peak was observed (Figure 6b). This ClONO₂ peak in the morning was observed about half the observation days during the campaign. With the net
270 ClONO₂ production rate from the observation, and the loss rate from the simulated ClONO₂ from photolysis, a production rate of 400 pptv h⁻¹ would be required to reconcile the observation. In the case of ClONO₂ observed on May 5th at TRF (an insert of Figure S6b), a maximum of 2.5 ppbv h⁻¹ of ClONO₂ production rate was required in the morning to reconcile the observations. At OP, 18 pptv h⁻¹ was required for the 7 averaged days. The ClONO₂ production rate required in the morning at TRF was much higher than the previous studies that have also reported high sustained levels of ClONO₂ in the morning (i.e., 20 - 200
275 pptv h⁻¹) (Faxon et al., 2015; Bannan et al., 2015; Tham et al., 2016). In these previous studies, three possibilities have been suggested that could explain the high sustained levels of ClONO₂ in the early morning : 1) entrainment of ClONO₂ from residual layer, 2) in-situ generation of ClONO₂, and 3) transport of ClONO₂ within the boundary layer. Each possibility is explored below.

At night time, the nocturnal boundary layer is decoupled from the residual layer (Stull, 1988), where the pollution from the previous day resides. Being removed from direct NO emissions near the surface, N₂O₅ can effectively accumulate in the
280 residual layer, with the major loss process being heterogeneous reaction on aerosols. Therefore, high levels of NO₂ and O₃ formed during the day can be trapped in the residual layer resulting in significant levels of ClONO₂ persisting throughout the night. Figure 7, shows (a) regional and (b) vertical distribution of airborne ClONO₂ throughout the campaign in the morning (8:00 - 8:30 LST) over the SMA region (lat: 37° 12' 0" N - 37° 38' 60" N, lon: 126° 54' 0" E - 127° 47' 60" E). During 3 flights (i.e., May 25th, May 31st, and June 10th), ClONO₂ was observed in the residual layer with a max of ~ 230 pptv. However, the
285 remaining flights observed an average of 17 ± 56 pptv of ClONO₂ (black circles). Even the three days (i.e., May 25th, 31st, and June 10th), that ClONO₂ was observed in the residual layer, the level (max 230 pptv) could not reconcile the observed levels at the TRF site, which was 342 ± 330 pptv when averaged over the corresponding 3 days at 8:00 - 8:30 LST.

In order to further explore the possibility of in-situ formation, box model simulations of ClONO₂ production from heterogeneous reaction of N₂O₅ and chloride containing aerosols were conducted. N₂O₅ was calculated assuming a photo-stationary
290 state of NO₃ (Brown et al., 2005). Aerosol surface area was taken from airborne observations over TRF. Based on the box model results in Figure 8, even with an assumption of 100 % yield, ClONO₂ from heterogeneous reaction was not able to reconcile the observed level. Box model simulation on gas phase production of ClONO₂ (i.e., Cl·_(g) + NO_{2(g)} + M → ClONO_(g) + M, Cl·_(g) + NO_{2(g)} + M → ClONO_{2(g)} + M) showed at most 2-10 pptv of ClONO₂ and ClONO (Figure S6).

Therefore, the third possibility, local transport within the boundary layer, would be the most likely explanation for the
295 high ClONO₂ in the morning based on our analysis. Although ClONO₂ readily photolyzes during the day ($\tau_{ClONO_2} \approx 30$ min at midday), the lifetime could be significantly long enough in the early morning to allow for transport of ClONO₂ to the ground sites. Based on the NCAR TUV v5.2 model, the lifetime of ClONO₂, averaged between 5:30 and 8:30 LST was ~ 2 hours under clear sky conditions. Figure 9 shows back trajectory analysis initiated at 9 am local time at TRF. At high ClONO₂ days with the morning peaks, most of the air masses were from the west. During KORUS, the DC-8 did not fly to the west of

300 the SMA in the early morning. However, there are large point sources, such as petrochemical facilities and industries, and vehicular emissions to the west and south west of the SMA region. Sullivan et al. (2019) reported that this resulted in enhanced levels of O₃ in receptor regions (i.e., Taehwa Research Forest) downwind when westerlies were prevalent. Therefore, favorable conditions such as high chloride content in aerosols from both anthropogenic and natural sources and high levels of NO_x-O₃ could have lead to significant levels of ClNO₂ to build up and transported to TRF before being completely photolyzed. During
305 the campaign, influence of large biomass burning was negligible as reported in Tang et al. (2018, 2019).

3.3 Impacts of ClNO₂ on O₃

Cl· produced from ClNO₂ photolysis can influence the local air quality through reactions with VOCs followed by enhanced production of O₃. The possible impact of Cl· initiated reactions on the local chemistry were investigated by running box model simulations constrained with measured ClNO₂. A 24 hour diurnal variation of ClNO₂ was averaged over the same selected
310 days as in Figure 6, and these were constrained throughout the model simulations. The results illustrate that when the model was constrained with ClNO₂ and Cl· initiated chemistry, higher levels of O₃ were simulated (Figure 10) compared to the base runs without ClNO₂. The averaged net O₃ production rate was enhanced by up to 2 % and 25 % at OP and TRF in the morning and by 1 % and 2 % when averaged during the day. The OP had 7 times lower Cl· than the TRF site due to low ClNO₂ levels (~60 pptv) in the morning. For ·OH, the net production rate at TRF increased by 2 % in the morning. The results particularly
315 from TRF are comparable with the previous study in the mountaintop site in Hong Kong, China (Wang et al., 2016). The enhancement of O₃ (max - min) was higher than their moderate ClNO₂ case (11 %) but lower than the high ClNO₂ plume case (41 %).

4 Conclusions

Comprehensive measurements of ClNO₂, Cl₂, other trace gases, and aerosol concentrations and properties have been conducted
320 on the NASA DC-8 and at two ground sites during the KORUS-AQ 2016 field campaign. The observed averaged diurnal variations are largely consistent with the previous observations and our understanding on the photochemistry of ClNO₂. The presence of ClNO₂ was substantially suppressed during strong stagnation events, which could have prevented the transport of chloride near the coast. During the night, Cl₂ and ClNO₂ levels were not correlated while moderate to strong positive relationships were observed at daytime. Through box model simulations, we presented a quantitative analysis on the daytime
325 observations. The results showed that heterogeneous reactions of ClONO₂ and HOCl in acidic aerosols may be responsible for the positive correlation between Cl₂ and ClNO₂, as well as its dependency on O₃. The second ClNO₂ peak in the morning, observed 4-5 hours after sunrise, required a significant source of ClNO₂ (up to 2.5 ppbv h⁻¹). Previous studies have attributed high sustained ClNO₂ in the morning to transport from the residual layer (Tham et al., 2016; Wang et al., 2016). In this study, box model runs of heterogeneous and gas-phase production of ClNO₂ could not reconcile the observed levels. Moreover,
330 airborne observations in the early morning showed negligible ClNO₂ levels in the residual layer in most of the days. Therefore, local transport of ClNO₂ from highly polluted airmasses from the west is the most plausible explanation. This shows that

different meteorological or chemical conditions of the sites can lead to various causes of high ClNO₂ levels in the early morning. Finally, box model simulations constrained with observations suggest that Cl⁻ initiated chemistry can lead up to ~25 % increase of net O₃ production rate in the morning.

335 *Data availability.* Dataset used in this study is open to public and can be downloaded at <https://www-air.larc.nasa.gov/missions/korus-aq/>

Author contributions. DJ, RS, DG, YL, DT, SK, and GH designed and executed field measurements for collecting ClNO₂ and Cl₂; BAN, JLJ, and PCJ provided the airborne AMS data; CK ran the FLEXPART analysis; TM and JS provided O₃ measurements; DRB provided the WAS data; DS and AG provided the PTR-ToF-MS data; RL provided NO_x and O₃ data; BA provided the data from LARGE; SRH and KU provided data from CAFS; HS provided AMS data at OP; SH provided HCHO measurements at TRF; YL, DK, and JA provided CO
340 measurements at TRF. DJ and SK prepared the original manuscript, and all other authors contributed in editing the manuscript.

Acknowledgements. This study is supported by NASA (NNX15AT90G) and NIER. CU HR-AMS measurements and pH and aerosol liquid water calculations (BAN, PCJ, and JLJ) were supported by NASA grant NNX15AT96G and 80NSSC18K0630. We thank the Wisthaler research group (University of Oslo, University of Innsbruck) for providing airborne VOC data, John Crounse and Paul Wennberg (CALTECH) for the HNO₃ data, Hwajin Kim (Korea Institute of Science and Technology) for the discussions on aerosol composition, and Siyuan Wang
345 (NCAR) for discussions on box model simulations. The authors appreciate logistical support from the research and supporting staff at Taehwa research forest operated by Seoul National University.

Table 1. Summary of the measurements carried out during the KORUS-AQ 2016 field campaign, used in this study.

Compound	Method		
	TRF	OP	DC-8
NO	^a CL	^b FRM	^c CL
NO ₂	^d CRDS	^e CAPS	^c CL
O ₃	^f DIAL	^g SL-UV	^c CL
SO ₂	^h PF	ⁱ UV florescence	x
CO	^j IR	^k NDIR	x
ClNO ₂ , Cl ₂	^l CIMS	^l CIMS	^l CIMS
VOCs	^m PTR-ToF-MS	^o QCL	^p PTR-ToF-MS
	ⁿ TILDAS		^q WAS
chloride (< 1 μm)	x		
nitrate (< 1 μm)	x	^r ToF-AMS	^s HR-ToF-AMS
sulfate (< 1 μm)	x		
surface area (< 200 nm)	x	x	^t SMPS
surface area (200 nm - 5 μm)	x	x	^u LAS
Jvalues	x	x	^v CAFS

^aChemiluminescence with a molybdenum converter (Thermo Scientific 42i - TL), ^bChemiluminescence detector (Federal Reference Method, Teledyne T200U), ^cNCAR 4-channel chemiluminescence (Weinheimer et al., 1994), ^dCavity Ring Down Spectroscopy (Los Gatos Research NO₂ analyzer), ^eCavity Attenuated Phase Shift spectroscopy (Teledyne T500U CAPS analyzer), ^fNASA TROPospheric OZone Differential Absorption Lidar (Sullivan et al., 2014), ^gUV photometric method (2B 211), ^hPulsed fluorescence method (Thermo Scientific 43i-HL), ⁱUV florescence method (KENTEK), ^jInfrared CO analyzer (Thermo Scientific 48i-HL), ^kNon-Dispersive Infrared CO analyzer (KENTEK), ^lChemical Ionization Mass Spectrometer (Slusher et al., 2004), ^mProton-Transfer-Reaction Time-of-Flight Mass Spectrometer (IONICON), ⁿTunable Infrared Laser Direct Absorption Spectroscopy (Aerodyne), ^oQuantum Cascade Laser spectrometer (Aerodyne), ^pUniversity of Oslo/Innsbruck Proton-Transfer-Reaction Time-Of-Flight Mass Spectrometer (Müller et al., 2014), ^qWhole Air Sampler (Colman et al., 2001), ^rAerosol Mass Spectrometer (Aerodyne), ^sUniversity of Colorado, Boulder, Aerosol Mass Spectrometer (Nault et al., 2018), ^tNASA, Scanning Mobility Particle Sizer, ^uNASA, Laser Aerosol Spectrometer, ^vNCAR, Charged-coupled device Actinic Flux Spectroradiometers (Shetter and Müller, 1999)

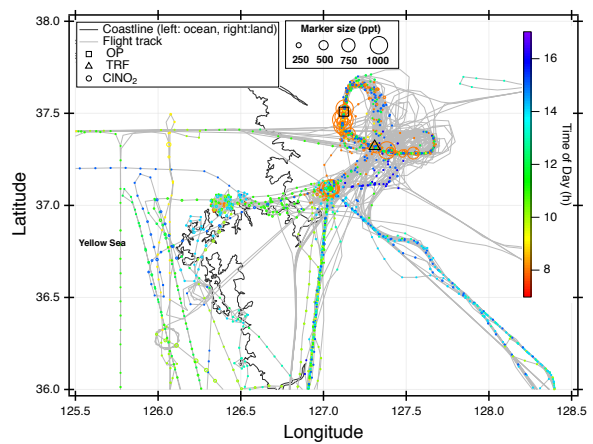

Figure 1. (a) Location of two ground sites (Taejwa Research Forest and Olympic Park) where the chemical ionization mass spectrometer (CIMS) was installed during the KORUS-AQ 2016 field campaign (b) Airborne measurements of ClNO_2 and DC-8 flight tracks during the whole campaign. The ClNO_2 data points are 60 sec averaged and color coded by time of day of the measurement. The marker size is proportional to the mixing ratio of ClNO_2 .

Figure 2. Temporal variation of trace gases measured at the (a) Olympic Park site (OP) and (b) Taehwa Research Forest (TRF). For both OP and TRF, the frequency of the averaged data is 10 min for NO_x and 1 min for O₃.

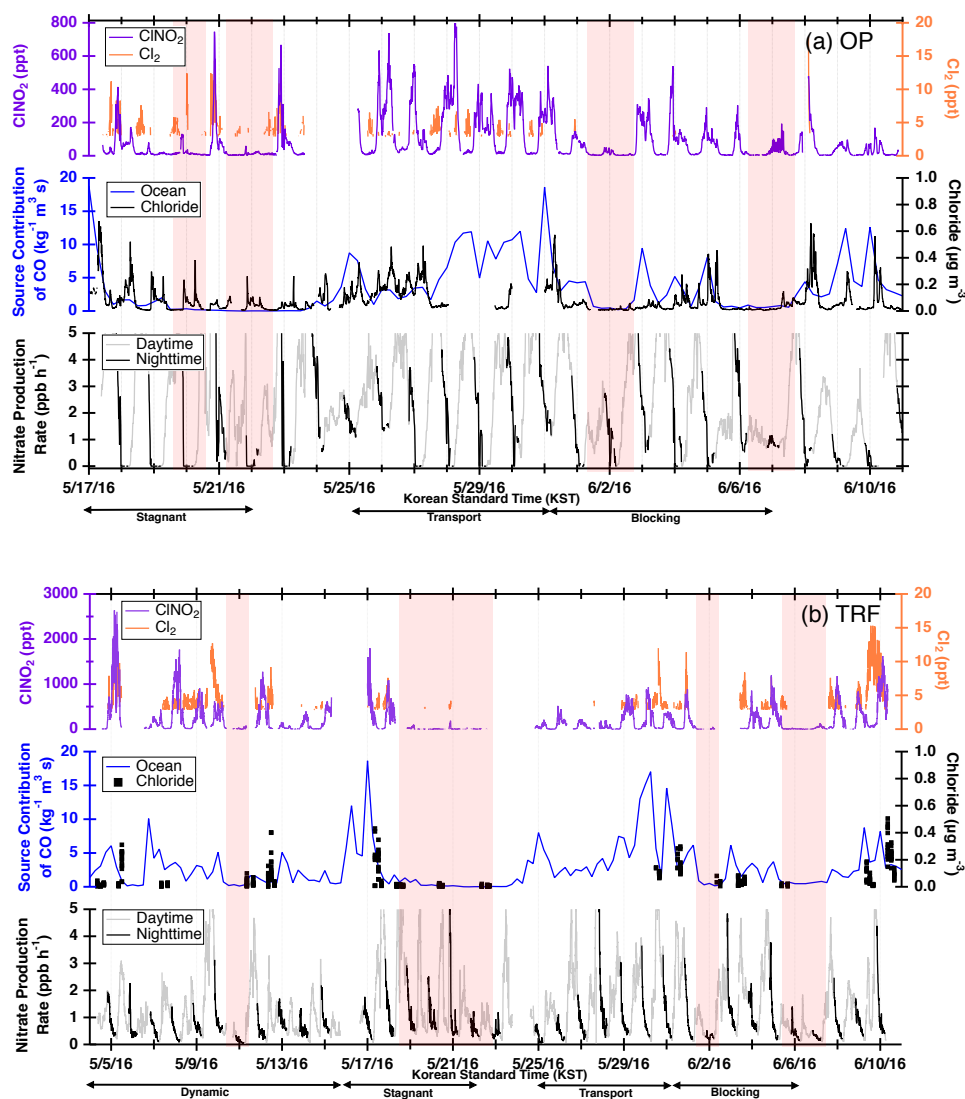

Figure 3. CINO₂ and Cl₂ observation results at (a) OP and (b) TRF averaged over 10 min and 5 min respectively. FLEXPART back trajectory analysis were made for source contribution of CO-like substance originating from the ocean, assuming inert CO. Aerosol chloride mass concentration (ambient $\mu\text{g m}^{-3}$) was measured at the ground for the OP site and on the NASA DC-8 for TRF. For the airborne chloride, measurements below 1 km over the TRF site is shown. Red shades are the time frame with limited CINO₂ production.

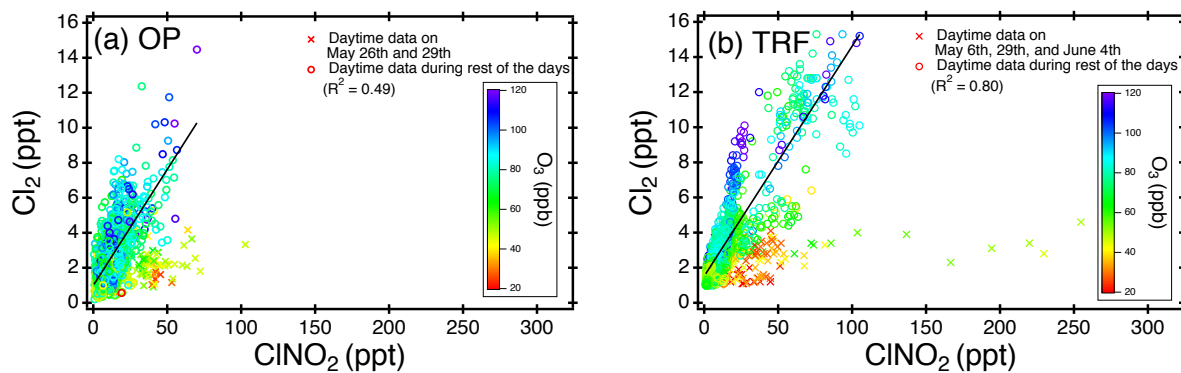

Figure 4. Scatter plot of daytime (11:00 - 18:00 local time) CINO₂ and Cl₂ at (a) OP and (b)TRF, color coded with measured O₃. 5 min averaged data for the whole campaign were used for both sites.

Figure 5. Correlation between box model simulated daytime (11:00 - 18:00 local time) Cl₂ and measured ClNO₂ at (a) OP and (b)TRF, color coded with measured O₃.

Figure 6. Diurnal variation CINO_2 and other trace gases measured during the campaign and averaged over selected days at (a) OP (7 days) and (b) TRF (9 days). Night time is shown as grey shades.

Figure 7. (a) Regional and (b) vertical distribution of airborne ClONO_2 measured over the Seoul Metropolitan Region (SMA) in the morning (8:00 - 8:30 local time).

Figure 8. Steady state CINO₂, simulated from a box model constrained with airborne measurements (blue) and ground site data from TRF (red), when there was a morning CINO₂ peak. Averaged values of the model runs are shown here with standard deviations.

Figure 9. FLEXPART back trajectories from Taehwa Research Forest. Trajectories were initialized at 9 am local time and went 24 h backwards. Only the center trajectories with the highest percentage of airmasses are presented. Trajectories for days with high levels of CINO₂ (> 500 pptv) at night are in red and the remaining days are shown in sky blue.

Figure 10. Box model simulations of chlorine radicals and O₃ at (a) OP and (b) TRF, constrained with ClNO₂ and other trace gases observed during the field campaign. Percent difference of net O₃ production rate (NetP(O₃), blue line) was calculated from the difference of the NetP(O₃) between simulations with and without ClNO₂ constrained in the model (i.e., $100 \cdot (w_{\text{ClNO}_2} - w_{\text{noClNO}_2}) / w_{\text{ClNO}_2}$).
