15

16 **Abstract.** Nitro-aromatic compounds (NACs), as important contributors to ultraviolet light absorption by brown carbon,
17 have been widely observed in various ambient atmospheres, however, few field studies has been focused on their formation
18 in urban atmospheres. In this work, NACs in Beijing were comprehensively quantified and characterized in summer, along
19 with major components in fine particulate matter and selected volatile organic compounds. Field observations in this high
20 NO_x-anthropogenic VOCs dominated urban atmosphere were analyzed to investigate the NAC formation and influence
21 factors. The total concentration of quantified NACs was 6.63 ng/m³, higher than other summertime studies (0.14- 6.44
22 ng/m³). 4-Nitrophenol (4NP, 32.4%) and 4-nitrocatechol (4NC, 28.5%) were the most abundant ones among all the
23 quantified NAC species, followed by methyl-nitrocatechol (MNC), methyl-nitrophenol (MNP) and dimethyl-nitrophenol
24 (DMNP). The oxidation of toluene and benzene in the presence of NO_x were found to be more dominant sources of NACs
25 than biomass burning emissions. The NO₂ level was an important factor influencing the secondary formation of NACs. A
26 transition from low- to high-NO_x regimes coincided with a shift from organic- to inorganic-dominated oxidation products.
27 The transition thresholds were NO₂-20 ppb for daytime and NO₂-25 ppb for nighttime conditions. Under low-NO_x
28 conditions, NACs increased with NO₂, while the NO₃⁻ concentrations and (NO₃⁻)/NACs ratios were lower, implying
29 organic-dominated products. Above the NO_x regime transition values, NO₂ was excess for the oxidation of ambient VOCs.
30 Under this condition, NAC concentrations did not further increase obviously with NO₂, while the NO₃⁻ concentrations and
31 (NO₃⁻)/NACs ratios showed significant increasing trends, when shifting from organic- to inorganic-dominated products.
32 Obvious nighttime enhancements of 3M4NC and 4M5NC, daytime enhancements of 4NP, 2M4NP and DMNP indicated
33 their different formation pathways. The aqueous-phase oxidation was the major formation pathways of 4M5NC and 3M5NC,

34 and photo-oxidation of toluene and benzene in the presence of NO₂ could be more important for the formation of nitrophenol
35 and its derivatives. Thus, the (3M4NC+ 4M5NC)/4NP ratios was employed to indicate the relative contribution of
36 aqueous-phase and gas-phase oxidation to NAC formation. The relative contribution of aqueous-phase pathways was
37 observed to increase at elevated ambient RH and remain constant at RH > 30%. In addition, the concentrations of VOC
38 precursors (e.g. toluene and benzene) and aerosol surface area were also important factors promoting NAC formation, and
39 photolysis was an important loss pathway of NACs.

40

41 1 Introduction

42 Organic nitrogen, including nitro-aromatic compounds (NACs), N-heterocyclic compounds, amines and other organic
43 nitrate compounds containing (-NO₂) or (-NO₃) functional groups, represent an important fraction of ambient organic
44 aerosols (Laskin et al., 2009; Wang et al., 2017b; Chow et al., 2016; Ge et al., 2011; Ng et al., 2017). Among organic
45 nitrogen, NACs, with the -NO₂ and -OH functional groups attached to an aromatic ring, have gained much attention due to
46 their impacts on light-absorption and human health (Mohr et al., 2013; Lin et al., 2017). NACs, including nitrophenols (NPs),
47 nitrocatechols (NCs) and their derivatives, are important contributors to ultraviolet light absorption by brown carbon (BrC)
48 (Mohr et al., 2013; Teich et al., 2017; Zhang et al., 2013; Xie et al., 2017), contributing 50-80% of the total visible light
49 absorption by BrC emitted from biomass burning (Lin et al., 2017). Moreover, NACs also lead to mutagenesis and
50 genotoxicity, thus posing a threat to human health (Purohit and Basu, 2000; Huang et al., 1995).

51 NACs have been widely observed in various ambient atmospheres, including urban, suburban, rural, as well as
52 background environments, with the quantified concentrations varying from 0.1 ng/m³ in rural background area to 147.4
53 ng/m³ in urban area (Inuma et al., 2010; Teich et al., 2017; Zhang et al., 2010; Mohr et al., 2013; Chow et al., 2016; Wang et
54 al., 2018b). Combustion processes, especially biomass burning, were one of the most important primary sources of NACs
55 (Harrison et al., 2005; Wang et al., 2018b). The emission factors of NACs from biomass burning were estimated 0.8-11.1
56 mg/kg (Wang et al., 2017a; Hoffmann et al., 2007). Field observation studies indicated NACs are usually associated with
57 fresh or aged biomass burning aerosols, which contributed 10- 21% of the total NACs in ambient aerosols (Chow et al., 2016;
58 Kitanovski et al., 2012; Mohr et al., 2013; Inuma et al., 2010; Wang et al., 2018b). Apart from direct emissions from
59 biomass burning, NACs could also form through the oxidation of volatile organic compounds (VOCs, e.g. cresol, catechol)
60 emitted from biomass burning in the smoke plumes (Inuma et al., 2010; Claeys et al., 2012). Methyl-nitrocatechols (MNCs)
61 could originate from NO_x oxidation of cresol or catechol, which are released during biomass burning as thermal degradation
62 products of lignin (Inuma et al., 2010; Finewax et al., 2018; Olariu et al., 2002).

63 Various gas-phase and condensed-phase oxidation of anthropogenic VOC precursors are also important contributors to
64 NAC formation, especially in urban atmospheres (Harrison et al., 2005). The main reactions leading to the secondary

65 formation of NPs, NCs, methyl-nitrophenols (MNPs) and MNCs are shown in Figure 1 (Jenkin et al., 2003). Nitrophenols
66 and its derivatives (e.g. MNPs) could originate through gas-phase oxidation of aromatic hydrocarbons (e.g. phenol, benzene
67 and toluene) by OH or NO₃ radicals in the presence of NO₂, which could represent the major sources of NPs in some
68 environments (Harrison et al., 2005; Yuan et al., 2016; Sato et al., 2007; Ji et al., 2017; Olariu et al., 2002). Nitrocatechols
69 dominated the composition of NACs formed in benzene/NO_x system (Xie et al., 2017). The NC formation could be initiated
70 by OH or NO₃ radicals to form β -hydroxyphenoxy/*o*-semiquinone radicals, which then react with NO₂ to form the final
71 products (Finewax et al., 2018). Compared with the gas-phase formation of NACs, the NAC formation via aqueous-phase
72 aromatic nitration is less well understood. Nitrophenols could form through the nitration and hydroxylation of benzene in the
73 presence of nitrite/nitrous acid or photo-nitration of phenol upon UV irradiation of nitrite in aqueous solutions (Vione et al.,
74 2004; Vione et al., 2001). It has been suggested that nighttime aqueous-phase oxidation is an important formation pathway
75 for methyl-nitrocatechols, especially in polluted high-NO_x environments and acidic particles (pH around 3) (Vidovic et al.,
76 2018). The proposed aqueous-phase formation processes of MNCs include electrophilic substitution route and consecutive
77 oxidation and conjugated addition route (Frka et al., 2016; Vidovic et al., 2018). The proposed loss pathways for NACs
78 include photolysis and reactions with OH, NO₃ radicals or chlorine atoms (Atkinson et al., 1992; Bejan et al., 2007; Bejan et
79 al., 2015; Chen et al., 2011; Yuan et al., 2016).

80 However, few studies have been conducted based on field observation to investigate the formation of NACs in urban
81 atmospheres. To get a comprehensive understanding on the characteristics and sources of NACs in high NO_x-anthropogenic
82 VOCs dominated atmospheres, an intensive field campaign was conducted in Beijing. A group of NACs (NPs, MNPs,
83 dimethyl-nitrophenols, DMNPs, NCs and MNCs) were comprehensively quantified and characterized using high
84 performance liquid chromatography- mass spectrometry (HPLC-MS). Focusing on the secondary formation of NACs,
85 previous lab study results were applied to the ambient atmosphere in urban Beijing and the influence factors of NAC
86 formation were comprehensively analyzed. This work illustrates the secondary formation of NACs in high
87 NO_x-anthropogenic VOCs dominated urban environments.

88 2 Methods

89 2.1 Sample collection

90 Within the bilateral Sweden-China framework research program on 'Photochemical smog in China', an intensive field
91 campaign was conducted in Beijing to improve the understanding on secondary chemistry during photochemical smog in
92 China (Hallquist et al., 2016). The campaign was conducted at Changping (40.14° N, 116.11° E), a regional site northeast of
93 Beijing urban area, from May 15 to June 5, 2016, when the site was obviously influenced by anthropogenic pollutants from

94 Beijing urban areas and under high-NO_x conditions (Tang et al., 2018; Wang et al., 2018a). During May 17- June 5, the daily
95 average concentrations of benzene, toluene and NO_x were 66-922 ppt, 47-1344 ppt and 4.0-32.3 ppb, respectively.

96 Ambient PM_{2.5} (particles with aerodynamic diameter less than 2.5 μm) samples were collected on prebaked quartz fiber
97 filters (Whatman Inc.) and Teflon filters (Whatman Inc.) using a high-volume sampler (TH-1000C, Tianhong, China) and a
98 4-channel sampler (TH-16A, Tianhong, China) during the campaign. The sampling flow rates were 1.05 m³/min and 16.7
99 L/min, respectively. The daytime samples were collected from 8:30 to 17:30 LT (UTC+8) and nighttime ones from 18:00 to
100 8:00 LT (UTC+8) the next morning. Field blank samples were collected by placing filters in the samplers with the pump off
101 for 30 min.

102 2.2 Quantification of NACs

103 An aliquot of 25 cm² was removed from each filter sample and extracted in ultrasonic bath three times using 3, 2 and 1
104 mL methanol containing 30 μL saturated EDTA solution in methanol-acetic acid consecutively, each time for 30 min. The
105 extracts were then filtered through a 0.25 μm polytetrafluoroethylene (PTFE) syringe filter (Pall Life Sciences), combined,
106 and evaporated to dryness under a gentle stream of high-purity nitrogen. The dried samples were re-dissolved in 50 μL
107 methanol/water (1:1) containing 100 ppb 4-nitrophenol-2,3,5,6-*d*₄ as internal standard. The solution was centrifuged and the
108 supernatant was used for analysis, using Agilent 1260 LC system (Palo Alto, CA) coupled to QTRAP 4500 (AB Sciex,
109 Toronto, Ontario, Canada) mass spectrometer. The LC-MS system was equipped with an electrospray ionization (ESI)
110 source operated in negative mode. More details of the extraction and optimized MS parameters have been described in our
111 previous study (Chow et al., 2016).

112 Chromatographic separation was performed on an Acquity UPLC HSS T3 column (2.1 mm×100 mm, 1.8 μm particle
113 size; Waters, USA) with a guard column (HSS T3, 1.8 μm). The column temperature was kept at 45 °C and the injection
114 volume was 5.0 μL. The mobile eluents were (A) water containing 0.1% acetic acid (v/v) and (B) methanol (v/v) containing
115 0.1% acetic acid at a flow rate of 0.19 mL/min. The gradient elution was set as follows: started with 1% B for 2.7 min;
116 increased to 54% B within 12.5 min and held for 1.0 min; then increased to 90% B within 7.5 min and held for 0.2 min; and
117 finally decreased to 1% B within 1.8 min and held for 17.3 min until the column was equilibrated.

118 The quantified NAC species are listed in Table 1. The NACs were identified and quantified using the [M-H]⁻ ions in the
119 extracted ion chromatogram (EIC), using authentic standards or surrogates with the same molecular formula (Table 1). The
120 standards included: 4-nitrocatechol (4NC), 4-nitrophenol (4NP), 2-methyl-4-nitrophenol (2M4NP), 3-methyl-4-nitrophenol
121 (3M4NP) and 2,6-dimethyl-4-nitrophenol (2,6DM4NP) from Sigma-Aldrich (St. Louis, MO, USA);
122 4-methyl-5-nitrocatechol (4M5NC) from Santa Cruz Biotech (Dallas, TX, USA). The concentration of dimethyl-nitrophenol
123 (DMNP) was the sum of three isomers.

124 2.3 Other online and offline measurements

125 Other online and offline instruments were also employed to obtain related database, which has been introduced in detail
126 in our previous paper (Wang et al., 2018c). A high resolution time-of-flight aerosol mass spectrometer (AMS) was used to
127 measure the chemical composition of PM₁ (Zheng et al., 2017). The aerosol surface area was calculated based on the
128 measurements of particle number and size distribution by a scanning mobility particle sizer (SMPS, TSI 3936) and an
129 aerosol particle sizer (APS, TSI 3321) (Yue et al., 2009; Wang et al., 2018a). VOCs were measured by a
130 proton-transfer-reaction mass spectrometer (PTR-MS). Gaseous NH₃ was measured using a NH₃ analyzer (G2103, Picarro,
131 California, USA) (Huo et al., 2015). Meteorological parameters, including relative humidity (RH), temperature, wind
132 direction and wind speed (WS) were continuously monitored by a weather station (Met one Instrument Inc.) during the
133 whole campaign.

134 Organic carbon (OC) was analyzed using thermal/optical carbon analyzer (Sunset Laboratory). The organic matter (OM)
135 concentration was calculated by multiplying OC by 1.6 (Turpin and Lim, 2001). Water soluble inorganic ions were
136 quantified by an ion chromatograph (IC, DIONEX, ICS2500/ICS2000) following procedures described in Guo et al. (2010).
137 Aerosol acidity was then calculated using the ISORROPIA-II thermodynamic model. ISORROPIA-II was operated in
138 forward mode, assuming the particles are “metastable” (Hennigan et al., 2015; Weber et al., 2016; Guo et al., 2015). The
139 input parameters included: ambient RH, temperature, particle phase inorganic species (SO₄²⁻, NO₃⁻, Cl⁻, NH₄⁺, K⁺, Na⁺, Ca²⁺,
140 Mg²⁺), and gaseous NH₃. More details and validation of the thermodynamic calculations have been described in our previous
141 paper (Wang et al., 2018c).

142 3 Results and discussion

143 3.1 Concentration and composition of NACs

144 The average concentration of quantified NACs was 6.63 ng/m³, ranging from 1.27 to 17.70 ng/m³ in summer in Beijing.
145 The concentrations of total NACs as well as individual species across this and prior studies were summarized and compared
146 in Figures 2, S1 and Table S1. The total NAC concentration was higher than other studies conducted in summer in mountain,
147 rural or urban environments (Teich et al., 2017; Kitanovski et al., 2012; Kahnt et al., 2013; Zhang et al., 2013; Chow et al.,
148 2016; Wang et al., 2018b), and comparable to the studies in summertime Wangdu, China (Teich et al., 2017; Wang et al.,
149 2018b) (Figure 2). Each NAC species (NP, NC, MNP and MNC), except DMNP, also showed elevated concentrations in
150 Changping, compared with those reported in other summertime studies (Figure S1). Influenced by the outflow from urban
151 Beijing air masses, the site was under typical high-NO_x conditions (Wang et al., 2018a), implying abundant potential
152 secondary formation of NACs during the observation period. A recent study suggested that nocturnal biogenic VOCs
153 (BVOCs) oxidation would transfer from low- to high-NO_x regimes and nearly all the BVOCs would be oxidized by NO₃

154 radicals, at a NO_x/BVOCs ratio higher than 1.4 (Edwards et al., 2017). When we roughly estimated the BVOCs
155 concentration to be the sum of isoprene, MVK+MACR (methyl vinyl ketone and methacrolein), and monoterpenes, the
156 NO_x/BVOC ratios were higher than 8 (nighttime ratios higher than 20) (Figure S2). Even considering the major
157 anthropogenic VOCs (toluene, benzene), NO_x/VOCs ratios were higher than 5 (nighttime ratios higher than 10) (Figure S2).
158 The high- NO_x conditions were expected to facilitate the oxidation of aromatic hydrocarbons and the secondary formation of
159 NACs during the campaign. Other emissions from biomass burning and coal combustion were also observed to be
160 contributors of organic aerosols during the campaign (Tang et al., 2018), which could also be the sources of NACs. Biomass
161 burning episodes occurred during Wangdu campaign, indicating obvious NAC emissions from biomass burning (Teich et al.,
162 2017; Tham et al., 2016), which explain the high NAC levels in summer in Wangdu. The NAC concentrations during
163 summer (including this study) are generally lower than those during spring, autumn or winter, when usually with higher
164 combustion emissions, especially biomass burning and coal combustion (Chow et al., 2016; Wang et al., 2018b; Kitanovski
165 et al., 2012; Kahnt et al., 2013).

166 The NAC compositions are shown in the inserted pie chart in Figure S1. 4-Nitrophenol and 4-nitrocatechol were the
167 most abundant ones among all the quantified NAC species, accounting for 32.4 % and 28.5 % of the total quantified NACs,
168 followed by methyl-nitrocatechol (4M5NC, 3M5NC and 3M6NC, 16.2%), methyl-nitrophenol (2M4NP and 3M4NP, 15.6%)
169 and dimethyl-nitrophenol (8.3%) (Table 1). Nitrophenols and nitrocatechols were generally reported among the most
170 abundant NAC species in previous studies (Table S1 and the references therein). Nitrophenols could form via the oxidation
171 of anthropogenic VOCs (e.g. benzene) in the presence of NO_2 and nitrocatechols dominate the composition of NACs formed
172 in benzene/ NO_x system (Xie et al., 2017; Harrison et al., 2005; Yuan et al., 2016; Sato et al., 2007; Ji et al., 2017; Olariu et
173 al., 2002). Thus, the high contributions of nitrophenol and nitrocatechol were not surprising in the typical high
174 NO_x -anthropogenic VOCs dominated environments in summer in Beijing.

175 The contribution of NP among the total NACs at Changping was higher than that in summer in Hong Kong, while that
176 of MNC was lower (Table S1 and the inserted pie charts in Figure S1). The gas-phase oxidation of aromatic hydrocarbons
177 (e.g. phenol, benzene) in the presence of NO_2 is a major source of NPs (Harrison et al., 2005; Yuan et al., 2016; Sato et al.,
178 2007; Ji et al., 2017; Olariu et al., 2002), while aqueous-phase oxidation represents the important formation pathway for
179 atmospheric MNC (Frka et al., 2016; Vidovic et al., 2018). Different NAC compositions between Changping and Hong
180 Kong potentially hint difference in the relative contribution of aqueous-phase and gas-phase pathways to NAC formation
181 under different environment conditions. The ambient RH in Hong Kong was obviously higher than that in summer in Beijing
182 (Zhao et al., 2016), thus the relative contribution of aqueous-phase pathways could be more dominant, promoting the
183 aqueous-phase formation of MNC in Hong Kong. The influence of ambient RH on NAC formation would be further
184 discussed in section 4.2. More abundant gas-phase formation of nitrophenol was expected in summer in Beijing, under
185 higher anthropogenic VOCs, high NO_x and low RH conditions. What's more, the temperature in summer in Changping was

186 lower than that in summer in Hong Kong (Zhao et al., 2016), which was more favorable for the partitioning of nitrophenol
187 products from gas phase into particle phase.

188 3.2 Temporal variation and sources of NACs

189 Temporal variations of the total quantified NAC concentrations in this study are shown in Figure 3, along with
190 particulate organics, nitrate, potassium ion, toluene, benzene, wind speed and RH. The correlation analysis between NACs
191 and other chemical components or meteorological conditions is shown in Table S2. During the observation period, four
192 pollution episodes (episodes I, II, III, IV) were identified based on the organic aerosols, marked by gray shading in Figure 3.
193 Elevated NAC concentrations were observed during each pollution episode, coincided with the increasing of toluene,
194 benzene and potassium. Their good inter-correlations (Table S2) suggested the sources of NACs from biomass burning
195 emissions and secondary oxidation of anthropogenic VOCs (benzene, toluene and their oxidation products). It was noticed
196 that NACs showed stronger correlations with toluene ($r=0.70$) or benzene ($r=0.64$) than those with potassium ($r=0.49$),
197 indicating the NO_x oxidation of anthropogenic VOCs as more dominant sources of NACs than biomass burning in summer
198 in Beijing.

199 To further investigate the secondary formation of NACs, the time series and day-night variations of individual NAC
200 species are shown in Figures 4, S3 and S4. Obvious daytime enhancements of 4NP, 2M4NP and DMNP, nighttime
201 enhancements of 3M4NC and 4M5NC were observed, and other NAC species didn't show obvious day-night variations
202 (Figures 4, S3 and S4), indicating different formation pathways for NAC species. Good inter-correlations were observed
203 among nitrophenol and its derivatives (2M4NP, 3M4NP, DMNP, $r=0.56-0.88$), as well as among nitrocatechol and its
204 derivatives (3M6NC, 3M5NC, 4M5NC, $r=0.49-0.84$). However, the correlations between nitrophenol derivatives and
205 nitrocatechol derivatives ($r=0.05-0.45$) were lower (Table S2). The correlation analysis indicated that the formation and loss
206 pathways as well as the influence factors were similar within each group (NP and NP derivatives, NC and NC derivatives),
207 while different between them. NC and its derivatives showed stronger correlations with toluene, benzene and K^+ , compared
208 with NP and its derivatives (Table S2). This was because the factors influencing the particulate NP distribution could be
209 more complicated. Gas-phase oxidation represents an important formation pathway for NP, thus the distributions of
210 particulate NP could largely dependent on gas-particle partitioning or their gas-phase loss pathways (e.g. photolysis).

211 Obvious nighttime enhancements of 4M5NC and 3M5NC were observed during the whole observation period,
212 especially during the first pollution episode (Figure 4). Strong inter-correlations between 4M5NC and 3M5NC and their
213 similar temporal variations indicated the similar formation pathways. It has been suggested that aqueous-phase oxidation
214 (including photooxidation and nighttime oxidation) is an important formation pathway for atmospheric MNC, especially in
215 polluted high- NO_x environments and relatively acidic particles (pH around 3) (Vidovic et al., 2018; Frka et al., 2016).
216 4M5NC and 3M5NC showed relatively stronger correlations with RH compared with other NAC species (Table S2),

217 implying the importance of water in their formation processes and the aqueous-phase pathway. During the campaign,
218 particles were generally acidic with a pH range of 2.0- 3.7 and under high-NO_x conditions (Wang et al., 2018c; Wang et al.,
219 2018a), which were suitable environments for the aqueous-phase oxidation formation of MNC. The daytime correlations
220 between 4M5NC or 3M5NC and RH or NO₂ were stronger than the nighttime (Table S3). The aqueous-phase NO_x oxidation
221 could be more dependent on ambient RH and NO₂ levels during the daytime, due to the lower RH and NO₂ concentrations
222 than those at night (Figures 3, S2). MNC also showed good correlations with potassium, as MNC could also form via the
223 oxidation of VOC precursors (e.g. cresol, catechol) emitted from biomass burning (Iinuma et al., 2010; Finewax et al., 2018;
224 Olariu et al., 2002). 3M6NC showed different temporal variations from 4M5NC or 3M5NC (Figures 4, S3) and their
225 correlations were lower than that between 4M5NC and 3M5NC (Tables S2, S3), which suggested different formation
226 pathway of 3M6NC from those of 4M5NC or 3M5NC. The quantum calculations have predicted the formation of 3M5NC
227 via aqueous-phase electrophilic substitution and nitration by NO₂⁺, while the formation of 3M6NC was negligible due to
228 higher activation barriers for nitration of 3-methylcatechol to form 3M6NC (Frka et al., 2016). A dominant presence of
229 3M5NC in ambient aerosols was also expected according to the theoretical predictions (Frka et al., 2016). The 3M5NC
230 concentration was obviously higher than that of 3M6NC in summer in Beijing, which is consistent with the study in Frka et
231 al. (2016).

232 Different from the nighttime enhancements of 4M5NC and 3M5NC, 4NP, 2M4NP and DMNP showed obvious daytime
233 enhancements during the whole campaign (Figures 4, S4), indicating the importance of photochemical oxidation for the
234 formation of NP and its derivatives. Previous study also suggested the daytime gas-phase oxidation of aromatics could
235 represent the major source of nitrophenols, while the contribution from nighttime reaction of phenol with NO₃ radicals was
236 relatively lower (Yuan et al., 2016). We did not find obvious correlation between 4NP and NO₂ when considering the whole
237 period (Table S2), while good correlations were observed when treating the daytime and nighttime conditions separately
238 (Table S3). The strong correlations between 4NP and benzene, toluene or NO₂ during daytime and nighttime indicated its
239 formation via oxidation of benzene and toluene in the presence of NO₂ (Table S3). The formation mechanisms of nitrophenol
240 were different during daytime (OH-initiated photooxidation of aromatics in the presence of NO₂) and nighttime
241 (NO₃-initiated oxidation of aromatics) (Harrison et al., 2005; Yuan et al., 2016; Sato et al., 2007; Ji et al., 2017; Olariu et al.,
242 2002), thus the role and influence of NO₂ on NAC formation were different. For DMNP, 2M4NP and 3M4NP, they also
243 showed good correlations with benzene, toluene and NO₂ during daytime, which indicated their potential formation
244 pathways via photooxidation of aromatics in the presence of NO₂. However, DMNP and 3M4NP didn't show correlations
245 with benzene, toluene or NO₂ at night. Their correlations with RH were higher at night, implying the possible formation
246 related to aqueous-phase pathways, while the potential precursors or mechanisms remain unknown.

247

248 **4 Discussion**249 **4.1 The NO₂ control of NACs formation**

250 NO_x oxidation of anthropogenic VOC precursors represented the dominant sources of NACs in summer in Beijing. To
251 further investigate the impacts of NO₂ on NAC secondary formation, we plot the concentrations of NACs, nitrate (NO₃⁻) and
252 the NO₃⁻/NAC ratios as a function of NO₂ levels (Figure 5). The variation of (NO₃⁻)/NACs ratios was employed to illustrate
253 the relative abundance of inorganic nitrate and oxidized organic nitrogen. The variation during daytime and nighttime were
254 separately considered due to the different atmospheric conditions and oxidation mechanisms (Figure 1).

255 Generally, higher concentrations of NACs and nitrate were observed with elevated NO₂ concentration levels, with
256 nonlinear responses (Figure 5). During the daytime, the NACs increased with NO₂, and the NO₃⁻ concentrations and
257 (NO₃⁻)/NACs ratios were lower at low-NO_x conditions (NO₂ < 20ppb). As NO₂ increased to higher than 20 ppb, the NAC
258 concentration did not obviously increase with NO₂ any more, indicating the transition from NO_x-sensitive to NO_x-saturated
259 regimes for NAC secondary formation. At the same time, the NO₃⁻ concentrations and (NO₃⁻)/NACs ratios showed
260 significant increasing trends (Figure 5a, b, c). It was likely that the daytime NO₂ was excess for the oxidation of ambient
261 VOCs and the NAC formation at NO₂ > 20 ppb. The excess NO₂ would be oxidized to form inorganic nitrate, indicating the
262 shift of products from organic- to inorganic-dominated conditions. Similarly, the transitions from the low- to high-NO_x
263 regimes and oxidation products from organic- to inorganic-dominated were also observed at NO₂ ~25 ppb at night under the
264 ambient environments in summer in Beijing (Figure 5d, e, f). The nighttime NAC formation would become independent of
265 NO₂ concentrations and inorganic nitrate dominated the NO_x oxidation products at NO₂ > 25 ppb. The simplified mechanisms
266 and schematic diagram of the competing formation of inorganic nitrates and NACs are shown in Figure S5. The nighttime
267 NO₂ transition value (~25 ppb) was higher than the daytime one (~20 ppb). The higher anthropogenic VOC precursors
268 (Figure S2) and different oxidation mechanisms at night (Figure 1) were the potential reasons for elevated NO₂ transition
269 value.

270 Taking NACs as an example, the result implied that the transition from low- to high-NO_x regimes and the oxidation
271 products shifting from organic- to inorganic-dominated conditions existed in the anthropogenic VOCs-NO_x interacted
272 conditions in polluted urban atmospheres. However, the mechanisms as well as transition thresholds were less understood
273 compared with the well-known BVOCs-NO_x interaction atmospheres. The NO_x transition regimes of more organic nitrogen
274 formation and the oxidation mechanisms during daytime and nighttime deserve comprehensive investigation in
275 anthropogenic VOCs-NO_x interacted urban atmospheres. Due to the complex VOC composition in ambient atmosphere and
276 the limited number of VOC species measured in this study, the NO_x regime transition value was expressed by NO₂
277 concentrations under the condition of urban Beijing atmospheres rather than NO₂/VOC or NO_x/VOC ratios. The NO_x regime
278 transition values deserve further investigation based on comprehensive lab simulation and field observations, which could be

279 expressed by NO_x/VOC ratios and applied to various atmospheric environments.

280 The formation pathways of different NAC species vary from each other based on the analysis in sections 3.2, thus the
281 role and influence of NO_2 on their formation are different. The variation of NAC compositions as a function of NO_2 levels is
282 shown in Figure 6 to investigate the influence of NO_2 on NAC compositions. The contributions of nitrocatechol and its
283 derivatives among the total NACs increased and those of nitrophenol and its derivatives decreased at elevated NO_2
284 concentrations. The NAC composition remained relatively constant at $\text{NO}_2 > 20$ ppb, which was approximately the transition
285 value from low- to high- NO_x regimes. The role of elevated NO_2 in promoting NC (and its derivatives) formation was more
286 obvious than that for NP (and its derivatives). The oxidation of aromatics (e.g. benzene, toluene and VOCs emitted from
287 biomass burning) in the presence of NO_2 represent the major formation pathway of NC and its derivatives based on the
288 analysis in section 3.2. The formation of NC and its derivatives would increase obviously as the increasing of ambient NO_2
289 concentration levels. The distributions of nitrophenol and its derivatives could also be obviously influenced by the
290 gas-particle partitioning and their loss pathways (e.g. photolysis), thus their increasing trend as a function of NO_2 was not as
291 obvious as those of NC and its derivatives.

292

293 4.2 Other influence factors of NACs formation

294 Nitration of aromatic hydrocarbons (e.g. benzene and toluene) represents the major source of NACs in summer in
295 Beijing. NACs generally increased with the increasing of anthropogenic toluene and benzene (Figure 7). During daytime,
296 when toluene was higher than 0.6 ppb and benzene higher than 0.4 ppb, the NACs concentrations would not increase further
297 with VOC concentrations (Figure 7a, b). It was likely that toluene or benzene was in excess and the NAC formation became
298 independent of anthropogenic VOC precursors under this condition. Similarly, the nighttime formation of NACs would be
299 independent of anthropogenic VOCs, when toluene was higher than 1 ppb and benzene higher than 0.6 ppb (Figure 7c, d).
300 The transition values of toluene or benzene was higher at night than those during the daytime. This could be due to the
301 significantly higher NO_2 levels (Figure S2), with higher capacity to oxidize VOC precursors, and different oxidation
302 mechanisms at night.

303 Though the total NACs didn't show good correlations with ambient RH, good correlations between 3M4NC, 4M5NC
304 and RH were observed (Table S2, Figure 8). The NAC products (e.g. nitrophenols) dominated by gas-phase formation
305 pathways were less affected by ambient RH. Aqueous-phase oxidation represented the major formation pathway of 3M4NC
306 and 4M5NC during the campaign, based on the analysis in section 3.2 and previous studies (Vidovic et al., 2018; Frka et al.,
307 2016). Elevated ambient RH would favor the water uptake of aerosols and decrease the aerosol viscosity, which favors the
308 exchange of organic precursors or other gas molecules into the particles, mass diffusion of reactants and chemical reactions
309 within the particles (Vaden et al., 2011; Booth et al., 2014; Renbaum-Wolff et al., 2013; Shrestha et al., 2015; Zhang et al.,

310 2015), and thereby enhance the formation of 3M4NC and 4M5NC in aqueous phase. The (3M4NC+ 4M5NC)/4NP mass
311 concentration ratios were employed to indicate the relative contribution of aqueous-phase and gas-phase pathways to NAC
312 formation. The variations of (3M4NC+ 4M5NC)/4NP ratios as a function of ambient RH during daytime and nighttime were
313 shown in Figure 9. The (3M4NC+ 4M5NC)/4NP ratios increased under higher RH conditions during the daytime, indicating
314 elevated contribution of aqueous-phase pathways to NAC formation. The relative contribution of aqueous-phase and
315 gas-phase pathways would not increase further as the increasing of RH at RH > 30%, indicated by the stable (3M4NC+
316 4M5NC)/4NP ratios (Figure 9a). The relative contribution of aqueous-phase and gas-phase pathways remained constant
317 under higher RH conditions (RH > 30%) at night (Figure 9b). The nighttime (3M4NC+ 4M5NC)/4NP ratios were obviously
318 higher than the daytime ones, which implied that the aqueous-phase oxidation played more important roles for NAC
319 formation at night. The results implied the importance of aqueous-phase oxidation for the secondary formation of oxidized
320 organic nitrogen at elevated ambient RH. Due to the limited sample number obtained by filter-based analysis in this study,
321 the influence of RH or aerosol liquid water content on NAC formation needs further investigation using online
322 measurements in the lab.

323 The NAC concentrations also showed good correlations with aerosol surface area (Figure 8b). Higher aerosol surface
324 area would provide a good interface for the partitioning of gas-phase NAC products into particle phase and also for the
325 aqueous-phase or heterogeneous oxidation processes to form NACs (Frka et al., 2016; Vidovic et al., 2018; Bauer et al., 2004;
326 Fenter et al., 1996). Photolysis is an important loss pathway of NACs and could be the dominant sink for nitrophenol in the
327 gas phase (Bejan et al., 2007; Yuan et al., 2016). The highest value of $J(O^1D)$ of each day was used to roughly represent the
328 photolysis intensity. The daytime NAC concentrations showed negative correlations with $J(O^1D)$ (Figure 8c, Table S3),
329 suggesting photolysis as an important sink for NACs during the daytime.

330

331 5 Conclusions

332 Nitroaromatic compounds (NACs), as important contributors to ultraviolet light absorption by brown carbon, have been
333 widely observed in various ambient atmospheres. An intensive field campaign was conducted in summer in Beijing, to
334 investigate the characterization and formation of NACs under high NO_x -anthropogenic VOCs dominated atmosphere. NACs
335 were comprehensively quantified and characterized using HPLC-MS. The total concentration of quantified NACs was 6.63
336 ng/m^3 , ranging from 1.27 to 17.70 ng/m^3 , generally higher than those reported in other studies conducted in summer.
337 4-Nitrophenol (32.4%) and 4-nitrocatechol (28.5%) were the most abundant NAC species, consistent with previous studies,
338 and followed by methyl-nitrocatechol, methyl-nitrophenol and dimethyl-nitrophenol.

339 The oxidation of anthropogenic VOC precursors (e.g. toluene, benzene and their oxidation products) in the presence of

340 NO₂ represented more important sources of NACs than biomass burning in summer in Beijing. NO₂ plays important roles in
341 the secondary formation of NACs. A transition from low- to high-NO_x regimes and oxidation products from organic- to
342 inorganic-dominated conditions were observed, which was NO₂~20 ppb for the daytime and NO₂~25 ppb for the nighttime
343 atmosphere. Under low-NO_x conditions, NACs were observed to increase with NO₂, and the NO₃⁻ concentrations and
344 (NO₃⁻)/NACs ratios were lower. As NO₂ increased to the high-NO_x regimes, the NAC concentration did not further increase
345 obviously with NO₂, and the NO₃⁻ concentrations and (NO₃⁻)/NACs ratios would show obvious increasing trends. Using
346 NACs as an example of organic nitrogen, the low- and high-NO_x regimes were observed in the anthropogenic VOCs-NO_x
347 interacted conditions in polluted urban atmospheres. While the mechanisms as well as transition threshold are still unclear,
348 which deserves comprehensive investigation in future studies.

349 Obvious nighttime enhancements of 3M4NC and 4M5NC, daytime enhancements of 4NP, 2M4NP and DMNP were
350 observed, indicating their different formation pathways. The aqueous-phase oxidation pathways are presumed to be
351 important for the formation of 4M5NC and 3M5NC, under the conditions of polluted high-NO_x and acidic particles during
352 the campaign. Photo-oxidation of toluene and benzene in the presence of NO₂ were more important for the formation of
353 nitrophenol and its derivatives. To further investigate the NAC formation pathways and influence of RH, the (3M4NC+
354 4M5NC)/4NP mass ratios was employed to represent the relative contribution of aqueous-phase and gas-phase pathways to
355 NAC formation. The (3M4NC+ 4M5NC)/4NP mass ratios would increase at elevated RH and remain relatively consistent at
356 RH> 30%, indicating elevated contribution of aqueous-phase pathways to NAC formation under higher RH conditions.
357 Aqueous-phase oxidation played more important roles in NAC formation at night than that during the daytime.

358 VOC precursors, aerosol surface area and photolysis were also important factors influencing the NAC formation.
359 Nitration of aromatic hydrocarbons (e.g. benzene and toluene) represents the major secondary source of NACs, thus NACs
360 generally increased with the increasing of toluene and benzene. The NAC formation would become independent of toluene
361 and benzene, when the daytime concentrations were higher than 0.6 and 0.4 ppb, or the nighttime ones higher than 1 and 0.6
362 ppb. In addition, aerosol surface area was also important factor promoting the NAC formation and photolysis could be an
363 important loss pathway of NACs during the daytime.

550

551 **Figures**

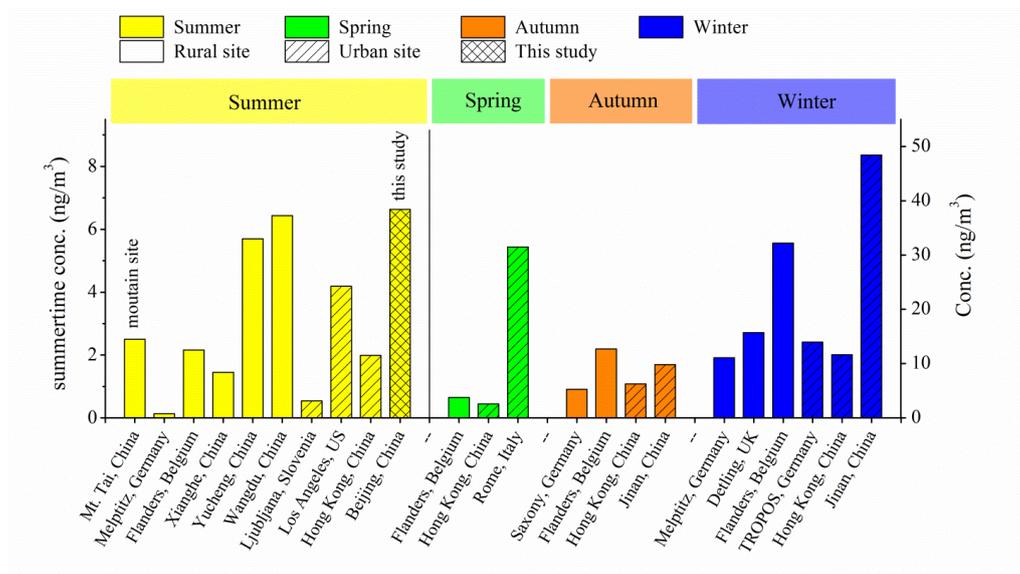

552

553

554 Figure 1 Formation of nitrophenols, nitrocatechols, methyl-nitrophenols and methyl-nitrocatechols from the oxidation of (a)
555 benzene and (b) toluene in the atmosphere (MCM v3.3). Reactions in red represent the daytime pathways and those in blue
556 represent the nighttime pathways. Other isomers for intermediate and final products are also expected, but not shown in the
557 figure for clarity.

558

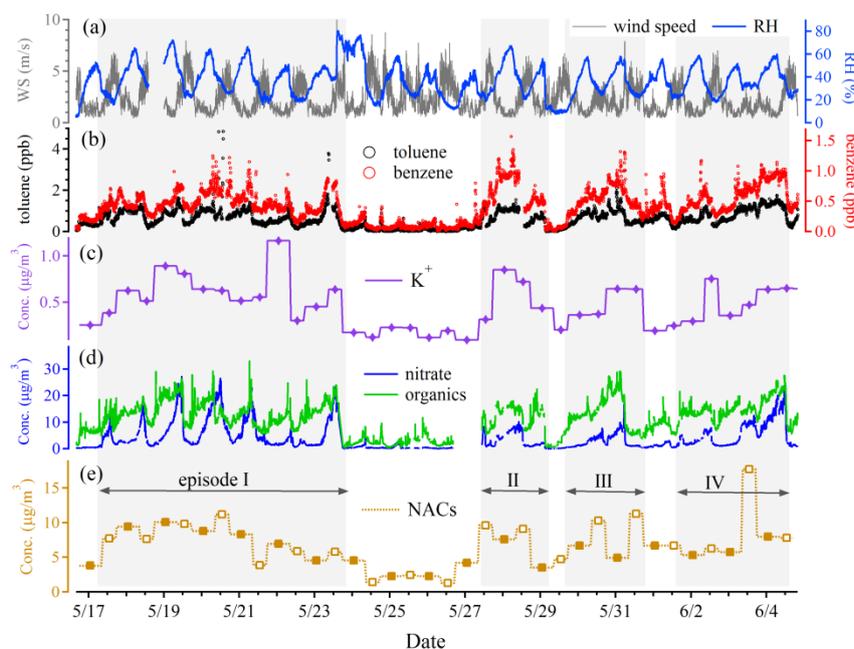

559

560 Figure 2 Summary of NAC concentrations cross this and prior studies (see Table S1 for the data and references therein). The

561 NAC concentrations in summer correspond to the left axis and other seasons correspond to the right axis.

562

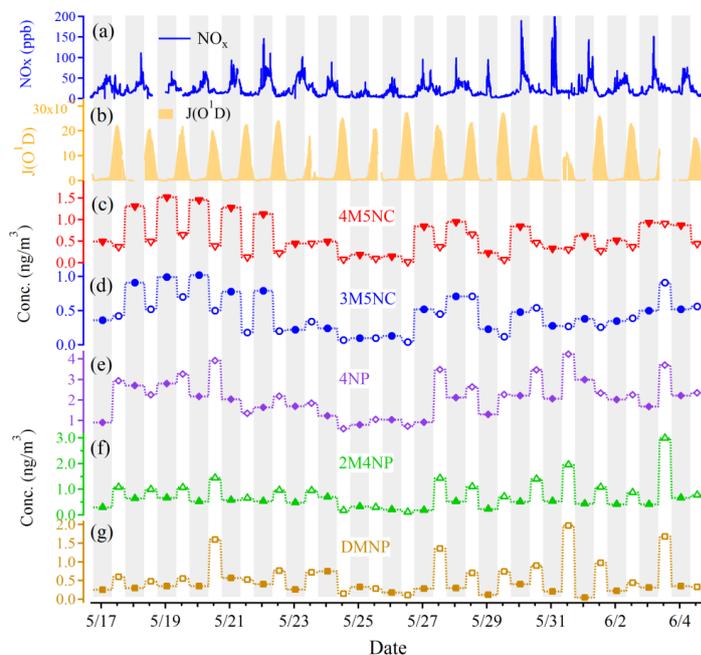

563

564 Figure 3 Time series of (a) wind speed (WS) and relative humidity (RH), (b) benzene and toluene, mass concentrations of (c)

565 K^+ , (d) organics and nitrate, and (e) NACs. The pollution episodes are marked by gray shading.

566

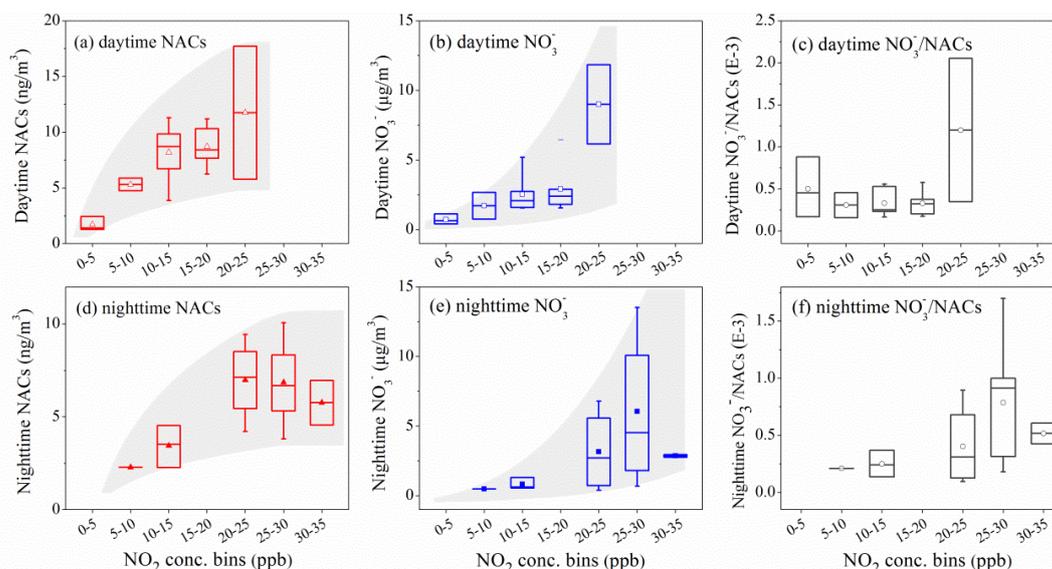

567

568 Figure 4 Time series of (a) NO_x , (b) $J(\text{O}^1\text{D})$, (c) 4-methyl-5-nitrocatechol (4M5NC), (d) 4-methyl-5-nitrocatechol (3M5NC),

569 (e) 4-nitrophenol (4NP), (f) 2-methyl-4-nitrophenol (2M4NP), and (g) dimethyl-nitrophenol (DMNP). The gray background

570 denotes the nighttime and white background denotes the daytime.

571

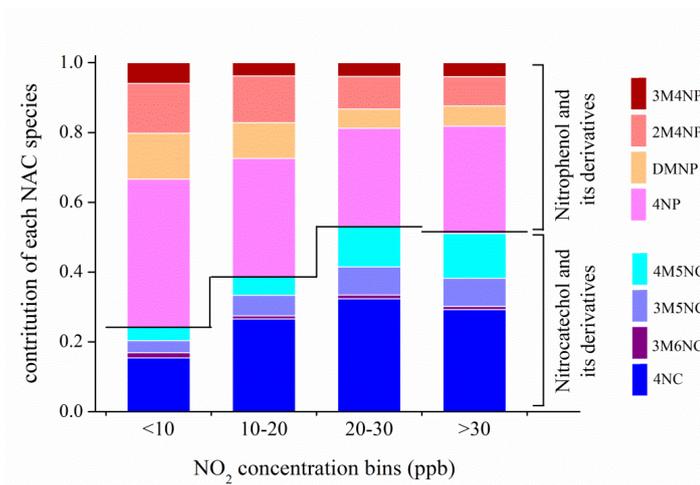

572

573 Figure 5 Concentrations of NACs, nitrate and NO_3^-/NAC ratios as a function of NO_2 concentration bins during daytime and

574 nighttime. The markers represent the mean values and whiskers represent 25 and 75 percentiles.

575

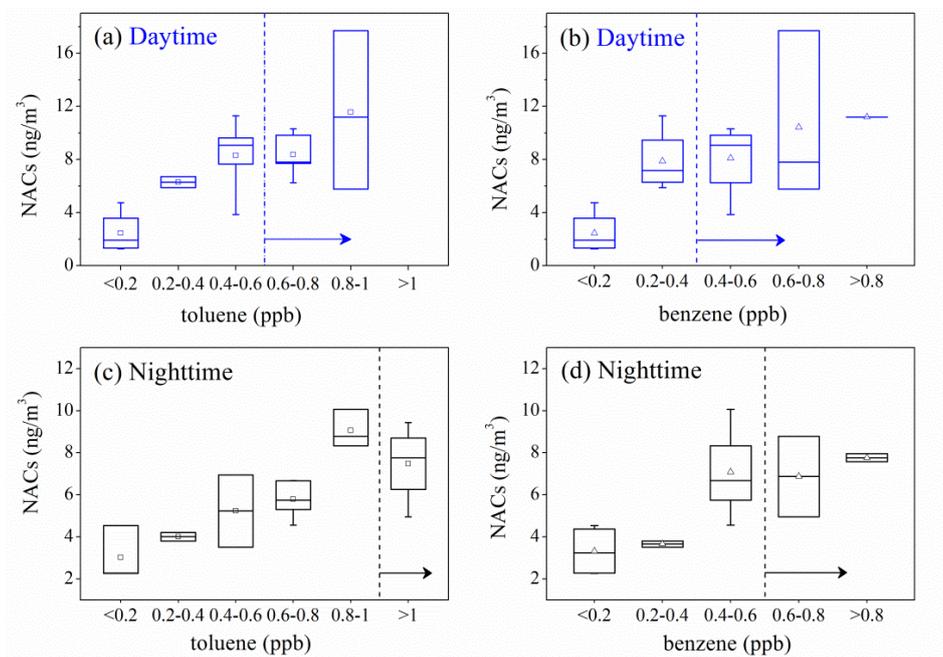

576

577

Figure 6 Variation of NAC compositions as a function of NO_2 concentration bins.

578

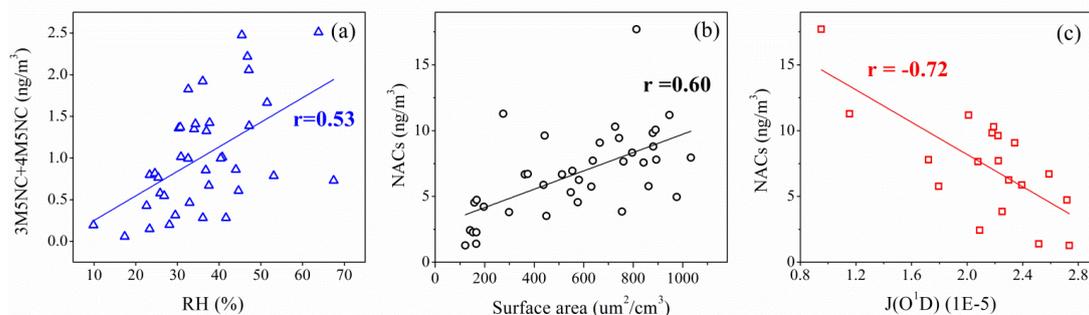

579

580 Figure 7 Concentrations of NACs as a function of toluene and benzene concentration bins during daytime and nighttime. The
 581 markers represent the mean values and whiskers represent 25 and 75 percentiles. The r value in each panel represents the
 582 correlation coefficient between NACs and toluene or benzene.

583

584

585

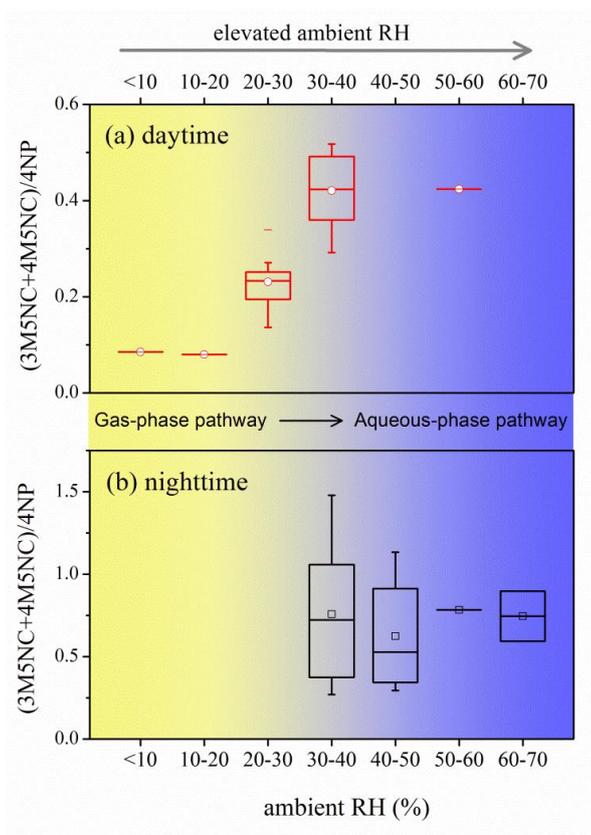

586

Figure 8 Correlation analysis (a) between (3M5NC+4M5NC) and RH, (b) between NACs and aerosol surface area, (c)

587

between NACs and $J(O^1D)$.

588

589

590

Figure 9 (3M5NC+4M5NC)/4NP concentration ratios as a function of ambient RH during (a) daytime and (b)

591

nighttime.
