S1. Stable carbon isotopic composition of EC

The stable carbon isotopic composition of EC was determined using a Finnigan MAT 251 mass spectrometer with a dual inlet system (Bremen, Germany) at the Stable Isotope Laboratory at the Institute of Earth Environment, Chinese Academy of Sciences. OC is removed by heating the filter pieces at 375 °C for 3 h in a vacuum-sealed quartz tube in the presence of CuO catalyst grains. Extraction of EC was done by heating the carbon that remained on the filters at 850 °C for 5 h. The evolved CO₂ from EC was isolated by a series of cold traps and quantified manometrically. The stable carbon isotopic composition of the purified CO₂ of EC was measured and determined as $\delta^{13}C_{EC}$. A routine laboratory working standard with a known $\delta^{13}C$ value was measured every day. The quantitative levels of ¹³C and ¹²C isotopes were characterized using a ratio of peak intensities of m/z 45 (¹³C¹⁶O₂) and 44 (¹²C¹⁶O₂) in the mass spectrum of CO₂. Samples were analyzed at least in duplicate, and all replicates showed differences less than 0.3 ‰. $\delta^{13}C$ values are reported in the delta notation with respect to the international standard Vienna Pee Dee Belemnite (V-PDB):

$$\delta^{13} C(\%_0) = \left[\frac{\binom{(^{13}C/^{12}C)_{\text{sample}}}{\binom{(^{13}C/^{12}C)_{\text{V-PDB}}}} - 1 \right] \times 1000.$$
(S1)

Details of stable carbon isotope measurements are described by our previous studies (Cao et al., 2011; Ni et al., 2018).

S2. Separation of fossil sources into coal and vehicle for EC using Bayesian statistics

Contributions from biomass burning and fossil sources to EC is separated by $F^{14}C_{EC}$ (Sect. 2.4). The relative contribution of fossil fuel combustion to EC ($f_{fossil}(EC)$) and biomass burning to EC ($f_{bb}(EC)$) constrained by $F^{14}C_{EC}$ is shown in Table S5. $f_{fossil}(EC)$ can be further separated into the fraction of EC contributed by coal combustion(f_{coal}) and vehicle emissions ($f_{vehicle}$) using $\delta^{13}C$ of EC in a Bayesian Markov chain Monte Carlo (MCMC) scheme:

$$\delta^{13}C_{\rm EC} = \delta^{13}C_{\rm bb} \times f_{\rm bb}(\rm EC) + \delta^{13}C_{\rm coal} \times f_{\rm coal} + \delta^{13}C_{\rm vehicle} \times f_{\rm vehicle} \,, \tag{S2}$$

$$f_{\text{coal}} + f_{\text{vehicle}} = f_{\text{fossil}}$$
 (EC), (S3)

where $\delta^{13}C_{bb}$, $\delta^{13}C_{vehicle}$ and $\delta^{13}C_{coal}$ are the $\delta^{13}C$ signature of EC emitted from biomass burning, vehicle emissions and coal combustion, respectively. The means and the standard deviations for $\delta^{13}C_{bb}$ (-26.7 ± 1.8 ‰ for C3 plants), $\delta^{13}C_{vehicle}$ (-25.5 ± 1.3 ‰) and $\delta^{13}C_{coal}$ (-23.4 ± 1.3 ‰) are established in Andersson et al. (2015) by a thorough literature search and full compilation of $\delta^{13}C$ source signatures for EC. In brief, the mean and standard deviation for $\delta^{13}C$ endmembers for the different sources are estimated as the average and standard deviation of the different data sets,

respectively.

The source endmembers for δ^{13} C are less well-constrained than $f_{bb}(EC)$ and $f_{fossil}(EC)$, as δ^{13} C varies with fuel types and combustion conditions. For example, the range of possible δ^{13} C values for vehicle emission overlaps to a small extent with the range for coal combustion, although EC from vehicle emissions are usually more depleted than from coal combustion. Uncertainties of source signatures of δ^{13} C (i.e., $\delta^{13}C_{bb}$, $\delta^{13}C_{vehicle}$, $\delta^{13}C_{coal}$), the calculated $f_{fossil}(EC)$ derived from F¹⁴C_{EC}, and the measured $\delta^{13}C_{EC}$ are propagated by the MCMC technique, where source signatures of δ^{13} C introduces a larger uncertainty than $f_{fossil}(EC)$ constrained by F¹⁴C.

MCMC was implemented in the freely available R software (https://cran.r-project.org/), using the *simmr* package (https://CRAN.R-project.org/package=simmr). Convergence diagnostics were created to make sure the model has converged properly. The simulation for each sample was run with 10,000 iterations, using a burn-in of 1000 steps, and a data thinning of 100. The results of the MCMC are the posterior probability density functions (PDF) for the relative contributions from the sources (Fig. S3).

S3. Gas-particle partitioning of OC fractions

Ambient OC has a large range of volatility and contains low to high volatility compounds. The low-volatility OC is in the particle phase, and high volatility OC is mostly in the gas phase. OC with intermediate volatility are semi-volatile (SVOC) and can either be in the particle or the gas phase depending on temperature, concentrations of OC etc. (Donahue et al., 2006, 2009).

In this study, particulate OC is collected on a single bare-quartz filter. mvOC (desorbed at 200 °C in He) on the quartz filters is influenced by evaporation of SVOC from collected particles and adsorption of organic vapors to the quartz fibers. To estimate the particulate fraction of mvOC, we estimate the gas-particle partitioning of individual OC fractions using the thermal/optical OC/EC analysis and a volatility basis set (VBS) model. The VBS bins the organic aerosol (OA) compounds according to the effective saturation concentrations (C^*). If we project concentrations of organic aerosol (OA) onto the basis set of saturation concentrations, we can estimate the volatility distribution of the organic material. The concentrations of OA (C_{OA}) and the equilibrium partitioning fractions (f_i) at equilibrium can be described by (Donahue et al., 2006, 2011):

$$f_i = \left(1 + \frac{c_i^*}{c_{\text{OA}}}\right)^{-1} \tag{S4}$$

where C_i^* is the *C** for OC fraction *i*. If C_i^* is equal to C_{OA} , then 50 % of OA mass will be in the particle phase, that is $f_i = 0.5$; if $C_i^* = 4 \times C_{OA}$, then the OA is more volatile, and only 20 % OA mass in the particle phase ($f_i = 0.2$).

Thermal-optical OC/EC analysis measures OC, not the OA. We use the OA/OC mass ratio to estimate OA concentrations from the OC concentrations. Then Eq. S4 can be reformulated as:

$$X_{\rm Pi} = \left(1 + \frac{C_i^*}{\frac{OA}{OC} \times C_{\rm OC}}\right)^{-1}$$
(S5)

where X_{Pi} is the particulate fraction in OC fraction *i*; C_{OC} can be quantified by the thermal-optical OC/EC analysis, and is the sum of particulate OC fractions;

The C^* value for each OC fraction are taken from Ma et al. (2016), where OC fractions are measured using the IMPROVE_A protocol, and are derived so that X_{Pi} stands for the particulate fraction of the total carbon found on the filter for each temperature step *i*. The IMPROVE_A temperature plateaus in the pure He phase are 140 °C, 280 °C, 480 °C, 580 °C, and the corresponding thermal carbon fractions are called OC_{140°C}, OC_{280°C}, OC_{480°C} and OC_{580°C}, where the subscript refers to the desorption temperature of the IMPROVE_A protocol, respectively. The empirical VBS consisting of bins separated by 0.5 of an order of magnitude in volatility at 300 K: the C^* for OC_{140°C} to OC_{580°C} are 10^{1.6}, 10^{1.1}, 10^{0.6} and 10^{0.1} µg m⁻³, respectively. The OA/OC is assumed to be 1.8 for urban environment (Turpin and Lim, 2001; Xing et al., 2013). In this study, samples in Beijing, Guangzhou, Shanghai, Taiyuan and Chongqing are measured using the IMPROVE_A protocol, thus X_{pi} for samples of these five cities are estimated using the empirical C^* , as shown in Fig. 8a in the main text.

The particulate fraction (X_{pi}) of OC fractions increases considerably from OC_{140°C} to OC_{580°C}, consistent with the temperature steps. The temperature of the OC/EC analysis is the desorption temperature rather than evaporation, but it is still reasonable to assume that the desorption temperature is closely related to the volatility. OC desorbed at higher temperature tends to have a low volatility and more likely to exist in the particle phase.

Increasing the particulate OC concentrations (C_{OC} in Eq. S5) increase the particulate fraction for each OC fraction ($X_{\text{p1}}, X_{\text{p2}}, X_{\text{p3}}$ and X_{p4}). For example, when C_{OC} increases from 8.8 µg m⁻³ to 64 µg m⁻³, particulate fraction of OC_{140°C} increases from 0.28 (i.e., 28 % OC_{140°C} in the particle phase) to 0.74 and particulate fraction of OC_{280°C} increases from 0.56 to 0.90. The desorption temperature for mvOC is 200 °C, falling within the 140 °C for OC_{140°C} and 280 °C for OC_{280°C}. We thus estimated the particulate fraction for mvOC will fall within the X_{p1} for OC_{140°C} and X_{p2} for OC_{28°C}.

Figure S1. Geographic locations of the six Chinese sampling sites. Cities in northern China are shown as blue circle, cities in southern China as blue triangle. In northern China, large quantities of coal are used for heating during a formal residential "heating season" (15 November to 15 March next year) in winter.

Figure S2. Selected samples for ¹⁴C analysis. 2-3 composite samples that represent high (H), medium (M) and low (L) TC concentrations are combined from several individual filter samples for each city (a. Xi'an; b. Beijing; c. Taiyuan; d. Shanghai; e. Chongqing; f. Guangzhou). Each sample is consisting of 2 to 3 24-hr filter pieces with similar TC loadings and air mass backward trajectories (Table S1).

Figure S3. Probability density function (PDF) of the relative source contributions of coal and vehicle to EC (f_{coal} , f_{vehicle}) constrained by δ^{13} C, calculated using the Bayesian Markov chain Monte Carlo approach (Supplement S2). Samples collected from other cities including Xi'an, Taiyuan, Chongqing were not measured for δ^{13} C_{EC}.

Figure S4. The PDF of *p* values (*p* is the fraction of EC from coal combustion in that from total fossil sources) for each sample, which is constrained by $\delta^{13}C_{EC}$. Calculation of *p* is present in Sect. 2.4. Other cities including Xi'an, Taiyuan, Chongqing were not measured for $\delta^{13}C$.

Figure S5. Reproducibility of desorption performed for test filter#1, test filter#2 and winter-H. The number on the *x*-axis represent the times of mvOC desorption. (a) the desorbed mvOC amount in μ gC per extraction; (b) the desorbed mvOC in μ g cm⁻² calculated by dividing the desorbed mvOC amount (μ gC) by the filter area (cm⁻²). The horizontal black line indicates the OC1 (μ g cm⁻²) measured by EUSAAR_2 protocol and the shaded area denotes its uncertainties. The two red squares represent the repeated mvOC extraction for sample winter-H using larger filter pieces. The panel (a) and (b) has the same *x*-axis.

Figure S6. An example PDF of SOC concentrations (in light blue), SOC_{fossil} (light green) and $OC_{o.nf}$ (approximately SOC_{nf}, orange) for sample Beijing-H. The estimated SOC and SOC_{fossil} concentrations are estimated by ¹⁴C-apportioned OC and EC in combination with *p* values randomly chosen from 0–1 (Sect. 2.4). The mean and median are indicated by the dashed and solid vertical lines. The mean and median are very close to each other due to the symmetric PDF. The median (interquartile range) and mean (± SD) values are given in Table S7 and Table S8, respectively.

Figure S7. (a) Concentrations of $mvOC_{nf}$ (green bar) and $OC_{o,nf}$ (approximately SOC_{nf} , orange bar); **(b)** Concentrations of $mvOC_{fossil}$ (dark green bar), and SOC_{fossil} . SOC_{fossil} is estimated based on ¹⁴C-apportioned OC and EC, combined with primary OC/EC ratios of coal combustion and vehicle exhaust, and *p* values. SOC_{fossil} estimated using using *p* values of 0–1 are shown in dark orange. For Chongqing, lower *p* values of 0–0.5 are used to estimate SOC_{fossil} , shown as bars filled with stripes. The panel (a) and (b) has the same *x*-axis.

Figure S8. Correlation between $mvOC_{nf}$ and SOC_{nf} . SOC_{nf} is estimated by subtracting primary OC from biomass burning (POC_{bb}) from OC_{nf} , where POC_{bb} is estimated by multiplying EC_{bb} with the OC/EC ratio of fresh biomass burning plumes(r_{bb}). Here we take r_{bb} = 5 (3–7; mean; minimum-maximum) and r_{bb} = 3 (2–4), higher and lower than our best estimate of r_{bb} (4, 3–5), respectively.

^a p is the contribution of coal combustion to fossil EC (Eq. 12), p was randomly chosen from 0–1, that is no constrains on p values. ^b Samples taken from Beijing, Shanghai and Guangzhou were measured for both F¹⁴C_(EC) and $\delta^{13}C_{EC}$, and p in these three cities is further constrained by $\delta^{13}C_{EC}$ (Supplement S2). ^c For Chongqing, we did a sensitive analysis for p and tried a smaller p of 0–0.5.

City	Sample Name	SOC concentrations		SOC _{fossil}		OC _{o,nf} (approximately SOC _{nf})
	Sumple Rume	<i>p</i> (0–1) ^a	<i>p</i> (0–0.5) ^b	<i>p</i> (0–1)	<i>p</i> (0–0.5)
