18  
19 **Abstract.** The impact of a major sudden stratospheric warming (SSW) in the Arctic in  
20 February 2018 on the mid-latitude mesosphere is investigated by performing the microwave  
21 radiometer measurements of carbon monoxide (CO) and zonal wind above Kharkiv, Ukraine  
22 (50.0°N, 36.3°E). The mesospheric peculiarities of this SSW event were observed using a  
23 recently designed and installed microwave radiometer in East Europe for the first time. Data  
24 from the ERA-Interim and MERRA-2 reanalyses, as well as the Aura Microwave Limb  
25 Sounder measurements, are also used. Microwave observations of the daily CO profiles in  
26 January–March 2018 allowed the retrieval of mesospheric zonal wind at 70–85 km (below the  
27 winter mesopause) over the Kharkiv site. Reversal of the mesospheric westerly from about 10  
28 m s<sup>-1</sup> to an easterly wind of about -10 m s<sup>-1</sup> around 10 February was observed. The local  
29 microwave observations at our NH midlatitude site combined with reanalysis data show wide  
30 ranging daily variability in CO, zonal wind and temperature in the mesosphere and stratosphere  
31 during the SSW of 2018. The observed local CO variability can be explained mainly by  
32 horizontal air mass redistribution due to planetary wave activity. Replacement of the CO-rich  
33 polar vortex air by CO-poor air of the surrounding area led to a significant mesospheric CO  
34 decrease over the station during the SSW and fragmentation of the vortex over the station at the  
35 SSW start caused enhanced stratospheric CO at about 30 km. The results of microwave

36 measurements of CO and zonal wind in the midlatitude mesosphere at 70–85 km altitudes,  
37 which still is not adequately covered by ground-based observations, are useful for improving  
38 our understanding of the SSW impacts in this region.

39

40

## 41 **1 Introduction**

42

43 Major sudden stratospheric warming (SSW) events which happen roughly [every other year](#) in  
44 the North Polar region are produced by strong planetary wave activity according to the model  
45 developed by Matsuno (1971) which is supported by numerous observations (Alexander and  
46 Shepherd, 2010; Kuttippurath and Nikulin, 2012; Tao et al., 2015). A major SSW event is  
47 accompanied by a sharp increase of the stratosphere temperature up to 50 K and the reversal of  
48 the zonal wind from climatological westerlies to easterlies over a period of several days  
49 (Charlton and Polvani, 2007; Chandran and Collins, 2014; Hu et al., 2014; Tripathi et al., 2016;  
50 Butler et al., 2017; Karpechko et al., 2018; Taguchi, 2018; Rao et al., 2018). The primary  
51 definition of a SSW event provided by the World Meteorological Organization requires a  
52 stratosphere temperature increase and an accompanying zonal wind reversal to easterlies at the  
53 10-hPa pressure level (approximately 30 km altitude) and 60° latitude (WMO, 1978). This  
54 definition was broadened and detailed in recent papers (Butler et al., 2015; Butler and Gerber,  
55 2018; Rao et al., 2019). The summarizing paper, where a SSW database is described, was  
56 published in Butler et al. (2017). This useful tool  
57 (<https://www.esrl.noaa.gov/csd/groups/csd8/sswcompendium/>) allows analysis of the  
58 conditions in the stratosphere, troposphere, and at the surface before, during and after each  
59 SSW event representing its evolution, structure, and impact on winter surface climate. The  
60 compendium is based on data from six different reanalysis products, covers the 1958–2014  
61 period and includes global daily anomaly fields, full fields, and derived products for each SSW  
62 event (Butler et al., 2017).

63 The source of the SSW is planetary wave activity born in the troposphere that propagates  
64 upward through the tropopause to the stratosphere (Matsuno, 1971; Alexander and Shepherd,  
65 2010, Butler et al., 2015). The enhanced wave activity results in the rapid warming of the polar  
66 stratosphere and the breakdown of the stratospheric polar vortex (Matsuno, 1971; de la Torre et  
67 al., 2012; Chandran and Collins, 2014; Pedatella et al., 2018). The important feature of a SSW  
68 event is its impact on lower altitudes, when temperature and wind anomalies descend  
69 downward into the high- and mid-latitude troposphere during the following weeks to month  
70 and influence the surface weather (Baldwin and Dunkerton, 2001; Zhou et al., 2002; Butler et

71 al., 2015; Yu et al., 2018). The major SSW events may also impact the atmospheric  
72 composition of the whole Northern Hemisphere (NH) stratosphere including mid-latitudes  
73 (Solomon et al., 1985; Allen et al., 1999; Tao et al., 2015).

74 During the SSW, vertical coupling covers not only the troposphere but extends upward to  
75 the mesosphere. Mesospheric responses to the SSW are observed as enhancement in planetary  
76 wave amplitude, zonal wind reversal and significant air cooling (Shepherd et al., 2014; Zülicke  
77 and Becker, 2013; Stray et al., 2015; Zülicke et al., 2018), substantial depletion of the metal  
78 layers (Feng et al., 2017; Gardner, 2018), mesosphere-to-stratosphere descent of trace species  
79 (Manney et al., 2009; Salmi et al., 2011). The SSW events are also accompanied by the rapid  
80 descent of the stratopause into the stratosphere at the SSW onset, **followed by** formation of the  
81 elevated stratopause in the lower mesosphere and gradual stratopause lowering toward its  
82 typical position in the SSW recovery phase (Manney et al., 2009; Chandran et al., 2011; Salmi  
83 et al., 2011; Tomikawa et al., 2012; Limpasuvan et al., 2016; Orsolini et al., 2010, 2017). The  
84 elevated stratopause events provide an evidence of the coupling between the stratosphere and  
85 the mesosphere.

86 Among the trace gases, the CO molecule is a good tracer of winter polar vortex dynamics in  
87 the upper stratosphere and mesosphere due to its long photochemical lifetime (Solomon et al.,  
88 1985; Allen et al., 1999; Rinsland et al., 1999, Shepherd et al. 2014). The CO mixing ratio  
89 generally increases with height in the upper stratosphere and mesosphere and increases with  
90 latitude toward the winter pole. This is due to the mean meridional circulation which transports  
91 CO from the source region in the summer hemisphere and tropics to the extratropical winter  
92 mesosphere and stratosphere (Shepherd et al., 2014). Therefore, large abundances of CO appear  
93 in the winter polar regions under conditions of large-scale planetary wave activity. Downward  
94 meridional transport causes descent of CO between the mesosphere and stratosphere and this  
95 process is sensitive to planetary wave amplitudes, and particularly the wave amplitude changes  
96 that occur during SSWs (Rinsland et al., 1999; Manney et al., 2009; Kvissel et al., 2012). Due  
97 to the large scale descent, high CO values of mesospheric origin are observed at stratospheric  
98 altitudes down to 25–30 km (Engel et al., 2006; Huret et al., 2006; Funke et al., 2009). At NH  
99 mid-latitudes, CO also exhibits significant variability during periods of planetary wave activity  
100 associated with SSWs, when the polar vortex splits and displaces off the pole (Solomon et al.,  
101 1985; Allen et al., 1999; Funke et al., 2009).

102 Recent atmospheric models are being extended up to 80–150 km and are used for the study  
103 of SSWs (de la Torre et al., 2012; Chandran and Collins, 2014; Shepherd et al., 2014;  
104 Limpasuvan et al., 2016; Newnham et al., 2016). For example, de la Torre et al. (2012) applied  
105 the Whole Atmosphere Community Climate Model (WACCM) and Shepherd et al. (2014) used

106 the Canadian Middle Atmosphere Model (CMAM) for SSW modeling. The reference wind  
107 profiles for the models are mainly retrieved from observations of the radiation of the  
108 mesospheric ozone molecules, which allow robust measurements at altitudes up to of  
109 approximately 65 km (e.g., Hagen et al., 2018). These data are generally consistent with the  
110 most commonly used reanalysis products. However, there are still insufficient observations of  
111 middle atmospheric winds at altitudes between 60 and 85 km made with a high vertical  
112 resolution to verify atmospheric models and possible long-term trends (Keuer et al., 2007;  
113 Hagen et al., 2018; Rüfenacht et al., 2018). This altitude range, where temperature generally  
114 decreases with height, which causes inherent vertical instability, is situated below the winter  
115 mesopause region at 95–100 km (e.g. Xu et al., 2009) and plays a significant role in the mass  
116 and energy exchange between the stratosphere and the mesosphere (Shepherd et al., 2014;  
117 Limpasuvan et al., 2016; Gardner, 2018).

118 Microwave radiometry is a ground-based technique that can provide vertical profiles of CO,  
119  $H_2O$  and  $O_3$  atmospheric gases and wind data in the upper stratosphere and mesosphere  
120 (Rüfenacht et al., 2012; Scheiben et al., 2012; Forkman et al., 2016). The upper stratosphere–  
121 mesosphere zonal winds at the 30–85 km altitude region can be measured using the Doppler  
122 shift between different observation directions in simultaneously measured spectra of transitions  
123 lines of carbon monoxide at 115.3 GHz and ozone  $O_3$  at 110.8 GHz (Rüfenacht et al., 2012;  
124 Forkman et al., 2016). Due to high altitude CO residence region, the simultaneous zonal wind  
125 measurements using both  $O_3$  and CO provide independent data that extend the wind  
126 measurement from the stratospheric to mesospheric altitudes, respectively (Forkman et al.,  
127 2016; Piddyachiy et al., 2017).

128 The first ground-based microwave measurements of CO were made in the 1970s and they  
129 confirmed theoretical estimations of the vertical CO profile (Waters et al., 1976; Goldsmith et  
130 al., 1979). Since the 1990s, the ground-based microwave radiometers measuring CO have been  
131 installed in the Northern Hemisphere at high and middle latitudes to provide measurements on  
132 a regular basis. Microwave radiometers are operating in Onsala and Kiruna, Sweden, since  
133 2008. The results are described in Hoffmann et al. (2011) and in Forkman et al. (2012). The  
134 microwave radiometer operated in Bern, Switzerland since 2010 aims to contribute to the  
135 significant gap that exists in the middle atmosphere between 40 and 70 km altitude for wind  
136 data (Rüfenacht et al., 2012). In the Arctic, the  $O_3$ ,  $N_2O$ ,  $HNO_3$ , and CO spectra were recorded  
137 using the Ground-Based Millimetre-wave Spectrometer GBMS (Muscati et al., 2007; Di Biagio  
138 et al., 2010).

139 Since 2014, the microwave measuring system for CO observations has been operated in  
140 Kharkiv, Ukraine (Piddyachiy et al., 2010; Piddyachiy et al., 2017). Microwave radiometer

141 measurements of CO are used to retrieve mesospheric winds nearby the mesopause region (70–  
142 85 km). Methods deriving the wind speed from mesospheric CO measurements are based on  
143 the determination of the CO and O<sub>3</sub> lines emission Doppler shift (Eriksson et al., 2011; Hagen  
144 et al., 2018).

145 Our observations in February 2018 using the new microwave radiometer at the mid-latitude  
146 Kharkiv station have recorded the mesospheric effects of a major SSW. In mid-February 2018,  
147 the stratospheric polar vortex in the Arctic splitted into two sister vortices (Fig. 1), the zonal  
148 wind reversed in the stratosphere–mesosphere from westerly to easterly and warm air  
149 penetrated into the polar cap regions (Rao et al., 2018; Karpechko et al., 2018; Vargin and  
150 Kiryushov, 2019). This caused large-scale disturbances in the middle atmosphere of the polar  
151 and middle latitudes. The major SSW in 2018 is not yet widely discussed in publications (Rao  
152 et al., 2018; Karpechko et al., 2018; Vargin and Kiryushov, 2019) and in this paper, we give a  
153 detailed description of the observed mesospheric CO and zonal wind variations.

154 In Sect. 2, the microwave radiometer and data processing software are briefly described.  
155 The SSW event in February 2018 is considered in Sect. 3. The effects of the SSW on mid-  
156 latitude mesosphere–stratosphere conditions in the Ukraine longitudinal sector are presented in  
157 Sect. 4. Discussion is given in Sect. 5 followed by conclusions in Sect. 6.

158

159

## 160 **2 Data and methods**

161

162 The microwave radiometer data set registered during the 2017/2018 winter campaign in  
163 Kharkiv (50.0°N, 36.3°E) is used in this study to investigate local effects of the winter 2018  
164 sudden stratospheric warming on the mesosphere and stratosphere. Since the ground-based  
165 microwave measurements are spatially limited by instrument coverage, data on air temperature,  
166 zonal wind [and](#) geopotential height were used from reanalyses and satellite databases to  
167 interpret the CO profile and the zonal wind microwave observations and to describe the SSW  
168 effects in the atmosphere of the surrounding mid-latitude region (30–40°E, 48–52°N).

169

170

### 171 **2.1 Microwave radiometer, method, and midlatitude data description**

172

173 The microwave radiometer (MWR) with high sensitivity, installed at Kharkiv, Ukraine, is  
174 designed for continuous observations of the atmospheric CO profiles and zonal wind speed in  
175 the mesosphere using emission lines at 115.3 GHz. The radiometer can continuously provide

176 vertical profiles up to the mesopause region during day and night, even in cloudy conditions  
177 (Hagen et al., 2018). However, precipitation, such as strong rain or snow, can prevent the  
178 measurements.

179 The receiver of the radiometer has the double-sideband noise temperature of 250 K at an  
180 ambient temperature of 10°C (Piddyachiy et al., 2010; 2017). The radiometer was tested during  
181 the 2014–2015 period for observation of the CO emission lines in the mesosphere over Kharkiv.  
182 These tests proved the reliability of the receiver system, on which further details are provided  
183 in Piddyachiy et al. (2017). Since 2015, the radiometer has been used for continuous  
184 microwave measurements of CO profiles and mesosphere wind investigations. The first  
185 observations of the atmospheric CO spectral lines over Kharkiv have confirmed seasonal  
186 variations in the CO abundance (Piddyachiy et al., 2017). Operation of the MWR in a double-  
187 sideband mode allows retrieval of wind speed from the Doppler shift of the CO line emission at  
188 the 115.3 GHz. Two methods are used to determine wind speed. Firstly the observed line shape  
189 is fitted by a Voigt profile and the center frequency is determined (Piddyachiy et al., 2017).  
190 Secondly radiative transfer calculations for a horizontally layered atmosphere are used to  
191 determine the wind profiles with the Qpack package, version 1.0.93 (Eriksson et al., 2005;  
192 Eriksson et. al., 2011), which is specifically designed to work with the forward model of the  
193 Atmospheric Radiative Transfer Simulator ARTS (Buehler et al., 2018;  
194 <http://www.radiativetransfer.org/>). The results obtained by both methods were almost the same  
195 within the error limits. In this paper, both methods were used and provided average values of  
196 the zonal wind speed for altitudes of 70–85 km. The time interval of the data used here was  
197 January 1 – March 31, 2018, which covers the main phases of the SSW 2018 event.

198

199

## 200 **2.2 Data from other sources**

201

202 In this study, daily datasets from ERA-Interim global atmospheric reanalysis of European  
203 Centre for Medium-Range Weather Forecast (ECMWF; Dee et al., 2011) were downloaded  
204 from (<https://www.ecmwf.int/en/forecasts/datasets/archive-datasets/reanalysis-datasets/era-interim>) and have been used for comparison with MWR observations. The ERA-Interim data  
205 were used to create temperature and zonal wind velocity profiles and to calculate geopotential  
206 height at the stratospheric pressure levels, in order to compare with the data measured over the  
207 Kharkiv site. Aura Microwave Limb Sounder (MLS) measurements of the air temperature were  
208 analyzed as well (Xu et al., 2009; <https://mls.jpl.nasa.gov/data/readers.php>; see details in the  
209 Supplement).

211 Zonal wave amplitudes in geopotential height were analyzed using the National Oceanic and  
212 Atmospheric Administration National Centers for Environmental Prediction, Global Data  
213 Assimilation System–Climate Prediction Center (NOAA NCEP GDAS–CPC) data at  
214 <https://www.cpc.ncep.noaa.gov/products/stratosphere/strat-trop/> and the MERRA-2 data from  
215 the National Aeronautics and Space Administration Goddard Space Flight Center, Atmospheric  
216 Chemistry and Dynamics Laboratory (NASA GFC ACDL) site at [https://acd-ext.gsfc.nasa.gov/Data\\_services/met/ann\\_data.html](https://acd-ext.gsfc.nasa.gov/Data_services/met/ann_data.html). The detailed description of the data used  
217 for analysis is given in the Supplement.

219

220

### 221 **3 Northern Hemisphere SSW effects**

222

223 Descending air masses are observed throughout the mesosphere and stratosphere of the winter  
224 polar region (Orsolini et al., 2010; Chandran and Collins, 2014; Limpasuvan et al., 2016;  
225 Zülicke et al., 2018). From Aura MLS vertical profiles, a layered descending sequence of  
226 alternating cool and warm anomalies over the polar cap was observed in the 2017/2018 winter  
227 (Fig. 2a). The SSW event in Fig. 2a is identified by the rapid warming in the stratosphere and  
228 cooling in the mesosphere (upward arrow) starting from 10 February 2018 (left vertical line).

229

230 This event was preceded by progressively descending warm and cold anomalies that formed  
231 in January (black and white dashed arrows, respectively). Oscillations in the intensity of the  
232 anomalies indicate that they were formed under the influence of large amplitude planetary  
233 waves of zonal wave numbers 1 and 2 (Fig. 2c–2e). From 1 January to 10 February (during 41  
234 days), descending warm anomalies with a velocity  $-850 \text{ m}\cdot\text{day}^{-1}$  were apparent in the  
235 mesosphere and the upper stratosphere (75 to 40 km; black dashed arrow in Fig. 2a). Below the  
236 warm anomaly, a cold anomaly descended between the upper and lower stratosphere (45 to 20  
237 km) with velocity  $-600 \text{ m}\cdot\text{day}^{-1}$  (white dashed arrow in Fig. 2a), while a cold mesospheric  
238 anomaly in February–March descended with average velocity  $-750 \text{ m}\cdot\text{day}^{-1}$  (white dotted  
239 arrow in Fig. 2a). Our velocity estimates are similar to those of Salmi et al. (2011) who found  
240 that mesospheric  $\text{NO}_x$  anomalies during the major SSW 2009 were transported from 80 to 55  
km in about 40 days, i.e. with velocity  $-600 \text{ m}\cdot\text{day}^{-1}$ .

241

242 The splitting of the polar vortex (Fig. 1) and the zonal wind reversal (Fig. 2b) started at the  
243 time of the wave 2 pulse on 10 February (Fig. 2d and dashed curve in Fig. 2e). Note that this is  
244 close to the SSW timing in Rao et al. (2018) and Vargin and Kiryushov (2019), where the SSW  
245 onset date was 11 February. As seen from Fig. 2c and solid curve in Fig. 2e, increasing wave 1  
amplitude contributed to the destabilization of the polar vortex during January–early February

246 and to temperature and zonal wind oscillations in the mesosphere and stratosphere (Fig. 2a and  
247 2b). These oscillations are usually associated with the propagation of planetary waves in the  
248 stratosphere and mesosphere (Limpasuvan et al., 2016; Rüfenacht et al., 2016). As noted in an  
249 earlier study (Manney et al., 2009; Rao et al., 2018), wave 1 amplitudes were also larger prior  
250 to the SSW in 2009, suggesting a role of preconditioning. During 10–15 February, the easterly  
251 zonal wind anomaly at the stratopause (about 1 hPa, ~50 km) increased to  $-60 \text{ m s}^{-1}$  (Fig. 2b).  
252 At the same time, warming in the polar stratosphere with the largest temperature anomaly of  
253 about 20 K was observed between 25 and 45 km in the same time interval (upward arrow in  
254 Fig. 2a). Both anomaly peaks are close in time to the wave 1 pulse after the SSW start (Fig. 2c  
255 and 2e). The descending negative temperature anomaly in the mesosphere between 50 and 90  
256 km persisted during and after the SSW and reached  $-15 \text{ K}$  (dotted arrow in Fig. 2a).

257

258

## 259 **4 The local SSW effects over the midlatitude station**

260

### 261 **4.1 CO variability**

262

263 Local variability in the conditions of the atmosphere during the microwave measurements in  
264 January–March 2018 at Kharkiv ( $50.0^\circ\text{N}$ ,  $36.3^\circ\text{E}$ ) is shown in Figs. 3–6. The sharp changes  
265 occurred in the 20-day interval from 10 February to 1 March coinciding with the SSW event  
266 2018, as indicated by red vertical lines in Figs. 3, 5 and 6. At this time the polar vortex divided  
267 into two parts producing two smaller vortices over the longitudinal sectors of North America  
268 and Eurasia (Fig. 1). Due to the planetary wave influence (Fig. 2c–2e), the two sub-vortices  
269 shifted zonally and meridionally, so that the SSW effects were observed not only in the polar  
270 region but also in the middle latitudes (Fig. 4).

271 The CO molecule volume mixing ratio (VMR) near the mesopause at 75–80 km decreased  
272 from 10 ppmv of background level to 4 ppmv on 19–21 February (Fig. 3a), when the sharp  
273 vertical CO gradient at the lower edge of the CO layer near about 6 ppmv increased in height  
274 by about 8 km (between 75 km and 83 km, thick part of the white curve in Fig. 3a). For  
275 comparison, the pre- and post-SSW vertical variations of the 6-ppmv contour were observed in  
276 a range 2–3 km (white curve in Fig. 3a). Moreover, similar variations in the zonal mean 6-  
277 ppmv level are much weaker (yellow curve in Fig. 3e). This indicates that local and regional  
278 mesosphere over the MWR site was disturbed by some source acted during the SSW, which is  
279 identified below. We take here the 6-ppmv contour as a conditional lower edge of the CO layer  
280 since the CO gradients sharply increase from  $0.2\text{--}0.3 \text{ ppmv km}^{-1}$  in a 10-km layer below to

281 0.6–0.8 ppmv  $\text{km}^{-1}$  in a 10-km layer above (below and above the white curve in Fig. 3a). The  
282 similar gradient change is a characteristic of the mesospheric CO profiles in boreal winter from  
283 ground-based and satellite observations (Fig. 4 in Koo et al., 2017; Fig. 5 in Ryan et al., 2017).

284 The local mesospheric CO variability from the MWR observations over Kharkiv agrees  
285 with regional one from the MLS data averaged over the adjacent area 47.5–52.5°N, 26–46°E  
286 (Fig. 3b, the white curve for 6 ppmv). However, the zonal mean CO profiles in the same zone  
287 do not show an anomalous decrease of the mesospheric CO during the SSW (yellow curve in  
288 Fig. 3a, 3b and 3e).

289 Unlike the mesosphere, the CO descent and an increase in CO abundance is observed in  
290 the stratosphere from both regional and zonal mean MLS data shortly after the SSW start  
291 (contour 0.1 ppmv in Fig. 3d and 3g, respectively). The CO-rich air of 0.1–0.5 ppmv, which is  
292 typical for the lower mesosphere (Fig. 3c) descended down to about 30 km (Fig. 3d and 3g), far  
293 exceeding typical stratospheric CO mixing ratios on the order of about 0.01–0.02 ppmv (Engel  
294 et al., 2006; Huret et al., 2006; Funke et al. 2009). The CO-rich stratospheric anomaly is close  
295 in time to the wave 1 peak on 10–15 February (solid curve in Fig. 2e), that was observed  
296 through the stratosphere down to the 30 km altitude (Fig. 2c).

297 Horizontal distributions of the CO VMR in the Northern Hemisphere at the stratospheric  
298 and mesospheric altitudes in Fig. 4 suggest causes of the different CO variability in the  
299 stratosphere and mesosphere in Fig. 3. The dynamical deformation, elongation, and  
300 displacements of the polar vortex relative to the pole lead to temporal shifts between the low  
301 and high CO amounts over the MWR site at Kharkiv (white circle in Fig. 4). The tendency of  
302 the planetary wave westward tilt with altitude (dashed lines in Fig. 4, see also Supplemental  
303 Figs. S1 and S2 for more details) also contributes to relative zonal shift between the  
304 stratosphere and the mesosphere of the low/high CO over Kharkiv.

305 The observed decrease of the local CO in the mesosphere during the SSW (white curve in  
306 Fig. 3a) is consistent with the regional data from the satellite observations (white curve in Fig.  
307 3b). The decrease is due to the displacement of the CO-rich air to the west relative to Kharkiv  
308 (white circle and contours outlined the CO-rich area in Fig. 4a–4c and 4e–4g). This is a result  
309 of the dominance of easterlies during the SSW that led to placing of the CO-poor air over  
310 Kharkiv with the lowest CO levels on 19–23 February (Fig. 4c and 4g) in correspondence with  
311 the MWR (Fig. 3a) and MLS (Fig. 3b) measurements. Recovery to the westerly regime in early  
312 March reversed the rotation of the vortex (2–6 March in Fig. 4d and 4h) and caused recovery of  
313 high CO level over Kharkiv (since about 1st of March in Fig. 3a and 3b).

314 The polar vortex split influenced the local CO change in the middle stratosphere (Fig. 4m–  
315 4o). The low CO level at ~30 km before the SSW start (Fig. 3d) is associated with the relatively

316 distant location of the CO-rich vortex from Kharkiv (Fig. 4m). The vortex split and easterly  
317 circulation caused displacement of the small vortex fragment with the CO level higher than 0.1  
318 ppmv to Kharkiv just at the SSW start (9–13 February in Fig. 4n) and corresponding sharp CO  
319 increase over the Kharkiv region around 30-km altitude (contour 0.1 ppmv in a few days after  
320 10 February in Fig. 3d). Vertical CO profiles in Fig. 3c and 3d show that downward penetration  
321 of the mesospheric CO-rich air into the stratosphere took place around 10 February. As seen  
322 from Fig. 4f, 4j, and 4n, the mesospheric CO-rich air appears to be contained inside the small  
323 sub-vortex over Kharkiv. The large sub-vortex (Fig. 4n and 4o) contributed to the stratospheric  
324 CO increase after 10 February in the zonal mean CO profile near 30 km (Fig. 3g). The two sub-  
325 vortices in Fig. 4n and 4o provided a longer duration of the mesospheric intrusion in the zonal  
326 mean (Fig. 3g) than a short-time influence of the single sub-vortex in regional data (Fig. 3d).

327 It should be noted that the lower edge of the mid-latitude CO-rich air descended in January  
328 – mid-February (dashed lines in Fig. 3d and 3g) similarly to the temperature anomaly in the  
329 polar region (Fig. 2a). Descent velocity was about  $-270$  and  $-220$   $\text{m}\cdot\text{day}^{-1}$  in the case of the  
330 regional and zonal mean data, respectively. This is a few times lower than in the vortex region,  
331 nevertheless, it is in the range of the winter descent velocity noted above (Ryan et al., 2018).

332 Note also that the vortex split in the CO distribution can be identified only in the middle  
333 and upper stratosphere (Fig. 4n and 4o and Fig. S1j and S1k), but not at the stratopause level  
334 (Fig. 4j and 4k) and in the mesosphere (Fig. S2, second and third columns for 9–13 and 19–23  
335 February 2018, respectively).

## 338 **4.2 Zonal wind variability**

339  
340 The reversal of the local zonal wind estimated from the CO measurements at the Kharkiv  
341 MWR site near the mesopause region was observed. The averaged wind velocity in the altitude  
342 range 70–85 km changed between  $10\text{ m s}^{-1}$  and  $-10\text{ m s}^{-1}$  around 10 February (Fig. 5a). After  
343 the active phase of the SSW, the zonal wind [recovers](#) to the westerly wind and enhances to  $20$   
344  $\text{m s}^{-1}$  reaching the highest velocity observed in January–March (Fig. 5a). This zonal wind peak  
345 in early March is accompanied by the CO peak at 18 ppmv around 85 km that is also the  
346 highest CO abundance over January–March (Fig. 3a). This is closely consistent with the MLS  
347 measurements at the 86-km altitude: Kharkiv was located on the 16-ppmv contour in early  
348 March (2–6 March in Fig. 4d).

349 During the SSW event, local zonal wind over the station became easterly between the lower  
350 stratosphere and lower mesosphere ( $-30\text{ m s}^{-1}$  up to  $-40\text{ m s}^{-1}$ , white contours in Fig. 5b). Note

351 that westerly zonal wind at the stratopause level ( $\sim 50$  km) in January 2018 (mid-winter, the  
352 pre-SSW conditions) sometimes increased to more than  $100 \text{ m s}^{-1}$  (black contours in Fig. 5b).

353 The [recovery](#) of the local westerly wind in the upper mesosphere began in late February  
354 (Fig. 5a) and later, in early March, in the lower mesosphere–stratosphere (Fig. 5b). The longer  
355 persistence of the westerly anomaly in the stratosphere than at the stratopause level [is also](#) seen  
356 in the polar region (Fig. 2b). This is a manifestation of the downward migration of the  
357 circulation anomalies in the SSW recovery phase, [while](#) a near-instantaneous vertical coupling  
358 is observed at the SSW start on 10 February (Fig. 2a–2d and Fig. 5).

### 361 **4.3 Temperature changes**

363 The MLS temperature profiles show that high temperature variability over the Kharkiv region  
364 concentrated at the stratopause level, particularly before and during the SSW 2018 (Fig. 6). As  
365 known, the SSW events are accompanied by polar stratopause descent to 30–40 km, by  
366 stratopause breakdown and subsequent reformation at very high altitudes of about 70–80 km  
367 (Manney et al., 2009; Chandran et al., 2011; Limpasuvan et al., 2016; Orsolini et al., 2017).  
368 The midlatitude stratopause exhibits less sharp, but significant oscillations between 40 and 50  
369 km in January–first half of February 2018 (dotted curve in Fig. 6) and the highest temperature  
370 near  $-5^\circ\text{C}$  after the SSW start on 12–13 February. The short-time stratopause elevation to the  
371 lower-mesospheric altitude  $\sim 60$  km was observed near 20 February, i.e. [close](#) in time to the  
372 maximum elevation of the 6-ppmv CO level in the mesosphere (Fig. 3a and 3b). Note that the  
373 wave 1 and wave 2 (Fig. 2c–2e), and zonal wind (Fig. 5) do not demonstrate strong anomalies  
374 this time. The post-SSW stratopause stabilized at the 50-km altitude and warmed from about  
375  $-20^\circ\text{C}$  to  $-10^\circ\text{C}$  (Fig. 6b).

376 Similarly to the CO profile in Fig. 3, the zonal mean temperature variability is much lower  
377 above the stratopause than the regional one (Fig. 6b and 6a, respectively). The stratosphere [is](#)  
378 equally disturbed in both regional and zonal mean characteristics (Fig. 3d and 3g and Fig. 6a  
379 and 6b). This difference may be associated with the influence of the splitted (non-splitted) polar  
380 vortex in the stratosphere (mesosphere). The vortex fragments introduce higher local/regional  
381 and zonal mean variability in the stratosphere; whereas the vortex region is more uniform in the  
382 mesosphere (Fig. 4). That results in the weaker zonal mean variability.

383 During the SSW, the regional stratospheric temperature in Fig. 6a was warmer by  $10\text{--}15^\circ\text{C}$   
384 in comparison with the pre- and post-SSW temperature. This is about two times lower warming

385 than in the polar region (Fig. 2a) and about three times lower than it is typically observed  
386 during the SSWs (see Section 1). It should be noted that this warm stratospheric anomaly in  
387 Fig. 6a (contour  $-50^{\circ}\text{C}$ ) rapidly descended between the upper and lower stratosphere (dashed  
388 arrow) in about 10 days. A similar tendency is seen in Fig. 6b from the zonal mean (contour  $-$   
389  $55^{\circ}\text{C}$ ) but with a descent within a few days (arrow). So, the SSW start in the midlatitude  
390 stratosphere [is not accompanied by](#) a near-instantaneous vertical coupling [as](#) observed in the  
391 polar region (Fig. 2a–2d). Midlatitude stratospheric warming in February 2018 occurred with  
392 increasing time lag between the upper and lower stratosphere.

393 As is known, upward propagation of the tropospheric planetary waves into the stratosphere  
394 is limited in the easterly zonal wind (Charney and Drazin, 1961). In the changed state of a  
395 zonal flow, the critical line for planetary waves (zero wind line) in the polar region descents in  
396 a few days that looks like downward propagation of an anomaly from above (Matsuno, 1971;  
397 Zhou et al., 2002). Possibly, this process may be delayed in the midlatitude, as seen from Fig.  
398 6.

399

## 400 **5 Discussion**

401

402 The observations of the major SSW effects in February 2018 in the NH midlatitude mesosphere  
403 by microwave radiometer at the Kharkiv site, Northern Ukraine ( $50.0^{\circ}\text{N}$ ,  $36.3^{\circ}\text{E}$ ), have been  
404 provided. The CO altitude profiles in the mesosphere have been measured by the MWR with  
405 one-day time resolution. Using the CO molecule as a tracer, the wind speed has been retrieved  
406 from the Doppler shift of the CO 115.3 GHz emission and the mesospheric winds reverse from  
407 westerly to easterly below the winter mesopause region (70–85 km) has been detected. A few  
408 ground-based observations in the mesosphere by the same method have been undertaken at  
409 midlatitudes (Sect. 1). The zonal wind and CO profile variability during the major SSW were  
410 compared with the daily zonal wind, temperature [and zonal wave 1/wave 2](#) datasets from the  
411 MLS data, the ERA-Interim, and MERRA-2 reanalyses. The SSW started with the polar vortex  
412 split around 10 February (Fig. 1), zonal wind reverse in the mesosphere and stratosphere (Fig.  
413 2b and Fig. 5) and enhanced stratosphere warming and mesosphere cooling (Fig. 2a).

414

### 415 **5.1 Wave patterns and CO level**

416

417 As noted in Sect. 1, CO abundance in the extratropical mesosphere increases with latitude  
418 toward the winter pole due to meridional transport. CO accumulation results in the formation of  
419 the CO layer with the sharp vertical gradient at its lower edge (Solomon et al., 1985; Shepherd

420 et al., 2014). Because of the horizontal CO gradient at the polar vortex edge, its split and  
421 displacement during the SSW cause a significant CO variability at the NH midlatitudes  
422 (Solomon et al., 1985; Allen et al., 1999; Funke et al., 2009; Shepherd et al., 2014).

423 In Sect. 4a, based on the MWR observations, we have defined the lower CO edge at 6 ppmv  
424 and this edge uplifted during the SSW by about 8 km (between 75 km and 83 km, thick part of  
425 the white curve in Fig. 3a). This uplifting noticeably stands out against the pre- and post-SSW  
426 variations of the 6-ppmv level occurring within 2–3 km (Fig. 4a). The MLS CO measurements  
427 show similar variations in the 6-ppmv level over the Kharkiv region (white curve in Fig. 3b)  
428 and their absence in the corresponding zonal mean (yellow curve in Fig. 3a, 3b, and 3e).

429 Mesospheric CO profile uplifting is usually associated with the stratopause elevation  
430 during the SSW, when air, poor in CO, enters the mesospheric CO layer from below (Kvissel et  
431 al., 2012; Shepherd et al., 2014). Similar ascending motions in the stratopause and mesopause  
432 regions were observed in the 2013 SSW from nitric oxide (NO) and showed that the NO  
433 contours deflected upwards throughout the mesosphere (Orsolini et al., 2017). Our analysis  
434 reveals that the local CO profile variations during the SSW 2018 were closely associated with  
435 the changes in the planetary wave patterns in the mesosphere.

436 The MLS CO distribution demonstrates how deformation, elongation (wave 2 effect) and  
437 rotation of the CO-rich polar area influence the local CO level over Kharkiv (white circle with  
438 respect to the CO contours in Fig. 4a–4h and Fig. S1). The highest elevation of the 6-ppmv CO  
439 level in Fig. 3a and 3b corresponds to the lowest CO level over Kharkiv on 19–23 February,  
440 when the most distant displacement of the CO contours 16 ppmv and 6 ppmv off the Kharkiv  
441 location was observed (Fig. 4c and 4g, respectively; see also the third column in Fig. S1). As  
442 known, the strong vertical CO gradient in the winter mesosphere is found at the higher altitudes  
443 in the tropics than in the extratropics (Solomon et al., 1985; Allen et al., 1999; Garcia et al.,  
444 2014). Then, poleward displacement of the low-latitude air masses is accompanied by the CO  
445 abundance decrease and vertical CO gradient elevation at the middle latitudes, as it is observed  
446 in Fig. 3a and 3b. A similar effect related to the wave 1 influence was observed during the  
447 2003–2004 Arctic warming (Funke et al., 2009): the vortex has shifted from the pole toward  
448 the western sector and mid-latitude air poor in CO filled the eastern sector (0–90°E) over 50–  
449 80°N and even over the pole.

450 The results of Fig. 4 and Fig. S1 show that meridional displacements of the low-latitude,  
451 CO-poor mesospheric air to the Kharkiv region occurred under the planetary wave influence  
452 and caused the local CO profile variations in the SSW 2018 (Fig. 3a and 3b). These results,  
453 thus, confirm that latitudinal displacements due to wave effects may dramatically affect the  
454 local densities of the atmospheric species (Solomon et al., 1985). Figure 6a demonstrates that

455 the local stratopause elevation in February 2018 to about 60 km was relatively small in  
456 comparison with the elevation that is characteristic for the polar region, up to 70–80 km  
457 (Chandran et al., 2011; Tomikawa et al., 2012; Limpasuvan et al., 2016; Orsolini et al., 2010,  
458 2017). No significant stratopause elevation was observed in the zonal mean for 47.5–52.5°N  
459 (Fig. 6b). Therefore, the meridional (poleward) and zonal displacements of the CO-rich air  
460 masses enclosed within the polar vortex (Solomon et al., 1985; Allen et al., 1999; Funke et al.,  
461 2009) rather than stratopause elevation (Kvissel et al., 2012; Shepherd et al., 2014) may be  
462 dominant cause of the CO profile uplift observed in the NH midlatitudes during the SSW 2018.

463 In March 2018, after the SSW, vertical CO profile has been re-established (Fig. 3a and 3b)  
464 according to the recovery phase following the SSW (Shepherd et al., 2014; Limpasuvan et al.,  
465 2016). In the MWR data, the SSW recovery phase in the mesosphere in early March started  
466 with the short-term but anomalously high peaks in the local CO (Fig. 3a) and westerly wind  
467 (Fig. 5a). These peaks reached the highest values in daily variations of CO and zonal wind over  
468 the three months of the observations (January–March). By analogy with the low-CO episode in  
469 February discussed above, the high-CO peak in early March 2018 caused by change in the  
470 vortex shape [and the return](#) of the CO-rich vortex edge region to the Kharkiv location (compare  
471 2–6 March in Fig. 4d and 4h with 19–23 February in Fig. 4c and 4g; see also the same dates in  
472 Fig. S2).

473 Wind measurements using the CO layer provide a further means to evaluate the validity of  
474 the modeled winds. Furthermore, by combining the measurements with ray tracing of gravity  
475 wave propagation (e.g. Kogure et al., 2018), this type of measurement may provide specific  
476 insights into wave-mean flow interactions, particularly where local temperature inversions alter  
477 gravity wave filtering (Hocke et al., 2018; Fritts et al., 2018).

478

479

## 480 **5.2 Descent of the midlatitude stratospheric anomalies**

481

482 Alternating altitudinal sequence of warm and cool anomalies progressively descended through  
483 the mesosphere and stratosphere of the polar region was observed in January–March 2018 (Fig.  
484 2a) in consistency with many observations (Zhou et al., 2002; Orsolini et al., 2010; Shepherd et  
485 al., 2014; de Wit et al., 2014; Zülicke et al., 2018). The warm anomaly sharply intensified in  
486 the stratosphere between 20 and 50 km with simultaneous strong cooling in the mesosphere in  
487 the active phase of SSW since 10 February (vertical arrow in Fig. 2a). Unlike this, the  
488 midlatitude temperature anomalies do not show the similar vertical arrangement and regular  
489 descent with respect to the same mean climatology 2005–2017 (Fig. [S3](#)).

490 During the SSW of 2018, the upper (lower) stratosphere over the Kharkiv region was cooler  
491 (warmer) up to 20°C (10°C) than climatological mean with stepwise descent relative to the pre-  
492 SSW one (Fig. S3a). However, excluding unstable anomalies at different altitudes, the air  
493 temperature through the mesosphere and stratosphere was close to the climatology during most  
494 of the time in January–March 2018 (light blue in Fig. S3a). The zonal mean temperature  
495 anomalies in Fig. S3b show steady warming of the air in the stratosphere and lower mesosphere  
496 and distinct tendency for the anomaly to descend between about 40 km and 20 km during the  
497 SSW (20 days,  $\sim -1 \text{ km}\cdot\text{day}^{-1}$ ). It could be concluded that the temperature anomaly profile  
498 observed in the NH midlatitudes may vary in time depending on the observing location and  
499 individual SSW event and, thus, differ from climatologically warm (cold) stratospheric  
500 (mesospheric) anomaly typical for the SSWs in the NH polar region (e.g. Chandran and  
501 Collins, 2014; their Fig. 1g).

502 The CO profiles in Fig. 3 demonstrate opposite tendencies in the vertical shift of the CO-  
503 rich air in the NH midlatitudes. The CO descent in the stratosphere occurred during January–  
504 February with velocities of about 270 and 220  $\text{m}\cdot\text{day}^{-1}$  in a case of the regional and zonal mean  
505 data, respectively (Fig. 3d and 3g). In general, this is in a range of the winter descent velocities  
506 observed in the polar vortex (Funke et al., 2009; Salmi et al., 2011; Ryan et al., 2018),  
507 however, a few times lower than in the polar vortex in the winter 2017–2018 (Fig. 2a). The  
508 deepest penetration of the mesospheric CO levels (0.1–0.5 ppmv) to  $\sim 30$  km was observed  
509 immediately after the SSW onset (Fig. 3d and 3g). Although this coincides with the peaks in  
510 the wave 1 and wave 2 amplitudes (Fig. 2e), the main reason in the CO increase in the  
511 stratosphere over Kharkiv is the location of the small sub-vortex of the split polar vortex (9–13  
512 February, Fig. 4n).

513 The MLS CO maps in Fig. 4 show that the high CO amount is concentrated inside the polar  
514 vortex and its fragments after splitting. This is a result of meridional and downward transport of  
515 CO that is strongest in the winter polar vortex (Rinsland et al., 1999; Manney et al., 2009;  
516 Kvissel et al., 2012; Shepherd et al., 2014). Before (4–8 February), during (19–23 February)  
517 and after (2–6 March) the SSW, Kharkiv was outside the stratospheric vortex/sub-vortices edge  
518 (Fig. 4m, 4o and 4p, respectively) and the CO amount was at low level typical for the  
519 midlatitude stratosphere (of about 0.01–0.02 ppmv; Engel et al., 2006; Huret et al., 2006; Funke  
520 et al. 2009). Descent of the 0.1-ppmv contour marked by dashed lines in Fig. 3d and 3g is  
521 observed due to the episodic shift of the vortex edge toward the Kharkiv region or to the  
522 corresponding zone 47.5–52.5°N, respectively.

523       Figure 4 demonstrates that the CO amount inside the polar vortex or its fragments is much  
524       higher than in the surrounding area not only in the mesosphere but also in the stratosphere. This  
525       leads to the possibility of the enhanced CO appearance even in the stratosphere at about 25–30  
526       km (Engel et al., 2006; Huret et al., 2006; Funke et al., 2009). By analogy, the vortex edge shift  
527       beyond the Kharkiv region (Fig. 4c and 4g) resulted in lowering of the regional CO mixing  
528       ratios in the mesosphere [consistent with](#) both ground-based and satellite observations (Fig. 3a  
529       and 3b, respectively). Meridional structure of the mesospheric CO (Sect. 1) provided the uplift  
530       of the 6-ppmv level during the SSW relative to pre- and post-SSW levels (Fig. 3a and 3b).

531

## 532       **6 Conclusions**

533

534       The impact of a major sudden stratospheric warming in February 2018 on the mid-latitude  
535       mesosphere was investigated using microwave radiometer measurements in Kharkiv, Ukraine  
536       (50.0°N, 36.3°E). The zonal wind reversal has been revealed below the winter mesopause  
537       region at 70–85 km altitudes during the SSW using the CO profiles. The reverse of the  
538       mesospheric westerly from about  $10 \text{ m s}^{-1}$  to easterly wind about  $-10 \text{ m s}^{-1}$  around 10 February  
539       has been documented. The data from the ERA-Interim and MERRA-2 reanalyses and the Aura  
540       MLS temperature profiles have been used for the analysis of stratosphere–mesosphere behavior  
541       under the SSW conditions. Our local microwave observations in the NH midlatitude combined  
542       with the reanalysis data show wide ranges of daily variability in CO, zonal wind and  
543       temperature in the mesosphere and stratosphere during the SSW 2018.

544       [Among the most striking SSW manifestations over the midlatitude station in February](#)  
545       2018, there were (i) zonal wind reversal throughout the mesosphere–stratosphere, (ii)  
546       oscillations in the vertical profiles of CO, zonal wind and temperature, (iii) descent of the  
547       stratospheric CO and temperature anomalies on the time scale of days to months, (iv) wave 2  
548       peak at the vortex split date and (v) strong mesospheric CO and westerly peaks at the start of  
549       the SSW recovery phase. Generally, the midlatitude SSW effects are known from many event  
550       analyses and in most cases they are associated with zonal asymmetry and polar vortex split and  
551       displacements relative to the pole (Solomon et al., 1985; Allen et al., 1999; Yuan et al., 2012;  
552       Chandran and Collins, 2014). Our results show that the local midlatitude atmosphere variability  
553       in the SSW 2018 includes both the large-scale changes in the zonal circulation and temperature  
554       typical for the SSWs and local evolution of the altitude-dependent planetary wave patterns in  
555       the individual vortex split event.

556       The observed local CO variability can be explained mainly by horizontal air mass  
557       redistribution due to planetary wave activity with the replacement of the CO-rich air by CO-

558 poor air and vice versa, in agreement with other studies. The MLS CO fields show that the CO-  
559 rich air masses are enclosed within the polar vortex. Horizontal (meridional and zonal)  
560 displacements of the edge of the vortex or vortex fragments relative to the ground-based  
561 midlatitude station may be a dominant cause of the observed CO profile variations during the  
562 SSW 2018. The small sub-vortex located over the station at the SSW start caused the  
563 appearance of the enhanced CO level not only in the mesosphere but also in the stratosphere at  
564 about 30 km. This indicates that the polar vortex contains the CO-rich air masses with much  
565 higher CO amount [than](#) in the surrounding area and this takes place over the stratosphere–  
566 mesosphere altitude range.

567 Microwave observations show that sharp altitudinal CO gradient below the mesopause  
568 could be used to define the lower edge of the CO layer and to evaluate oscillation and  
569 significant elevation of the lower CO edge during the SSW and its trend on a seasonal time  
570 scale. The presented results of microwave measurements of CO and zonal wind in the  
571 midlatitude mesosphere at 70–85 km altitudes, which is still not adequately covered by ground-  
572 based observations (Hagen et al., 2018; Rüfenacht et al., 2018), are suitable for evaluating and  
573 potentially improving atmospheric models. Simulations show that planetary wave forcing by  
574 westward propagating wave 1 dominates between 40 and 80 km in the winter polar region  
575 during the SSW (Limpasuvan et al., 2016). Our spectral analysis reveals that the westward  
576 wave 1 during the SSW 2018 is a dominant wave component through the midlatitude upper  
577 stratosphere–mesosphere. Instability of the westward polar jet suggested in previous studies  
578 (e.g. Limpasuvan et al., 2016) should be analyzed in the context of the westward wave 1  
579 generation in the midlatitude upper stratosphere–mesosphere.

580 Our observation of variability of the CO layer during the SSW deserves further study,  
581 particularly in relation to the implications for modelling of wave dynamics and vertical  
582 coupling (Ern et al., 2016; Martineau et al., 2018) and chemical processes (Garcia et al., 2014)  
583 in the mesosphere.

585

586 *Conflict of Interest.* The authors declare that the research was conducted in the absence of any  
587 commercial or financial relationships that could be construed as a potential conflict of interest.

588

589 *Author contributions.* GM coordinated and led the efforts for this manuscript. VS initiated the  
590 microwave measurements during the SSW event in Kharkiv. VS, DS, VM and AA developed  
591 equipment and provided microwave measurements with data processing by AP and DS. GM,

592 VS, YW, OE, AK, and AG analyzed the results and provided interpretation. GM, OE, AK, VS,  
593 and WH wrote the paper with input from all authors.
