

32 can be explained by the intricate interplay between the changes in partitioning of the semi-volatile
33 compounds and their gas-phase chemical aging reactions.

34 1. Introduction

35 Atmospheric aerosol plays an important role in the Earth's energy balance by absorbing
36 and scattering solar radiation (direct effect) and influencing the properties and lifetime of clouds
37 (indirect effects) (IPCC, 2014). At the same time, certain particles may have significant negative
38 effects on human health, including premature death, increases in respiratory illnesses and
39 cardiopulmonary mortality (Pope et al., 2009; Caiazzo et al., 2013).

40 Aerosol particles contain a wide variety of inorganic and organic compounds, with organics
41 representing about 50% of the fine ($< 1 \mu\text{m}$) aerosol particle mass concentration, on average
42 (Zhang et al., 2007). OA originates from many different natural and anthropogenic sources and
43 processes. It can be emitted directly from fossil fuel and biomass combustion (so-called primary
44 organic aerosol, POA) or can be formed by the atmospheric oxidation of organic vapors (secondary
45 organic aerosol, SOA). The oxidation pathways of organic compounds are complex and the
46 corresponding reactions lead to hundreds or even thousands of mostly unknown oxygenated
47 products. As a result, our understanding of OA formation mechanisms and its chemical and
48 physical properties remains incomplete.

49 The use of lumped species is a computationally efficient approach for the representation of
50 OA in atmospheric chemical transport models (Pandis et al., 1992). The volatility basis set
51 framework (VBS, Donahue et al., 2006) lumps these compounds into surrogates along an axis of
52 volatility. This approach typically employs species with effective saturation concentrations at 298
53 K separated by one order of magnitude, with values ranging from, say, 0.01 to $10^6 \mu\text{g m}^{-3}$. By
54 quantifying the volatility distributions of primary and secondary OA, a physically reasonable, yet
55 suitable for large-scale chemical transport models (CTMs), description of semi-volatile organics
56 can be obtained (Lane et al., 2008).

57 The VBS framework was extended by Donahue et al. (2011; 2012a) adding another
58 dimension, the oxygen content (expressed as the ratio of oxygen to carbon atoms; O:C), for the
59 description of the OA chemical aging reactions. In the first application of this framework in a
60 CTM, Murphy et al. (2011) used 12 logarithmically spaced volatility bins (effective saturation
61 concentration C^* varying from 10^{-5} to $10^6 \mu\text{g m}^{-3}$ at 298 K) and 13 bins of O:C (from 0 to 1.2 with

62 a step of 0.1). In this way, 156 surrogate species were included in the model for each OA type.
63 Five organic aerosol types were simulated separately: anthropogenic secondary organic aerosol
64 (aSOA-v) produced during the oxidation of anthropogenic VOCs, biogenic secondary organic
65 aerosol (bSOA), fresh primary organic aerosol (POA), secondary organic aerosol from the
66 oxidation of semivolatile OA (SOA-sv) and SOA from the oxidation of intermediate volatility
67 compounds (SOA-iv) as analytically described in Murphy et al. (2014).

68 Murphy et al. (2011; 2012) used a one-dimensional Lagrangian CTM (PMCAMx-Trj), as
69 the host model for the simulations. PMCAMx-Trj simulates the chemical evolution of a column
70 of air as it travels towards a user-selected receptor site. Three alternative parameterizations of the
71 OA formation and chemical aging were evaluated using measurements of O:C and OA in three
72 European sites (Murphy et al., 2011; 2012). The simplest approach parameterizing the chemical
73 aging of anthropogenic compounds, assuming a net reduction of volatility by one bin during every
74 aging reaction step accompanied by an increase of one or two oxygen atoms with an equal
75 probability was the most successful. A more complex formulation of the chemical aging, assumed
76 that functionalization was the only process taking place, and overpredicted the OA concentration
77 while it underpredicted O:C in most cases. Adding fragmentation reactions together with the
78 functionalization gave promising results, but it was clear that the various parameters of the scheme
79 were not well constrained leading to large uncertainties in the simulation results, especially during
80 summertime. Murphy et al. (2012) concluded that the 2D-VBS scheme that was used needs
81 additional testing before it is ready for application in three-dimensional CTMs.

82 In Murphy and Pandis (2009; 2010) and Murphy et al. (2012) formation of significant
83 bSOA during second and later generation aging reactions led to overestimation of OA
84 concentration at both urban and rural sites. However, the first generation products of the oxidation
85 of biogenic VOCs do continue to react in the atmosphere (Ng et al., 2006; Tritscher et al., 2011;
86 Zhao et al., 2015; Szidat et al., 2006; Gilardoni et al., 2011; Yttri et al., 2011). The net effect on
87 ambient bSOA levels of these chemical aging reactions remains uncertain.

88 Fragmentation of organic compounds during chemical aging is an important reaction
89 pathway (Chacon-Madrid and Donahue, 2011; Murphy et al., 2011; Hermansson et al., 2014).
90 During fragmentation reactions carbon bonds break, resulting in smaller compounds, which are
91 more volatile than their precursors. A fragmentation probability, depending on O:C, has been used
92 in the 2D-VBS framework (Donahue et al. 2011; 2012). A fragmentation probability, ranging from

93 0-0.4, has been used in the statistical oxidation model (SOM) that uses the carbon (C) and oxygen
94 (O) atoms per compound as the independent variables (Cappa and Wilson, 2012). While the
95 fragmentation pathways are clearly important for the OA levels, their parameterizations in existing
96 models remain quite uncertain (Murphy et al., 2012).

97 The effect of temperature on the partitioning of OA components between the gas and
98 particulate phases represents another source of uncertainty. Sheehan and Bowman (2001),
99 concluded that a 10 °C decrease in temperature can result in an increase of SOA by as much as
100 150% depending on the assumed vaporization enthalpy. This effect can theoretically lead to
101 significant OA vertical gradients. Applying the 2D-VBS to FAME-08 in Finokalia, Greece,
102 Murphy et al. (2011) reported low sensitivity of the OA concentration and O:C ratio measurements
103 to the assumed vaporization enthalpy, with higher values leading to slightly lower O:C.

104 In this study, we evaluate different chemical aging mechanisms in the 2D-VBS approach
105 focusing on the Po Valley in Italy. Extensive measurements were performed both at the ground
106 and aloft from June 6 until July 8, 2012. Po Valley has major air quality problems due to both
107 industrial and agricultural sources. A number of alternative chemical aging mechanisms are
108 evaluated comparing the 2D-VBS predictions against the PEGASOS measurements. The role of
109 bSOA chemical aging is explored. Finally, the sensitivity of the model to the assumed effective
110 vaporization enthalpy is quantified in an effort to constrain this uncertain variable using the
111 measurements aloft.

112

113 2. Lagrangian CTM Description

114 A one-dimensional Lagrangian chemical transport model (PMCAMx-Trj) (Murphy et al.,
115 2011; 2012), simulating the air parcels that arrive at the desired receptor location, is used as the
116 host for the 2D-VBS module. The model solves the general dynamic equation taking into account
117 the following relevant atmospheric processes: atmospheric transport, gas and aqueous phase
118 chemistry, dry and wet deposition of gases and aerosols and vertical turbulent dispersion together
119 with area and point emissions. Ten computational cells are used to cover heights up to 3 km. The
120 lowest cell has a height of 60 m. The SAPRC-99 (Carter, 2000) chemical mechanism is used for
121 the simulation of gas-phase chemistry. The meteorological parameters (horizontal winds,
122 temperature, pressure, vertical dispersion coefficients, water vapor, clouds, rainfall and land use)
123 used as inputs in the model are provided by the Weather Research and Forecasting (WRF) model.

124 The WRF simulation was periodically re-initialized (every 3 days) to ensure the accuracy of the
125 inputs to the CTM. Area and point emissions, both anthropogenic and biogenic, were also provided
126 as hourly inputs for the European domain. The Global and regional Earth-system Monitoring using
127 Satellite and in-situ data (GEMS) dataset (Visschedijk et al., 2007) is used for the emissions of
128 anthropogenic gases. Anthropogenic emissions of organic and elemental carbon are based on the
129 Pan-European Carbonaceous Aerosol Inventory developed during EUCAARI (Kulmala et al.,
130 2009). Biogenic gridded emissions are produced from the combination of three different models.
131 The Model of Emissions of Gases and Aerosols from Nature (MEGAN) provides the emissions
132 from ecosystems (Guenther et al., 2006) and the O'Dowd et al. (2008) model provides the marine
133 aerosol emissions. Finally, wildfire emissions are also included (Sofiev et al., 2008a, b). Details
134 of the emission inventory used for Europe can be found in Fountoukis et al. (2011). In order to
135 implement these emissions in our 2D-VBS model, we used the same volatility distribution of the
136 emissions as in the original work (Fountoukis et al., 2011) and used the Murphy et al. (2012)
137 methodology for mapping these to the 2D-VBS. Vertically resolved initial conditions and the top
138 boundary conditions for PMCAMx-Trj were obtained from the corresponding output of the
139 PMCAMx regional scale three-dimensional simulation for the same period.

140

141 **2.1 Simulated periods**

142 Six air parcels arriving at 3:00, 7:00, 11:00, 15:00, 19:00 and 23:00 local time (UTC+1) in
143 the ground site of San Pietro Capofiume were simulated for a total of 7 days (15, 26, 27, and 28 of
144 June and 4, 5 and 8 of July 2012). The air masses in the simulated trajectories originated all from
145 Europe (mostly Portugal or France) or the Atlantic Ocean. We avoided days during which air
146 masses originated from Africa since emission inventories for Africa are quite uncertain. We chose
147 days for which the trajectories at the different altitudes originated all from the same region. The
148 Hybrid Single Particle Lagrangian Integrated Trajectory HYSPLIT model (Draxler et al., 2009)
149 was used to calculate 72 h back trajectories arriving at the receptor site. For consistency, we used
150 the same WRF meteorological data as input to HYSPLIT to calculate the back trajectories.
151 Following Murphy et al. (2011) we used the ensemble average of 20 trajectories with varied
152 heights from 60 m up to 3 km.

153 The twenty 72 h HYSPLIT back trajectories arriving at San Pietro Capofiume at 3:00 LT on
154 July 8, 2012 are shown in Figure 1 as an example. They all originated from the eastern Atlantic

155 Ocean, passed a day over the ocean and then travelled over Portugal and Spain for another day.
156 The air masses continued over the Mediterranean Sea, Western Italy, and a few hours later arrived
157 in the receptor site of San Pietro Capofiume. The HYSPLIT clustering analysis utility was used to
158 estimate the average trajectory that was used in the simulations (Figure 1).

159 Zeppelin flights over Po Valley took place on 20, 21, 22 and 24 of June of 2012 and 1, 3 and
160 4 of July 2012. The HYSPLIT model was once again used to calculate trajectories arriving at the
161 receptor site around Po Valley. All the flights took place between 4:00 LT until 13:00 LT. The
162 flight path of the Zeppelin for June 4, 2012 is shown in Figure S1 as an example. The flight took
163 place between 5:00 LT and 10:00 LT and the measurements took place in the nighttime boundary
164 layer, the residual layer, but also in the mixed layer later in the day.

165

166

167 **2.2 Chemical Aging Schemes**

168 In our simulations, we considered three different functionalization schemes, two bSOA chemical
169 aging parameterizations and explored the use of fragmentation mechanisms. These are
170 summarized below.

171 **2.2.1 Functionalization schemes**

172 **(a) Simple scheme**

173 The first functionalization scheme (1-bin) used in our simulations was the simple scheme of
174 Murphy et al. (2012) that had the best performance in the cases simulated in that study. In this
175 scheme, there is one volatility bin reduction for every reaction with a simultaneous increase in
176 oxygen atoms, with a probability of 50% for an increase of 1 oxygen atom and 50% probability
177 for an increase of 2 oxygen atoms. The calculation of the O:C change from the number of added
178 oxygen atoms is based on Donahue et al. (2011). The chemical aging reaction constants that are
179 used for the reactions with OH are the same as in the base case of Murphy et al. (2011) with values
180 equal to $1 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ for anthropogenic SOA from VOCs (aSOA-v) and biogenic SOA
181 (bSOA) and $4 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ for SOA from semivolatile OA (SOA-sv) and intermediate
182 volatility compounds (SOA-iv).

183

184

185 **(b) Two-bin shift simple scheme**

186 In the second functionalization scheme (2-bin), a two-volatility bin reduction is assumed for
187 every reaction with a simultaneous increase in oxygen atoms. A 50% probability for the increase
188 of 1 oxygen atom and 50% probability for the increase of 2 oxygen atoms are used. The calculation
189 of the O:C shift in bins from the number of added oxygen atoms is based again on Donahue et al.
190 (2011). This functionalization scheme assumes a more rapid reduction in volatility for every
191 reaction and uses the same reaction constants for the reactions with OH as in the base case of
192 Murphy et al. (2011).

193

194 **(c) Detailed scheme**

195 The third aging scheme is the detailed functionalization scheme (DET) introduced by
196 Donahue et al. (2011). This is a more rigorous scheme compared to the previous two conservative
197 aging parameterizations. Following Murphy et al. (2012), there is a 30% probability of adding one
198 O atom, 50% probability of adding two O atoms, and 20% probability of adding three O atoms.
199 Each addition of O atoms results in a different distribution of volatility reductions, with an average
200 reduction of -1.75 in $\log_{10}C^*$ per oxygen group added. These additions of O atoms are translated
201 to changes of O:C ratios following Murphy et al. (2012). The functionalization kernel is applied
202 to all species in the 2D-VBS upon OH reaction. Again the chemical aging reaction constants that
203 are used for the reaction with OH are the same as the two functionalization schemes described
204 above.

205

206 **2.2.2 bSOA aging parameterizations**

207 Two different parameterizations of bSOA aging are explored. In the first scheme, the
208 chemical aging of biogenic SOA is assumed to result in a negligible net change in volatility but an
209 increase in O:C (Murphy et al., 2011). This scheme is consistent with the lack of bSOA aging that
210 has been used in PMCAMx (Murphy and Pandis, 2009; 2010) and is called in the rest of the paper
211 no-bSOA aging even if the O:C of bSOA does change.

212 In the second scheme, bSOA components are assumed to age similarly to aSOA, with their
213 processing leading not only to changes in O:C, but also to a net reduction of their volatility. We
214 explore all three functionalization schemes, the simple scheme (1-bin), the faster functionalization

215 (2-bin) and the detailed functionalization scheme (DET) together with the two bSOA aging
216 parameterizations.

217

218 **2.2.3 Fragmentation parameterizations**

219 Fragmentation parameterizations will be examined that lead to products with lower carbon
220 numbers than the precursor. As in Murphy et al. (2012) the bond cleavage is assumed to happen
221 randomly and to be uniformly distributed throughout the carbon backbone. For these fragmented
222 compounds, the functionalization kernel is applied and this will lead to increases in volatility. The
223 fragmentation probability in our simulations is allowed to range from zero (for no fragmentation)
224 to unity.

225

226 **2.3 Combination of parameterizations**

227 In our simulations, we used all combinations of the three functionalization schemes (1-bin, 2-
228 bin or DET), the two bSOA aging schemes and simulated fragmentation assuming fragmentation
229 probability b ranging from zero to 1. In Table 1, we summarize the parameterizations that were
230 finally chosen for the simulations. For each of the six combinations of functionalization and bSOA
231 aging, we assumed zero fragmentation probability (6 cases) plus we determined the fragmentation
232 probability b that resulted in the minimum error for the average OA concentration. The
233 determination of the “optimum” fragmentation probability for each case is shown in Figure C.4.
234 For the 1-bin functionalization scheme and considering no bSOA production during aging, the OA
235 was underpredicted for fragmentation probabilities even low as 5% so in this case the optimum b
236 was equal to zero and this became the same as the 1-bin simple scheme of Murphy et al. (2012).

237

238 **2.4 Evaluation of parameterizations**

239 The prediction skill of our simulations is quantified in terms of the fractional error, the
240 fractional bias, the absolute error, the absolute bias and the root mean square error. These are
241 calculated using:

$$242 \text{ Fractional Error} = \frac{2}{n} \sum_{i=1}^n \frac{|P_i - M_i|}{(P_i + M_i)}$$

243

$$244 \text{ Fractional Bias} = \frac{2}{n} \sum_{i=1}^n \frac{(P_i - M_i)}{(P_i + M_i)}$$

245

246

247

$$\text{Absolute Error} = \frac{1}{n} \sum_{i=1}^n |P_i - M_i|$$

248

249

$$\text{Absolute Bias} = \frac{1}{n} \sum_{i=1}^n (P_i - M_i)$$

250

251

$$\text{Root Mean Square Error} = \sqrt{\frac{1}{n} \sum_{i=1}^n (P_i - M_i)^2}$$

252

253

254 where P_i represents the model prediction value, M_i is the corresponding measured value from the
255 ground or above the site with the Zeppelin measurements and n is the total number of data points.

256

257 3. Results

258 3.1 Simple functionalization (1-bin case)

259 The first set of simulations used the simple functionalization scheme (1-bin), assuming
260 negligible addition/production of bSOA during aging (no bSOA aging) and neglected
261 fragmentation assuming that the employed functionalization scheme represents the net effect of
262 these pathways. This case is the same as the base case of Murphy et al. (2012). In this scheme,
263 there is a modest volatility reduction as the organic vapors react with OH. The prediction skill
264 metrics of the model 4-hour average O:C and OA concentration against the averaged ground
265 measurements for the seven selected days during PEGASOS 2012 campaign are summarized in
266 Tables 2 and 3 respectively.

267 The average predicted diurnal variation of O:C at the ground level, is presented in Figure 2.
268 Given the uncertainty introduced by the use of a trajectory model (e.g. a small error in the path of
269 the air parcels can introduce significant error in the predictions), we rely on the average
270 concentrations instead of the predictions of individual hours. Predicted O:C increased during the
271 afternoon due to the production of secondary OA and photochemical processing (evaporation,
272 oxidation in the gas phase and re-condensation) of the primary OA. The model predictions, agree
273 within experimental error with the measurements, with some discrepancies in the afternoon where
274 the model tends to overpredict O:C. They both suggest relatively oxidized OA with modest average

275 diurnal O:C variation. The average predicted O:C is 0.64 and the average measured is 0.58 (Table
276 2). The fractional error and bias for the 4-hour average O:C were less than 10%.

277 The predicted average O:C vertical model profile is compared to the airborne
278 measurements, in Figure 3a. Model predictions, agree with the measurements within experimental
279 error and both suggest an oxidized aerosol. The average predicted O:C was equal to 0.59, while
280 the average measured O:C was 0.58. The vertical profile for both the predictions and Zeppelin
281 measurements was relatively flat inside the lowest 1 km.

282 The predicted average diurnal profile of the OA particle mass concentration for the 1-bin
283 case is shown in Figure 4. The average predicted OA is equal to $2.6 \mu\text{g m}^{-3}$ and is predicted to be
284 higher during the night time for this specific period. The measurements suggest a relatively flat
285 profile; however, the model predicts higher particle mass concentrations during night time due to
286 increased levels of SOA. The average measured particle mass concentration during the same
287 period was $2.8 \mu\text{g m}^{-3}$. The absolute error was equal to $0.78 \mu\text{g m}^{-3}$ and the fractional bias was
288 12%. The anthropogenic SOA and SOA from IVOC oxidation dominate the predicted OA
289 composition, with biogenic SOA increasing during night time. SOA-iv is predicted to contribute
290 36% to the total OA. Anthropogenic and biogenic SOA are predicted to account for 22 and 17%
291 respectively and SOA-sv and POA represent around 10% each (Figure S3). The predicted average
292 diurnal profile of the POA particle mass concentration compared to the HOA concentration from
293 the AMS-PMF results from the ground from Sullivan et al. (2016) are also shown in Figure S4.
294 The particle mass concentrations are always less than $0.25 \mu\text{g m}^{-3}$ and the diurnal profiles seem to
295 agree satisfactorily. The biomass burning contribution is not present during these summer months.

296 The average vertical predicted profile for all Zeppelin flights is compared with the
297 corresponding measurements in Figure 3b. The average measured OA for these periods was equal
298 to $4.7 \mu\text{g m}^{-3}$ while the average predicted $4.2 \mu\text{g m}^{-3}$. Model predictions are within experimental
299 error, for altitudes lower than 700 m. The three data points at higher altitudes are all from a single
300 flight on June 20, 2012 during which the model underpredicted the OA aloft.

301

302 **3.2 Effect of functionalization scheme**

303 Using the 2-bin simple functionalization scheme the fractional error and bias for O:C are
304 around 10%, similar to the 1-bin parameterization. The average predicted OA is equal to $3.4 \mu\text{g}$
305 m^{-3} (Table 3) with similar fractional error and bias with the 1-bin case. The average volatility

306 distribution and O:C of OA at the ground level is shown in Figure S2. The OA mass, using this
307 functionalization scheme is distributed towards smaller volatilities, compared to the 1-bin case,
308 almost one bin to the left (Figure S2b), while the OA mass is distributed around similar values for
309 the O:C with a diurnal ground average equal to 0.63 (Table 2), where 0.58 is the average for the
310 measurements.

311 The detailed functionalization scheme, underpredicted the O:C, with fractional bias equal to
312 34% and an average O:C equal to 0.41 (Table 2), when the average measured was 0.58. This is
313 consistent with the conclusions of Murphy et al. (2011; 2012), about the tendency of this
314 aggressive functionalization scheme to seriously underpredict O:C. The performance of this
315 scheme, was better for the OA mass concentration with an average predicted value equal to $3.2 \mu\text{g m}^{-3}$
316 m^{-3} (Table 3) close to the average measured value ($2.8 \mu\text{g m}^{-3}$). The OA particle mass concentration
317 fractional bias was equal to 11% while the fractional error was 21%. In this functionalization
318 scheme, the predicted OA has a wider distribution in the 2D space than the 2 previous schemes
319 and lower O:C and volatilities. (Figure S2c).

320

321 **3.3 Effect of bSOA production during aging**

322 The average predicted O:C for the ground level using the 1-bin/bSOA parameterization is
323 0.55, which is consistent with the measured 0.58 (Table 2). The fractional error and bias of O:C
324 are less than 10%. However, the OA concentration is overpredicted with an average value of 3.8
325 $\mu\text{g m}^{-3}$, compared to the measured $2.8 \mu\text{g m}^{-3}$ (Table 2). The OA particle mass concentration
326 fractional bias and error were 26% and 30% respectively. This is consistent with the conclusions
327 of Hermansson et al. (2014), Lane et al. (2008) and Murphy and Pandis (2009) that treating only
328 the functionalization of bSOA while neglecting fragmentation leads to overpredictions of OA
329 concentrations.

330 The same behavior was observed in the 2-bin/bSOA simulation in which PMCAMx-Trj
331 predicted an average ground O:C equal to 0.53 with fractional bias less than 10% but overpredicted
332 OA with an average equal to $5 \mu\text{g m}^{-3}$ and a high fractional bias of 54%. Finally, in the DET/bSOA
333 case, the model seriously underpredicted O:C with an average value equal to 0.35 and fractional
334 bias equal to 50% and overpredicted OA concentration with an average equal to $5.4 \mu\text{g m}^{-3}$ and a
335 high fractional bias of 60%. In all of these cases, addition of significant later generation bSOA
336 production leads to significant errors in the model predictions.

337 3.4 The role of fragmentation

338 To explore the role of fragmentation the 1-bin simple functionalization scheme was first used,
339 assuming additional production of bSOA during aging combined with the fragmentation
340 parameterization varying the fragmentation probability from zero to one. An optimum
341 fragmentation probability equal to 0.15 was estimated (Figure S5b). The average predicted O:C
342 for this model configuration (1-bin/bSOA/b=0.15) was equal to 0.56 in good agreement with the
343 measurements and a fractional bias of 4% (Table 2). The average predicted OA was equal to 2.9
344 $\mu\text{g m}^{-3}$ with a fractional bias of just 2%.

345 The second functionalization scheme (2-bin case) was also tested without and with bSOA
346 aging, (2-bin and 2-bin/bSOA cases respectively). In the first case, the optimum b was estimated
347 to be equal to 0.1 and in the second case, assuming bSOA aging, it was equal to 0.4 (Figures S5c
348 and S5d) For both model configurations, the performance was satisfactory (fractional biases less
349 than 10% and fractional errors less than 25%) for both O:C and OA mass (Table 2 and 3).

350 In the last test, the detailed functionalization scheme (DET case) was used. In the previous
351 simulations, the DET and DET/bSOA parameterizations resulted in high underpredictions of the
352 O:C and overprediction of the OA concentration for DET/bSOA case. In the DET
353 parameterization, the optimum b was estimated to be equal to 0.3 and in the second case, assuming
354 bSOA aging, it was equal to 0.7 (Figures S5e and S5f). These schemes performed well with
355 fractional biases less than 10% and fractional errors less than 25% for OA and less than 10% for
356 O:C.

357 For all three aging schemes, including suitable fragmentation schemes, resulted in satisfactory
358 results compared to the measurements at the ground level. In Figure S4 all the parameterizations
359 had similar POA concentrations compared to the HOA concentrations from the ground PMF-AMS
360 measurements. The situation was similar for the Zeppelin measurements as shown in Figure S6 in
361 the Supplementary Information. All these parameterizations resulted in similar vertical profiles of
362 O:C and OA with similar agreement with the measurements.

363

364 3.5 Synthesis of results

365 The previous results suggest that there are seven aging parameterizations from those examined
366 that reproduce well both the ground and Zeppelin measurements. These are:

- 367 • the simple functionalization scheme and assuming negligible bSOA aging (1-bin case)
- 368 corresponding to the base case in Murphy et al. (2011),
- 369 • the 1-bin shift with bSOA aging and a fragmentation probability equal to 15% (1-
- 370 bin/bSOA/b=0.15),
- 371 • the 2-bin shift without bSOA aging (2-bin),
- 372 • the 2-bin shift without bSOA aging and a fragmentation probability equal to 10% (2-
- 373 bin/b=0.1),
- 374 • the 2-bin shift with bSOA aging and a fragmentation probability equal to 40% (2-
- 375 bin/bSOA/b=0.4),
- 376 • the detailed functionalization scheme, without bSOA aging and a fragmentation probability
- 377 equal to 30% (DET/b=0.3),
- 378 • the detailed functionalization scheme with bSOA aging and fragmentation probability
- 379 equal to 70% (DET/bSOA/b=0.7).

380 Parameterizations that appear to be inconsistent with the measurements are the ones that use the
381 detailed functionalization scheme, without any fragmentation schemes, leading to underprediction
382 of the O:C. Parameterizations including net bSOA production during the chemical aging reactions
383 and neglecting fragmentation were also inconsistent with the measurements resulting in
384 overprediction of the OA levels.

385 These seven aging schemes predict different OA composition (Figure 5), while all perform
386 well enough compared to the measurements. Considering the modeling uncertainty introduced by
387 the use of a 1-D trajectory model and the corresponding measurement uncertainties, all models
388 perform satisfactorily. While statistically, the performance of the 2-bin/bSOA/b=0.4 scheme is a
389 little better than the others, this difference is clearly within experimental/modeling error.
390 Anthropogenic SOA from VOCs is predicted to contribute between 14 and 27% of the total OA
391 (Figure S3a). It is a high contributor for the simulations assuming negligible additional production
392 of bSOA during chemical aging. The parameterization using the faster functionalization scheme
393 (2-bin) predicts the highest percentage of 27% while the scheme with the detailed
394 functionalization, additional bSOA production and rapid fragmentation (DET/ bSOA/b=0.7)
395 predicts the lowest (14%).

396 The predicted contribution of biogenic SOA was the most variable ranging from 16 to 45%
397 of the total OA depending on the scheme (Figure S3b). The highest contribution, as expected, was

398 predicted by the schemes assuming production of bSOA during aging. The highest fraction (45%)
399 was predicted using the 2-bin shift functionalization parameterization and fragmentation by 40%
400 (2-bin/bSOA/b=0.4. The lower bSOA mass concentrations were predicted by the four schemes
401 assuming negligible net bSOA production during aging.

402 SOA from the oxidation of intermediate volatility compounds varied between 19 and 36%
403 depending on the model (Figure S3c). The lowest contributions were predicted by the simulations
404 in which the bSOA mass concentration was high. The primary OA varied from 5 to 6%, the OA
405 from long range transport from 6 to 8%, and the SOA from evaporation of the primary and
406 subsequent oxidation from 7 to 11%.

407 These results are encouraging because the various parameterizations even if they are quite
408 different they give a rather consistent picture (with exception of the picture of the bSOA maybe)
409 about the various pathways contributing to the OA levels in this area. Additional constraining of
410 these schemes will require applications of the corresponding models in other areas, additional
411 measurements, and probably additional laboratory studies.

412

413 **3.6 The role of vaporization enthalpy**

414 The vaporization enthalpy is a physical property that has always been assumed in chemical
415 transport models with values ranging from very low as 20 to even 200 kJ mol⁻¹ that have been
416 suggested after constraining these values with experimental data (Stanier et al., 2007; Offenber
417 et al., 2017). In our model, three different effective vaporization enthalpies equal to 30, 75 and 150
418 kJ mol⁻¹ were assumed and used together with the simple functionalization scheme (1-bin case).
419 All three simulations, predicted the same flat diurnal profile for both the O:C and OA
420 concentration, with differences less than 20%, mostly in the first hours of the day (Figure 6a and
421 b). The predictions of the scheme with the higher vaporization enthalpy tend to be a little closer to
422 the ground measurements of O:C. As vaporization enthalpy increased, the predicted O:C decreased
423 and OA concentration increased (Table S1) However, the differences were small with the average
424 O:C ranging from 0.59 for the 150 kJ mol⁻¹ case to 0.64 for the 30 kJ mol⁻¹ case, while the measured
425 average value was 0.58. The fractional biases for O:C were similar ranging from 2% for a
426 vaporization enthalpy equal to 150 kJ mol⁻¹ to 10% for 30 kJ mol⁻¹. The results for the OA
427 concentration were similar.

428 The comparison of the model predictions with the vertical profiles from the Zeppelin
429 measurements showed similar results (Figure 6c and d). The predicted vertical profiles of O:C and
430 OA particle mass concentration were once more not that sensitive to the assumed effective
431 vaporization enthalpy. This lack of sensitivity can be explained by the intricate interplay between
432 the changes in partitioning of the semi-volatile compounds and their gas-phase chemical aging
433 reactions. The sensitivity of the vaporization enthalpy was examined with all aging mechanisms
434 and the conclusions were the same.

435 For values of ΔH_{vap} that favor the partitioning of the OA components to the gas phase the
436 resulting decrease in OA concentrations is partially offset by an acceleration of the gas-phase
437 chemical aging reactions and the additional SOA production. Vice-versa for ΔH_{vap} values that
438 favor the partitioning to the particulate phase the resulting OA increase is balanced by a reduction
439 in the aging rate.

440

441 4. Conclusions

442 The effects of the parameterization of the chemical aging processes of atmospheric organic
443 compounds on organic aerosol (OA) particle mass concentration and chemical composition were
444 investigated by using different formulations of the two-dimensional Volatility Basis Set (2D-VBS)
445 together with ground and airborne measurements in the Po Valley in Italy.

446 We applied firstly the simple aging mechanism of the base case (Murphy et al., 2012),
447 presented here as the 1-bin case. The predictions of the model were satisfactory, both at the ground
448 and aloft, within experimental variability and with fractional biases for the 4-hour average O:C
449 and OA concentration around 10%. The average diurnal POA concentration was similar to the
450 HOA concentration from the PMF-AMS ground measurements with concentrations less than 0.25
451 $\mu\text{g m}^{-3}$. The vertical profile for both predictions of the 1-bin case and Zeppelin measurements was
452 relatively flat inside the lowest 1 km and the diurnal variation in O:C ratio was modest. They both
453 suggested a relatively oxidized OA for the Po Valley, Italy, with an average O:C around 0.6.
454 Anthropogenic SOA and SOA from intermediate volatility compounds oxidation dominated the
455 predicted OA composition based on this parameterization.

456 Seven aging schemes (out of more than a hundred tested), with different assumed
457 functionalization algorithms, bSOA aging and fragmentation were found to reproduce well the
458 ground and Zeppelin O:C and OA measurements. Anthropogenic SOA from VOCs was predicted

459 to contribute between 15 and 25% of the total OA and SOA from the oxidation of intermediate
460 volatility compounds oxidation between 20 and 35%. The contribution of biogenic SOA varied
461 from 15 to 45%, depending on the parameterization scheme. POA was around 5%, with almost
462 similar average diurnal profiles between the different parameterizations and similar to the HOA
463 concentrations from the PMF-AMS ground measurements. The OA from long range transport
464 varied from 6 to 8% and the SOA from evaporation of the primary and subsequent oxidation from
465 7 to 11%. These results are encouraging because despite the uncertainty introduced by the different
466 schemes, their predictions about source contributions are relatively robust.

467 Addition of bSOA produced during the corresponding chemical aging reactions in the
468 functionalization-only schemes resulted in overpredictions of the OA mass concentration.
469 Addition of significant fragmentation (fragmentation probabilities ranging from 15 to 70%) was
470 necessary to balance this additional source. This is clearly a topic that deserves additional research
471 both in the laboratory and in the field.

472 There was also surprising low sensitivity of predicted OA particle mass concentration and
473 O:C both at the ground and aloft to enthalpy of vaporization. Using three different vaporization
474 enthalpies equal to 30, 75 and 150 kJ mol⁻¹, the model predictions showed a very similar flat
475 diurnal profile for O:C and OA particle mass concentration at the ground with differences less than
476 20% and being within experimental variability. Similar were the conclusions for the vertical
477 profiles of the model in comparison to the Zeppelin measurements. The interplay between the
478 partitioning of the compounds and the chemical aging reactions as well as the small temperature
479 sensitivity, for altitudes until 600 m might explain this small sensitivity to vaporization enthalpy.
480 There was some weak evidence though that the higher values (like 150 kJ mol⁻¹) are in better
481 agreement with the O:C observations at the ground and aloft. Probably this low sensitivity is also
482 a feature of analyzing within the boundary layer during only the summer. Future work with three-
483 dimensional models and measurements with high altitude predictions and/or annual simulations
484 with wintertime predictions may be useful.

786 **Figure 3.** Average vertical predicted and measured (1-bin case) (a) O:C ratio and (b) organic
787 aerosol mass concentration for all the Zeppelin measurements over Po Valley. The black line shows
788 the model predictions and the shaded areas the standard deviation. The red symbols represent the
789 AMS Zeppelin measurements and the error bars correspond to one standard deviation.

805 **Figure 4.** Average diurnal profile at the ground level OA in San Pietro Capofiume (1-bin case).
806 With dark blue we represent the OA from long range transport, with blue the anthropogenic SOA
807 produced during the oxidation of anthropogenic VOCs (aSOA-v), with cyan the biogenic SOA
808 (bSOA), with yellow the SOA from oxidation of intermediate volatility compounds (SOA-iv), with
809 red the SOA from the oxidation of semivolatile OA (SOA-sv) and finally with dark red the fresh
810 primary organic aerosol (FPOA). The ground AMS measurements are shown with black symbols
811 and the error bars correspond to one standard deviation.
