Abstract

31

32 Aerosol effect on lightning is still under debate. In this study, the relative roles of meteorology
33 and aerosols on lightning activities in Africa are investigated from a climatological perspective,
34 based on the 11-year worth of lightning flashes from Lightning Imaging Sensor onboard Tropical
35 Rainfall Measuring Mission, aerosol optical depth (AOD) from Moderate Resolution Imaging
36 Spectroradiometer onboard Aqua, meteorological variables from the Medium-Range Weather
37 Forecasting ERA-Interim reanalysis and aerosol composition data from the Modern-Era
38 Retrospective analysis for Research and Application. Six meteorological variables are selected:
39 sea level pressure (SLP), potential temperature (θ) at 2 m above ground level, mid-level relative
40 humidity (RH), convective available potential energy (CAPE), vertical wind shear (SHEAR), and
41 200 hPa divergence (Div). To differentiate two dominant aerosol types in Africa and to account for
42 their distinct climate regimes that all affect lightning, we separate two regions of interest (ROIs):
43 the northern Africa (ROI_1) and the southern Africa (ROI_2) dominated by dust and smoke
44 aerosols, respectively. As compared with dust in ROI_1, smoke aerosols in ROI_2 exhibit huge
45 contrast between dry and wet season. Irrespective of regions, the lightning exhibits large diurnal
46 variation with an afternoon peak and strong seasonality with a summertime peak, while the
47 pronounced differences in lightning under relatively clean and polluted conditions signify the
48 potential influences of aerosols. Lightning is dictated mostly by RH and CAPE in the dust
49 dominant region (ROI_1). In the smoke dominant region (ROI_2), the effect of SLP is also
50 significant. Systematic changes of boomerang shape are found in lightning frequency with AOD,

51 with a turning point at around $AOD=0.3$, below which lightning flashes increase monotonously
52 with increasing AOD in both ROIs. As AOD approaches the optimal value, lightning activity seems
53 to be saturated under smoky condition, likely due to the tradeoff between the aerosol invigoration
54 effect and the radiative effect that tends to enhance and suppress lightning, respectively. In contrast,
55 lightning activity in ROI_1 is suppressed by dust aerosol presumably due to the more dominant
56 radiative heating effect of dust aerosol under dry environment.

57 **1.Introduction**

58 Lightning can be considered as a key indicator of strong atmospheric convection [*Betz et al.*,
59 2008], generally accompanied with a concomitant severe storms. Lightning activities have been
60 linked with two major factors: meteorology and aerosols (e.g. Bell et al., 2009; Bell et al., 2008;
61 Boccippio et al., 2000; Christian et al., 2003; Farias et al., 2014; Guo et al., 2016; Lucas et al.,
62 1994; Orville et al., 2001; Williams and Stanfill, 2002; Williams et al., 2004; Williams et al., 2005).

63 Since the pioneering work in 1990's by Westcott (1995) who attempted to link the summertime
64 cloud-to-ground lightning activity to anthropogenic activities, the roles of aerosols in lightning
65 have been increasingly recognized, as comprehensively reviewed on the topic associated with
66 aerosol-cloud-precipitation interactions (e.g. Tao et al., 2012, Fan et al., 2016; Li et al., 2016;
67 2017a). The aerosol effect can be generally divided into radiative and microphysical effects
68 (Boucher et al., 2013; Li et al., 2017b). The radiative effect suggests aerosols can heat the
69 atmospheric layer and cool the surface by absorbing and scattering solar radiation, thereby
70 reducing the latent heat flux and stabilizing the atmosphere (Kaufman et al., 2002; Koren et al.,
71 2004; Koren et al., 2008; Li et al., 2017a). As a consequence, convection and electrical activities
72 are likely inhibited (Koren et al., 2004). By acting as cloud condensation nuclei (CCN) with the
73 constrained water, increasing aerosols loading tends to reduce the mean size of cloud droplets,
74 suppress coalescence and delay the onset of warm-rain processes (Rosenfeld and Lensky, 1998),
75 which permits more liquid water to ascend higher into mixed phased region where it fuels lightning.
76 A conspicuous enhancement of lightning activity was found to be tightly connected to volcanic

77 ashes over the western Pacific Ocean (Yuan et al., 2011) and aerosol emissions from ships over the
78 equatorial Indian Ocean (Thornton et al., 2017). In terms of the response of clouds to aerosols, an
79 optimal aerosol concentration was found to exist, based on observation analysis (Koren et al., 2008;
80 Wang et al., 2015) and a simple parcel model calculation (Rosenfeld et al., 2008). Biomass burning
81 activities, anthropogenic emission and desert dust are the three major atmospheric aerosol sources
82 (Rosenfeld et al., 2001; Li et al. 2011; Fan et al. 2018), which are recognized to have different
83 climate effects. The increased rainfall in the south China and drought in the north China are thought
84 to be related with increased black carbon aerosols (Menon et al., 2002) while the effect of dust on
85 cloud properties tends to decrease precipitation from a feedback loop (Rosenfeld et al., 2001).

86 However, most studies on aerosol-convection interactions account for aerosol burden (i.e.
87 AOD, the number concentration of aerosol, PM_{2.5}, or CCN) rather than aerosol species. It was not
88 until recently that the effect of aerosol species in modulating lightning activities was investigated
89 (e.g. Stolz et al., 2015; 2017), which prompts us to perform more detailed analyses in this study.

90 The lightning and convection strength are controlled by various meteorological variables and
91 indices such as air temperature (T) (Price, 1993; Williams, 1994; 1999), the convective available
92 potential energy (CAPE) and its vertical distribution (normalize CAPE, NCAPE) (Bang and Zipser,
93 2016; Stolz et al., 2015), vertical wind shear (SHEAR) (Fan et al., 2009; 2013; Igel and Heever,
94 2015; Khain et al., 2008), relative humidity (RH) in the lower and middle troposphere (Fan et al.,
95 2007; Wall et al., 2014), cloud base height (Williams et al., 2005), updraft velocity (Williams et
96 al., 2005; Zipser and Lutz, 1994), and warm cloud depth (Stolz et al., 2015, 2017).

97 Depending on aerosol properties and atmospheric conditions, aerosols may enhance (Fan et al.,

98 2007; Khain et al., 2005; 2008) or suppress convection (Khain et al., 2004; Rosenfeld, 2000;
99 Rosenfeld et al., 2001; Zhao et al., 2006). In general, aerosols tend to suppress convection for
100 isolated clouds formed in relatively dry condition but to invigorate convection for convective
101 systems inside a moist environment. Under conditions of strong vertical wind shear, aerosols tend
102 to reduce the strength of single deep convection clouds due to higher detrainment and larger
103 evaporation of cloud hydrometeors (Richardson et al., 2007; Fan et al., 2009), thereby altering the
104 lightning activities (Altaratz et al., 2010; Farias et al., 2014). Apart from invigoration effect
105 induced by aerosol, lightning activities are enhanced by increases in NCAPE and SHEAR, but
106 inhibited by increasing RH and warm cloud depth (Stolz et al., 2015).

107 Most previous studies were based on short-term data, while we try to employ long-term (11
108 years) lightning and meteorological data to investigate and quantify the relative roles of aerosol
109 and meteorology on lightning. Section 2 describes the dataset and method used in this study,
110 Section 3 shows regions of interest, and Section 4 examines (1) long-term climatological features
111 of lightning and aerosol, (2) differences of lightning, AOD, meteorological variables under
112 relatively clean and polluted conditions, (3) response of lightning to meteorology, (4) contrast in
113 the response of lightning to dust and smoke aerosol, and (5) relative roles of meteorology and AOD
114 in lightning activity, finally followed by a summary of the key findings in section 5.

115 **2. Data and Method**

116 *2.1 Data*

117 *2.1.1 Lightning data*

118 We employ lightning data from the Lightning Imaging Sensor (LIS) onboard Tropical Rainfall
119 Measuring Mission (TRMM), which is designed to acquire and investigate the distribution and
120 variability of total lightning (i.e. intra-cloud and cloud-to-ground) on a global basis, span all
121 longitudes between 38°N-38°S, during day and night (Boccippio, 2002; Christian et al., 2003).
122 The LIS on TRMM monitors individual storms and storm systems at a nadir field of view
123 exceeding 580 km×580 km with a detection efficiency of 69%-90%. We employ the gridded
124 lightning climatology dataset during a 11-year period (2003-2013) called the low resolution
125 monthly time series (LRMTS) that provides flash rate per month at a 2.5°×2.5° spatial resolution
126 and is recorded in coordinated universal time (UTC). The low-resolution diurnal climatology
127 (LRDC) depicts the mean diurnal cycle in local solar time (LT) on the same spatial resolution
128 (Cecil et al., 2001; 2006; 2014) .

129 *2.1.2 Aerosol data*

130 Aerosol loading is characterized by aerosol optical depth (AOD), which is obtained from
131 observations collected by the Moderate Resolution Imaging Spectroradiometer (MODIS) onboard
132 Aqua satellite that passes at ~ 13:30 local time (LT). Here, the level 3 atmosphere monthly global
133 product (MYD08_M3) on 1°×1° grid is used. This AOD is retrieved at 0.55 μm, based on dark
134 target-deep blue combined algorithm, which is particular suitable over desert regions (Hubanks et
135 al., 2015; Levy et al., 2013) . The Modern Era Retrospective-analysis for Research and Application
136 (MERRA) is a NASA meteorological reanalysis taking advantage of satellite data dated to 1979
137 till present using the Goddard Earth Observing System Data Assimilation System Version 5

138 (GEOS-5). The assimilation of AOD in the GEOS-5 involves very careful cloud screening and
139 data homogenization by means of a Neural Net scheme that translates MODIS radiances into
140 Aerosol Robotic Network (AERONET) calibrated AOD. The MERRA Aerosol Re-analysis
141 (MERRAero) provides dust, black carbon, organic carbon, and total extinction AOD, and the total
142 Angstrom Exponent (AE) at a spatial resolution of $0.625^\circ \times 0.5^\circ$ (da Silva, et al., 2015). These data
143 characterize aerosol species and particle size.

144 *2.1.3 Meteorological data*

145 Meteorological data utilized are from the Medium-Range Weather Forecasting (ECMWF)
146 ERA-Interim reanalysis product (Dee et al., 2011), including the surface upward sensible heat flux
147 (SHF), surface upward latent heat flux (LHF), sea level pressure (SLP), 2m air temperature (T),
148 convective available potential energy (CAPE), relative humidity (RH), wind field at 925 hPa and
149 500 hPa (U, V), divergence at 200 hPa (Div) with a spatial resolution of $1^\circ \times 1^\circ$. With reference to
150 the findings from previous studies, we choose the following factors to characterize meteorology:

151 1) Convective available potential energy (CAPE). CAPE is the most commonly used
152 thermodynamic parameter, which describes the potential buoyancy available to idealized rising
153 air parcels and thus denotes the instability of atmosphere (Riemann-Campe et al., 2009;
154 Williams, 1992). The bigger it is, the atmosphere is more unstable, and more favorable to the
155 occurrence and development of convection. Lightning activity increases with the CAPE
156 (Williams, 1992). The conversion efficiency of CAPE to updraft kinetic energy (Williams et
157 al., 2005) depends on the strength and width of updraft. Unfortunately, we don't have any

- 158 reliable updraft measurements to tackle with its role in this study.
- 159 2) Sea level pressure (SLP). It's widely known that pressure is a key meteorological factor
160 affecting the weather, for it defines basic weather regimes. Low pressure systems are usually
161 associated with strong winds, warm air, and atmospheric lifting, thus normally producing
162 clouds, precipitation, and severe weather events such as storms and cyclones. The implication
163 of summertime SLP anomalies in the tropical Atlantic region shows the inverse relationship
164 between SLP and tropical cyclones (Knaff, 1997).
- 165 3) Potential temperature (θ). Many researchers have studied the role of air temperature in
166 influencing lightning activities (Markson, 2003; Williams, 1992; 1994; 1999; Williams et al.,
167 2005). However, the direct comparison of temperature for different regions is problematic
168 because air temperature is systematic decline with altitude. We choose potential temperature
169 instead, which corrects for the altitude dependence and provides a more meaningful
170 comparison. Here, potential temperature θ is calculated from 2 m air temperature T (K):
- 171
$$\theta = T \left(\frac{1000}{p} \right)^{0.286} \quad (1)$$
- 172 4) Relative humidity (RH). As one of the important thermodynamic factors, RH has been
173 identified to affect the relationship between aerosols and convection (Fan et al., 2007; Fan et
174 al., 2009; Khain and Lynn, 2009). It was found that for isolated clouds formed in a relative dry
175 condition convection is suppressed by aerosols, whereas for convective systems inside a moist
176 environment convection is invigorated (Khain and Lynn, 2009; Khain et al., 2008). The mean
177 RH values at 700 and 500 hPa levels (mid-level RH) are employed in this study.
- 178 5) Wind Shear. The vertical shear of horizontal wind (U , V), hereafter simply referred as wind

179 shear or SHEAR, has been shown not only to affect the dynamical flow structures around and
180 within a deep convective cloud (Coniglio et al., 2006; Rotunno et al., 1988; Weisman and
181 Rotunno, 2004), but also qualitatively determines whether aerosols suppress or enhance
182 convective strength (Fan et al., 2009). It is calculated from daily wind field at 925hPa and
183 500hPa as follows:

$$184 \quad \text{SHEAR} = \sqrt{(U_{500} - U_{925})^2 + (V_{500} - V_{925})^2} \quad (2)$$

185 6) Divergence (Div). Air divergence is especially useful, because it can be linked to diabatic
186 heating processes, of which, the non-uniformity gives rise to atmospheric motion (Homeyer et
187 al., 2014; Mapes and Houze, 1995). Fully developed clouds are usually accompanied by upper-
188 level divergence especially in raining regions (Mapes and Houze, 1993). A pronounced
189 divergence maximum exists between 300 and 150 hPa due to deep convective outflow
190 (Mitovski et al., 2010).

191 Besides, bowen ratio (BR) is calculated from SHF and LHF to describe surface property:

$$192 \quad \text{BR} = \frac{\text{SHF}}{\text{LHF}} \quad (3)$$

193 2.2 Method

194 2.2.1 Data collocation

195 A roughly three-month smooth average is chosen to allow LIS to progress through the diurnal
196 cycle at a given location twice (Cecil et al., 2014), and show the normal annual variation of
197 lightning activity due to the seasonal meridional migration of the intertropical convergence zone
198 (Thornton et al., 2017; Waliser and Gautier, 1993). In order to match lightning data, all AOD and

199 meteorological data are calculated by taking 3-month running mean and resampled to $2.5^{\circ} \times 2.5^{\circ}$
200 resolution grids in the climatic analysis. In order to make the comparison within the same AOD
201 range and increase the number of data samples, climatological features of lightning, AOD and
202 meteorology under polluted and clean conditions are limited to the cases with $AOD < 1.0$ over both
203 ROIs. The top third of AOD is labeled as polluted case and the bottom lowest third is labeled as
204 clean case. All data are sorted by AOD, and divided into three equal-sample subsets to create
205 sufficient contrast between polluted and clean conditions.

206 *2.2.2 Statistical analysis method*

207 Correlation coefficients are used in statistics to measure how strong a relationship between
208 lightning flashes and one predictor (SLP, θ , RH, CAPE, SHEAR, Div, AOD). Pearson correlation
209 is commonly used in measuring linear correlation. And partial correlation is performed to control
210 other predictors and make it possible to study the effect of each predictor separately. The
211 correlation is considered to be significant when it passes the significant test at 0.05 level.

212 In order to explore the relative roles of meteorological variables and AOD in lightning
213 activities, we use multiple-linear regression method follow previous studies (e.g. Igel and van den
214 Heever, 2015; Stolz et al., 2017) and establish standardized regression equation for AOD greater
215 and less than 0.3 respectively. This subsection regression is performed to reduce nonlinear effect
216 of AOD. Note that, all data used here are processed by averaging 10 samples sorted by AOD from
217 small to large to mitigate data uncertainties. The standardized regression equation with seven
218 predictor variables x_1, x_2, \dots, x_7 (SLP, θ , RH, CAPE, SHEAR, Div, AOD) and a response y

219 (lightning flashes), can be written as:

$$220 \quad y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_i x_i \quad i = 1, \dots, 7 \quad (4)$$

221 Here, y and x_i are standardized variables, which are derived from raw variables Y and X_i by

222 subtracting the sample mean (\bar{Y} , \bar{X}_i) and divided by the sample standard deviation (δ_Y , δ_i):

$$223 \quad y = \frac{Y - \bar{Y}}{\delta_Y}, \quad x_i = \frac{X_i - \bar{X}_i}{\delta_i}, \quad i = 1, \dots, 7 \quad (5)$$

224 The sample mean is calculated of N valid samples:

$$225 \quad \bar{Y} = \frac{\sum_1^N Y_j}{N}, \quad \bar{X}_i = \frac{\sum_1^N X_{ji}}{N}, \quad i = 1, \dots, 7; \quad j = 1, \dots, N \quad (6)$$

226 The sample standard deviation is:

$$227 \quad \delta_Y = \sqrt{\frac{1}{N-1} \sum_1^N (Y_j - \bar{Y})^2}, \quad \delta_i = \sqrt{\frac{1}{N-1} \sum_1^N (X_{ji} - \bar{X}_i)^2}, \quad i = 1, \dots, 7; \quad j = 1, \dots, N \quad (7)$$

228 Standardized regression coefficients ignore the independent variables' scale of units, which make

229 slope estimate comparable and show the relative weights to the changes of lightning flashes.

230 **3. Region of Interest (ROI)**

231 The northern and southern Africa has high aerosol loadings of dust and smoke aerosols

232 respectively, as seen in Fig. 1. Northern Africa is the world's largest source of mineral dust

233 (Lemaître et al., 2010), with the most widespread, persistent dust aerosol plumes and the most

234 dense particulate contribution found on Earth (Prospero et al., 2002). It has been estimated about

235 2-4 billion tons of blown dust globally comes from the Saharan desert (Goudie and Middleton,

236 2001). Dust of relevance to atmospheric processes are the minerals that can be readily suspended

237 by wind (Shao, 2008) with particle size up to 70 μm . Besides, Africa is also the single largest

238 source of smoke emissions due to widespread biomass burning, accounting roughly for 30 to 50%

239 of the total amount of vegetation burned globally each year (Andreae, 1991; Roberts et al., 2009;
240 van der Werf et al., 2003; 2006). In Central and Southern Africa, biomass burning due to wildfires
241 and human-set fires has strong diurnal and seasonal variability (Ichoku et al., 2016; Roberts et al.,
242 2009).

243 The upper left panel of Figure 1 shows the global distribution of mean aerosol optical depth
244 (AOD) from the MODIS onboard Aqua satellite during the period from 2003 to 2013. The lower
245 left panel is the Angstrom Exponent (AE) obtained from the Modern-Era Retrospective analysis
246 for Research and Application (MERRA) Aerosol Reanalysis (MERRAero) at a $0.625^\circ \times 0.5^\circ$ spatial
247 resolution for analysis of contributions from different aerosol species, chiefly, dust, black carbon
248 (BC), organic carbon (OC) and total extinction AOD. Note that the satellite retrievals of the AE
249 have too large uncertainties over land. The Africa stands out very distinctly with very large AOD
250 in two regions: Sahara covered by dust (the upper right panel) and central to south (lower right
251 panel) Africa by smoke, characterized by small and large values of angstrom index (lower left
252 panel). Due to their distinct differences in aerosol species, they are selected as the regions of our
253 interest ROI_1 and ROI_2 (Fig. 2a). The ratios of dust (ROI_1) or (BC+OC) (ROI_2) extinction
254 AOD to total extinction AOD are larger than 50% averaged over the period 2003-2013, which
255 enables us to study any different effects on lightning activities.

256 4. Results and Discussion

257 4.1 Long-term climatological features of lightning and aerosol

258 Figure 2a shows the mean wind vector at 850 hPa from the ERA-Interim re-analysis at a spatial

259 resolution of $1^\circ \times 1^\circ$ over the Africa and the neighbouring ocean over the region defined in Fig. 1
260 (red rectangle). Figure 2 also shows the the diurnal cycle (b) and monthly variation (c, d) of AOD
261 and lightning flashes as caculated under relatively clean and polluted (dusty/smoky) conditions
262 over dust dominant region (ROI_1) and smoke aerosol dominant region (ROI_2) with color orange
263 and black, respectively. Note that AOD used hereinafter is derived from MODIS, and the lowest
264 (highest) third of AOD is labeled as clean (polluted) condition. The diurnal curves in Fig. 2b show
265 the same afternoon peak in lightning activities, which is in accordance with the strong convection
266 in terms of both the number and intensity of convective clouds in afternoon over land (Nesbitt and
267 Zipser, 2003). Over both ROI_1 and ROI_2, the lightning peak times under polluted (dusty/smoky)
268 conditions are delayed by about 1h compared with that under clean condition. This result is
269 consistent with the obsevation-based finding in southern China (Guo et al., 2016) and model
270 simulation results by Lee et al. (2016). Numerous studies have noted that aerosols modulate
271 convection and lightning activities through both radiative and microphysical processes, as
272 reviewed extensively by Li et al. (2016) in Asia and around the world (Li et al., 2017b). When we
273 look into the monthly variation, dust loading changes little through the whole year (Fig. 2c), while
274 smoke shows pronounced seasonal variation of a huge contrast between dry and wet seasons (Fig.
275 2d). Lightning in both regions is most active in summer and rarely occurs in winter, which implies
276 that lightning activity is mainly controlled by thermodynamic conditions. Besides, also shown in
277 Fig. 2 is the apparent enhancement of lightning activity under smoky conditions superimposed on
278 both the diurnal and seasonal cycles. Under dusty conditions, however, the impact is much weaker.
279 Apart from different aerosol effects, different climate conditions between dust and smoke aerosol

280 dominant region may also contribute. A key factor is relative humidity which is much lower over
281 the desert region of ROI_1 ($BR > 10$) than over the moist region of ROI_2 covered with rain forest
282 ($BR < 0.4$). It's widely known that high values of relative humidity are more favorable for the
283 invigoration effect and vice versa (Fan et al., 2008; 2009; Khain, 2009; Khain et al., 2008), which
284 is likely a major cause for the difference. Besides, ROI_1 locates in the vicinity of the African
285 Easterly Jet (AEJ) (Burpee, 1972) while ROI_2 locates in the ITCZ (Waliser and Gautier, 1993)
286 that lead to differences in wind shear and instability.

287 *4.2 Response of lightning to meteorology*

288 As thermodynamic condition is considered to play the main role in lightning diurnal and
289 seasonal variation. Firstly, we have a look at the response of lightning to thermodynamic condition
290 which is characterized by six meteorological variables (SLP, SHEAR, θ , CAPE, RH and Div).
291 Violin plot is an effective and attractive way to visualize the distribution of the data and the shape
292 of distribution that allows quick and insightful comparison of multiple distributions across several
293 levels of categorical variables, and is used in the analysis between lightning and meteorological
294 variables. It synergistically combines the box plot and the density trace into a single display (Hintze
295 and Nelson, 1998).

296 Figure 3 shows the linear relationships between lightning flashes and six meteorological
297 variables in ROI_1. CAPE, RH and Div are the top three meteorological variables strongly and
298 positively correlated with lightning flashes ($R > 0.7$), which suggests that high RH and CAPE are
299 conducive to the development of intense convection and lightning occurrence that is always

300 associated high level divergence. One thing to notice is the variable density shape in Fig. 3f. The
301 bimodal distribution indicates that small to moderate high level divergence may due to atmosphere
302 movement in clear sky or in-cloud with smaller updraft velocity that doesn't produce lightning,
303 while large divergence usually characterize strong upward movement which is closely associated
304 with lightning activity. Figures 3a, e show inverse correlations of lightning flashes to SLP and
305 SHEAR and Figure 3b shows weak correlation to θ , all with quite small correlation coefficients
306 that can not be considered as correlated.

307 Figure 4 shows the linear correlations between lightning flashes and six meteorological
308 variables associated with strong convection for ROI_2. It is evident that RH, CAPE, and Div are
309 positively associated with the occurrence of lightning, in sharp contrast to SLP, θ , and SHEAR that
310 are negatively connected with lightning. In particular, Figures 4a, c, d, e show that CAPE, RH,
311 Div, and SLP are significantly correlated with lightning ($|R| > 0.75$, $p < 0.05$), indicating that these
312 four meteorological variables could be the major factors modulating the changes in lightning. By
313 comparison, the weak linear relationship exists between lightning and θ ($R = 0.47$), which is case
314 for the relationship between lightning and SHEAR ($R = -0.08$), indicative of their minor effect on
315 lightning (Figs. 4b, 4g). Note that the correlation coefficients obtained here can only describe the
316 possible dependencies between lightning and meteorological variables, which cannot imply the
317 causal relationship.

318 In order to give a visual comparison of ROI_1 and ROI_2, we show the spatial distribution of
319 correlation coefficients between lightning and meteorological variables. Spatially, Figure 5 shows
320 that lightning flashes are well correlated with RH, CAPE, and Div throughout ROI_1 and ROI_2.

321 After we constrain the variations of AOD and other five meteorological variables, partial
322 correlation analyses show that only CAPE and RH are the top two factors affecting lightning
323 activities (Fig. 6).

324 4.3 Contrast in the response of lightning to dust and smoke aerosol

325 Aerosols can modulate lightning activities through participating in radiative and microphysical
326 processes. The roles of dust and smoke aerosols in modulating lightning activity are examined in
327 Fig. 2 and Fig. 7. The diurnal cycle of lightning flashes in Fig. 2 shows that, for both dust and
328 smoke aerosols, the lightning peak times under polluted conditions are delayed by about 1h.
329 Besides, smoke aerosols tend to apparently enhance lightning activity on both diurnal and seasonal
330 cycles, while the impact of dust is much weaker.

331 Figure 7 shows that from clean to polluted condition, lightning response to AOD in an apparent
332 boomerang shape (Koren et al., 2008) in both dust and smoke aerosol dominant regions, with a
333 turning point around $AOD=0.3$. In order to reduce the effect of non-linearity, data are divided into
334 two subsets before and after the turning point when perform correlation and regression. For AOD
335 less than 0.3, lightning flashes increase monotonously with increasing aerosol loading in both
336 regions. Clusters of the data are aligned around the regression lines rather tightly, implying that
337 lightning flashes are strongly and positively correlated ($R>0.75$) with AOD. However, for AOD
338 exceeding 0.3, the data points are more scattered and the trend is reversed, which imply that under
339 large aerosol loadings, lightning is mainly influenced by other factors, such as meteorology.
340 Specifically, under smoky conditions, the correlation coefficient becomes negative (-0.15) and fails

341 the significant significance test at 0.01 level, suggesting a suppressing effect is yielding to the
342 invigoration effect. Under dusty conditions, the negative correlation is more significant with a
343 correlation coefficient of -0.41, suggesting a stronger suppression under heavy dust conditions
344 (Farias et al., 2014). Besides, we can easily find that lightning activity is much more intense in
345 smoke aerosol dominant region that located in ITCZ where air is hot and humid, regardless of
346 aerosol loading. In contrast, dust dominant region is much drier that is not so easy to produce
347 intense convection and lightning.

348 *4.4 Environmental dependence of aerosol effect*

349 To further clarify the joint influences of meteorology and aerosols on lightning activity, the
350 distribution of lightning flashes with AOD and the top two influential meteorological variables RH
351 and CAPE (based on the results in Figs. 3-6) are examined in Fig. 8. Lightning flashes are classified
352 into 100 discrete cells by ten decile bins of AOD – CAPE, AOD – RH, and CAPE – RH
353 respectively, which ensures approximately equal sample sizes among the cells. The mean values
354 are calculated in each cell. Results show that, for each CAPE bin, lightning flashes increase with
355 increasing aerosol loadings under relatively clean condition, but decrease after the turning point
356 around AOD=0.3 in both regions. When AOD is fixed, lightning flashes monotonically increase
357 with CAPE. Irrespective of aerosol loadings and regions, lightning rarely occurs when CAPE is
358 less than 100 J kg^{-1} from a climate perspective, that accounts for about half of the data in ROI_1.
359 Systematically higher CAPE in ROI_2 induces more intense lightning activity than in ROI_1.
360 However, lightning flashes response to RH in different ways for ROI_1 and ROI_2 when AOD is

361 fixed (Figs. 8b, 8d). In dust dominant region, lightning flashes monotonically increase as RH
362 increases under any level of aerosol loadings, but changes a little as AOD increases in each RH
363 bin. This suggests that, apart from CAPE, RH is another constraint of lightning activity in ROI_1.
364 But for smoke aerosol dominant region, high lightning flashes appear in the environment of
365 moderate RH and high aerosol loadings. When RH is fixed, the response of lightning flashes to
366 AOD also shows a turning point in AOD around $AOD=0.3$, beyond 0.3, lightning flashes remain
367 high value. When looking into the common role of RH and CAPE on lightning, the data distributes
368 along the diagonal which shows that RH is highly correlated with CAPE, and they affect lightning
369 activity in the same direction. Generally, intense lightning activity occurs under the condition of
370 both high RH ($>40\%$) and high CAPE ($>100 \text{ J kg}^{-1}$) in ROI_1. In ROI_2, high CAPE and high RH
371 are still conducive to lightning production, but data disperse in a larger range, which suggests that
372 the correlation of RH and CAPE are not as high as in ROI_1, and the restriction of RH is reduced.

373 As shown in Fig. 2 and Figs. 7, 8, the differences of lightning response to aerosols in ROI_1
374 and ROI_2 may also contribute to different climate conditions. In order to isolate the signal
375 attributed to aerosol loadings from that attributed to environmental forcing, lightning flashes are
376 separated by six meteorological variables (SLP, SHEAR, θ , CAPE, RH and Div) respectively.
377 Figure 9 shows the differences of lightning flashes between polluted and clean conditions (polluted
378 minus clean datasets) as a function of SLP, SHEAR, θ , CAPE, RH and Div. Generally, there are
379 more lightning flashes for all these meteorological variables under polluted conditions when
380 compared with that under clean conditions in both ROI_1 and ROI_2. All the lightning enhancement
381 under polluted conditions are highly significant ($>99\%$), based on Student's test. The differences

382 of lightning flashes between polluted and clean conditions are smaller in ROI_1 than in ROI_2.
383 Besides, to note that, when SLP gets lower and RH gets larger, the differences of lightning flashes
384 (polluted minus clean datasets) becomes larger. This suggests that under conducive condition,
385 aerosols are more likely to participate in cloud process, convection development and thus modulate
386 lightning activity.

387 *4.5 Relative roles of meteorology and AOD in lightning*

388 The response of lightning to changes in AOD may indicate an aerosol effect on lightning
389 activity, but can also be the result of meteorology impacting on aerosol loadings and cloud
390 microphysical process that is closely associated with lightning production. To further explore this
391 complex process, the correlation of aerosol – lightning, meteorological variables – lightning,
392 aerosol-meteorological variables were examined before and after the turning point (AOD=0.3)
393 respectively, results are shown in Fig. 10.

394 For clean condition (AOD<0.3) in the ROI_1, all meteorological variables and AOD show
395 good correlations with lightning (Pearson1: $|R| > 0.5$). Considering the interaction between
396 aerosol and meteorology, the correlation coefficients between AOD and six meteorological
397 variables are calculated. Results show strong and positive correlation between AOD and RH,
398 CAPE, Div, θ (Pearson2: $R > 0.6$), negative correlation between AOD and SLP, SHEAR (in order
399 of correlation strength, so as the following). To investigate the relative roles of these variables
400 (AOD and six meteorological variables), we carry out partial correlation analyses between
401 lightning and any influential factor while constraining all the others, and establish the standardized

402 multiple regression equation, of which the coefficients represent the relative importance of each
403 factor. After the common effects are constrained, partial correlation coefficients are much smaller
404 compared to Pearson correlation coefficients, and the correlation between lightning and SLP, θ ,
405 AOD are not significant any more. It's envisioned that lightning doesn't respond much to dust
406 aerosols directly, but dust can affect convection and lightning activities through modulating
407 meteorological variables. From these analyses, the top three factors are found to be RH, CAPE, and
408 Div for dust dominant region under relatively clean condition. For clean ROI_2, the analyses show
409 strong positive correlation between lightning and CAPE, AOD, Div (Pearson1: $|R| > 0.7$), strong
410 negative correlation between lightning and SLP (Pearson1: $R = -0.94$), weak negative correlation
411 between lightning and θ , SHEAR (Pearson1: $|R| < 0.4$). Main interplay exists between AOD and
412 SLP, CAPE (Pearson2: $|R| > 0.75$). The partial correlation coefficients and coefficients of
413 standardized multiple regression equation reveal top three factors: CAPE, AOD, and RH (Partial:
414 $R > 0.35$). Different from RH as the top restraint factor in dust dominant region, here it plays a
415 smaller role in the humid environment. Besides, AOD becomes more important. In both regions,
416 aerosols correlate well with meteorology, which could be the reason for the tight cluster distribution
417 for AOD less than 0.3 in Fig. 9. CAPE measures the amount of moist static energy that is available
418 to drive the convection (Rosenfeld et al., 2008). The high correlation between AOD and CAPE in
419 both regions suggests that aerosol might modulate environment variables and participate in cloud
420 microphysical process. A possible explanation is that more aerosols acting as CCN, lead to
421 narrower cloud droplet size spectrum, delay warm-rain process, allow more liquid water to ascend
422 higher into mixed-phase cloud, thus release more latent heat, produce more unstable atmosphere

423 and larger CAPE which is conducive to convection development. The aerosol invigoration effect
424 may play the key role during this stage ($AOD < 0.3$).

425 Under polluted conditions, CAPE and RH are still of paramount importance for lightning
426 activity (Pearson1: $R > 0.8$; Partial: $R > 0.35$), but the correlation between aerosol and meteorology
427 are weakened. This weak connection between aerosol and meteorology results in a large dispersion
428 of lightning flashes under polluted conditions in both regions. The most important finding appears
429 to be that the negative correlation of AOD with CAPE (Pearson2: $R = -0.51$), and RH (Pearson2:
430 $R = -0.33$) in ROI_1 suggests that increasing dust aerosols may make environment drier, and
431 atmosphere more stable through aerosol radiative effect which leads to the suppression of
432 convection and lightning. While in ROI_2, AOD is negatively correlated with RH (Pearson2: $R = -$
433 0.24) and θ (Pearson2: $R = -0.74$) which indicate the similar role of smoke aerosols in making
434 environment drier and surface cooling through radiative effect. But, there's no significant
435 correlation between AOD and CAPE (Pearson2: $R = 0$, $p > 0.05$), which may imply the radiative
436 effect and invigoration effect are comparable under heavy loading condition.

437 5. Conclusions

438 Depending on specific environmental condition, aerosols are able to invigorate or suppress
439 convection induced lightning activity in previous studies, the majority being case based. The
440 controversial conclusions motivate us to study the long-term effects of aerosols and meteorology
441 on lightning activity. Here, meteorology is characterized by six variables: sea level pressure (SLP),
442 potential temperature (θ) at 2 m above ground level, mid-level relative humidity (RH), convective

443 available potential energy (CAPE), vertical wind shear (SHEAR), and 200 hPa divergence (Div).
444 The current study investigates the response of lightning activity to meteorology and AOD over
445 dust and smoke dominant regions from a climatological perspective. In particular, 11-year (2003-
446 2013) worth of coincident data are used, including lightning data from LIS/TRMM, AOD from
447 MODIS/Aqua, and meteorological variables from ECMWF ERA-Interim reanalysis.
448 Climatological features of diurnal and seasonal variations of lightning flashes show the peak in the
449 afternoon and local summer respectively, which suggests a dominant role by thermodynamics,
450 while the differences in lightning under relatively clean and polluted conditions signify the
451 potential influences of aerosols. Specifically, under all stratified meteorological environments,
452 lightning flashes are larger under polluted conditions than under clean condition. And the
453 differences of lightning flashes in ROI_2 are larger than in ROI_1. Besides, lightning flashes
454 increased much more when SLP gets lower and RH gets larger.

455 Despite complex and diverse climatic conditions, the response of lightning to dust and smoke
456 aerosols show in a boomerang shape with an optimum value of AOD around 0.3. We performed
457 correlation analysis and standardized multiple regression analysis in attempt to constrain the
458 effects of meteorology, and quantify the relative roles of these factors in modulating lightning.
459 Under relative clean conditions, standardized multiple regression coefficients of meteorology and
460 AOD on lightning in both regions exhibit $R_M^2 \geq 0.92$, with RH and CAPE being the top two
461 determinant factors. The contribution of RH is comparable with that of CAPE in dust dominant
462 region, and less in smoke aerosols dominant region. The narrow distribution and high correlation
463 between aerosol and meteorology imply that the impact of AOD on lightning activities is likely to

464 be exerted through microphysical effect which modulate meteorological variables. Beyond the
465 optimum value, lightning shows more dispersed distribution and has much weaker dependence on
466 AOD, which may be the consequence of competition between aerosol microphysical effect and
467 radiative effect. Under smoky conditions, R_M^2 for the standardized multiple regression equation
468 diminishes to 0.77 with a strong negative correlation ($r=-0.74$) with θ , and weak negative
469 correlation with mid-level RH and no correlation with CAPE. Note that aerosol cools surface and
470 warms mid-level atmosphere through radiative effect, which may be less (for $AOD < 0.3$), more
471 ($AOD > 0.3$) or equal ($AOD = 0.3$) to the aerosol microphysical effect. Under dusty condition, the
472 standardized equation has a higher R_M^2 (0.83), aerosol radiative effect plays a dominant role,
473 possibly leading to stable atmosphere, and suppression of convection and lightning. Lightning
474 responds to AOD in different ways between ROI_1 and ROI_2 mainly because of the different
475 humidity conditions. Totally, for dust dominant region, moisture is the maximum constraint, high
476 CAPE, high RH and moderate aerosol help intensify lightning activity. For smoke dominant region,
477 large values of CAPE, RH and AOD (up to 0.3) fuel lightning. However, the influences of state
478 variables or transient variables (SHEAR, Div) are largely filtered out from the climatological
479 perspective. Until now, we cannot totally filter out, but constrain the confounding effect of
480 meteorological variable on lightning based on observations alone. More insightful analyses are
481 warranted in the future based on a combination of state-of-the-art observations and convection-
482 revolved model simulation.

751

752

753 **Figure 1.** Global spatial distribution maps of (a) AOD (550 nm) as derived from MODIS at a
754 spatial resolution of $1^\circ \times 1^\circ$, and (b) Total aerosol angstrom parameter (470-870 nm) from MERRA
755 dataset on a $0.625^\circ \times 0.5^\circ$ grid for the period 2003-2013. Also shown is the distribution of the ratio
756 of dust AOD to total AOD over the region of interest outlined in red box (in panel a), and panel d
757 is same as panel c, but for the ratio of (BC+OC) AOD to total AOD. Dust, black carbon, organic
758 carbon and total extinction AOD used here are all derived from MERRAero dataset (da Silva et
759 al., 2015).

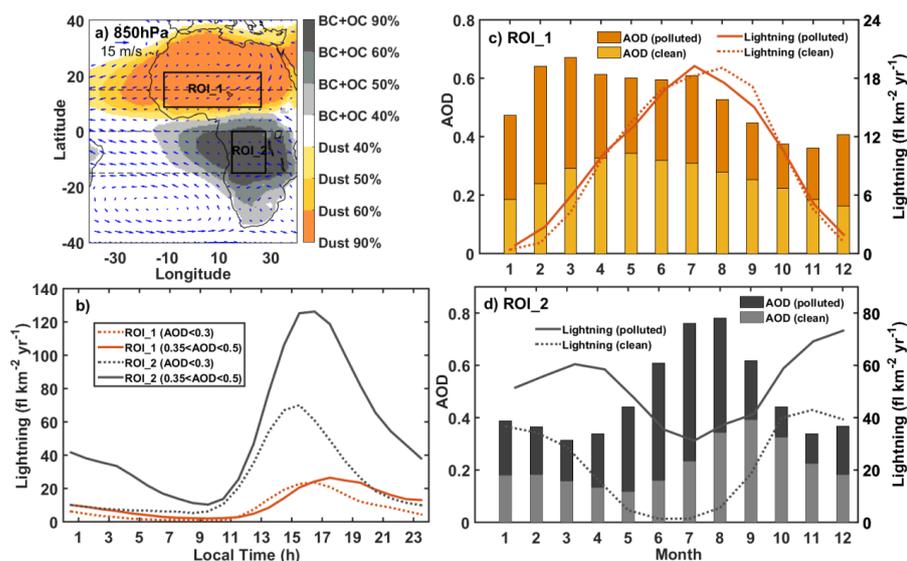

Figure 2. (a) The distribution of 850 hPa mean wind field from ERA-Interim re-analysis with a spatial resolution of $1^\circ \times 1^\circ$ showing the prevailing wind direction over Africa and the neighbouring ocean over the region of interest (ROI) defined in Fig. 1. ROI_1 and ROI_2 (highlighted in black rectangles) are chosen with the ratio of dust or (BC+OC) extinction AOD to total extinction AOD being greater than 50% averaged over the period from 2003 to 2013, which enable us to better understand the potential effect of dust or smoke aerosols on lightning, respectively. Also shown are the diurnal cycle (b) and monthly variation (c, d) of AOD and lightning flashes as calculated under relatively clean and polluted (dusty/smoky) conditions in dust dominant region (ROI_1) and smoke dominant region (ROI_2), respectively. Unless noted otherwise, AOD used in this study is derived from MODIS, and the lowest (highest) third of AOD is labeled as clean (polluted) condition. Lightning flashes come from the low resolution monthly time series (LRMTS) and the low resolution diurnal climatology (LRDC) products on a $2.5^\circ \times 2.5^\circ$ grid (Ceil et al., 2001; 2006; 2014).

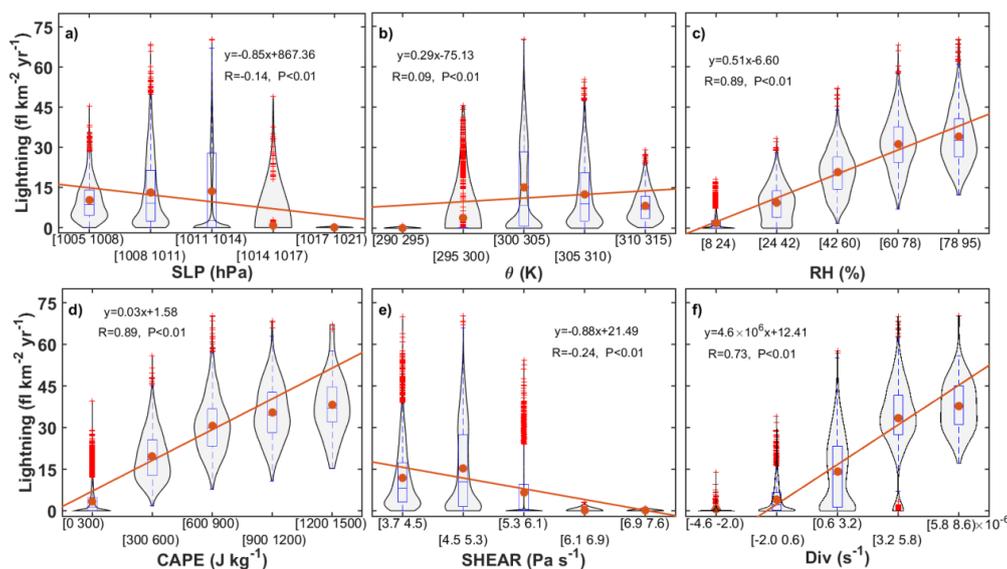

Figure 3. Violin plots of lightning dispersion showing the relationship of lightning with six meteorological variables (SLP, θ , RH, CAPE, SHEAR, Div) in ROI_1. The five bins are equally-spaced. Box plots represent the interquartile range (the distance between the bottom and the top of the box), median (the band inside the box), 95% confidence interval (whiskers above and below the box) of the data, maximum (the end of the whisker above), minimum (the end of the whisker below), mean (orange dot) in each bin. Red '+' represent outliers. On each side of the black line is the kernel estimation to show the distribution shape of the data. The estimate is based on a normal kernel function, and is evaluated at 100 equally spaced points. Wider sections of the violin plot represent a high probability that members of the population will take on the given value; the skinnier sections represent a lower probability. The equations show the linear relationships (orange lines) between lightning and meteorological variables. Also given are Pearson correlation coefficients (R), p values and linear regression lines (in orange).

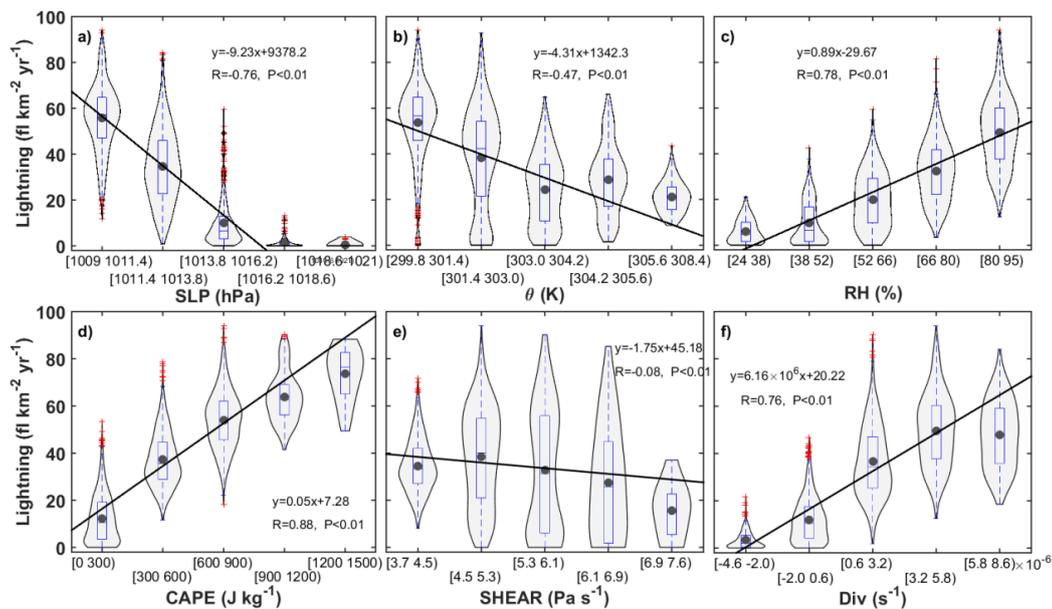

Figure 4. Same as in Fig. 3, but for ROI_2. The mean values are represented by black dots, and the linear regression lines are shown in black.

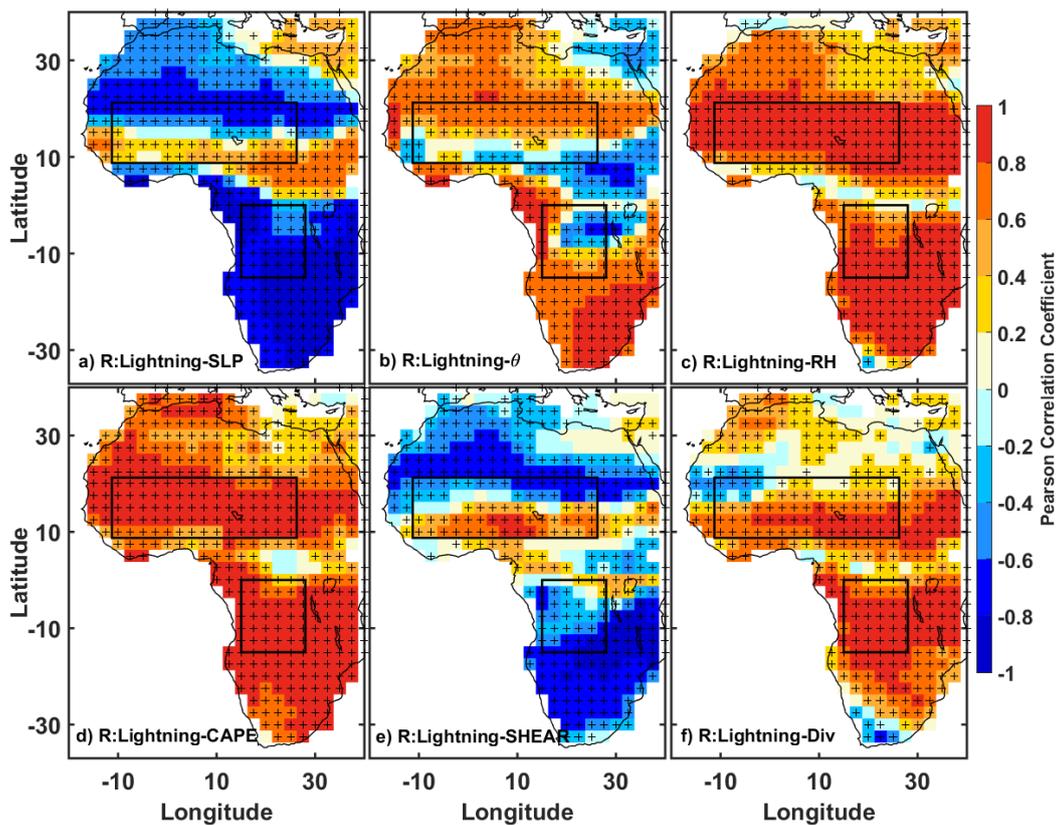

Figure 5. The map of Pearson correlation coefficients between lightning flashes and (a) sea level pressure (SLP), (b) potential temperature (θ), (c) mid-level relative humidity (RH), (d) mean convective available potential energy (CAPE), (e) vertical wind shear (SHEAR), and (f) 200 hPa divergence (Div) over Africa. ROI_1 and ROI_2 (see Fig. 2. left panel) are outlined with black boxes. '+' denotes those grids which pass the significance test of 0.05.

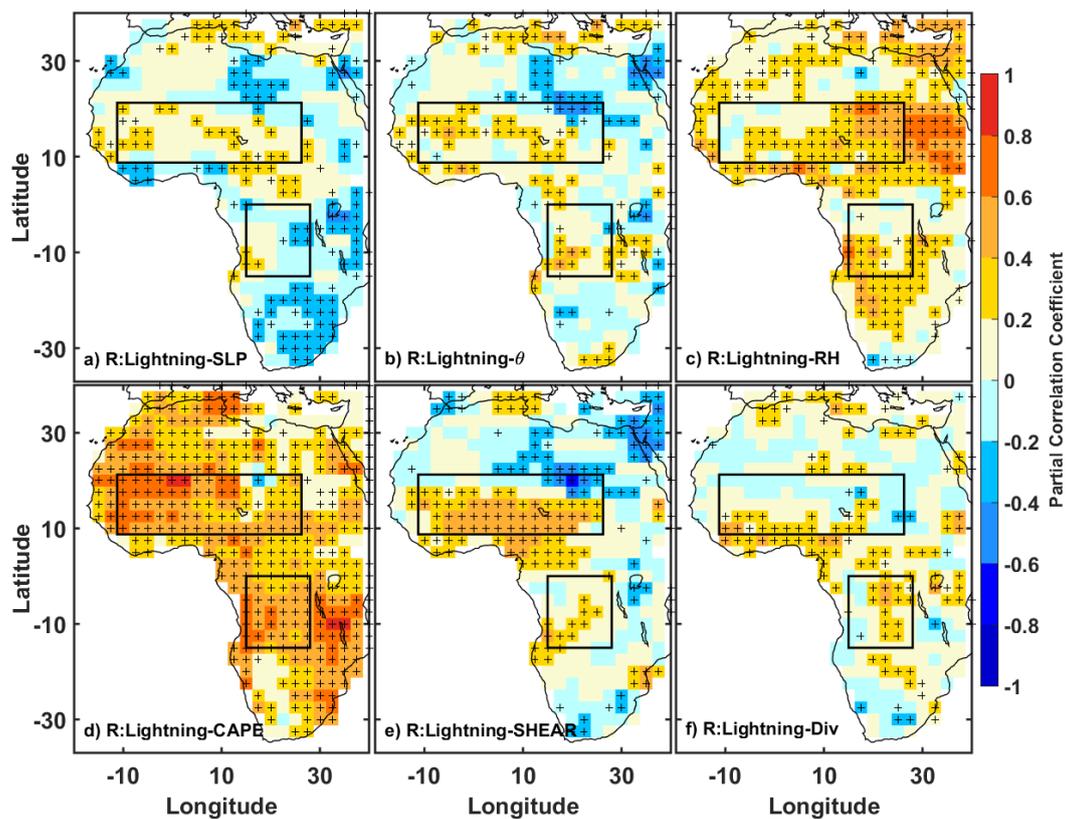

Figure 6. Same as in Fig. 5, but for partial correlation coefficients between lightning flashes and any meteorological variable while controlling AOD and the other five meteorological variables.

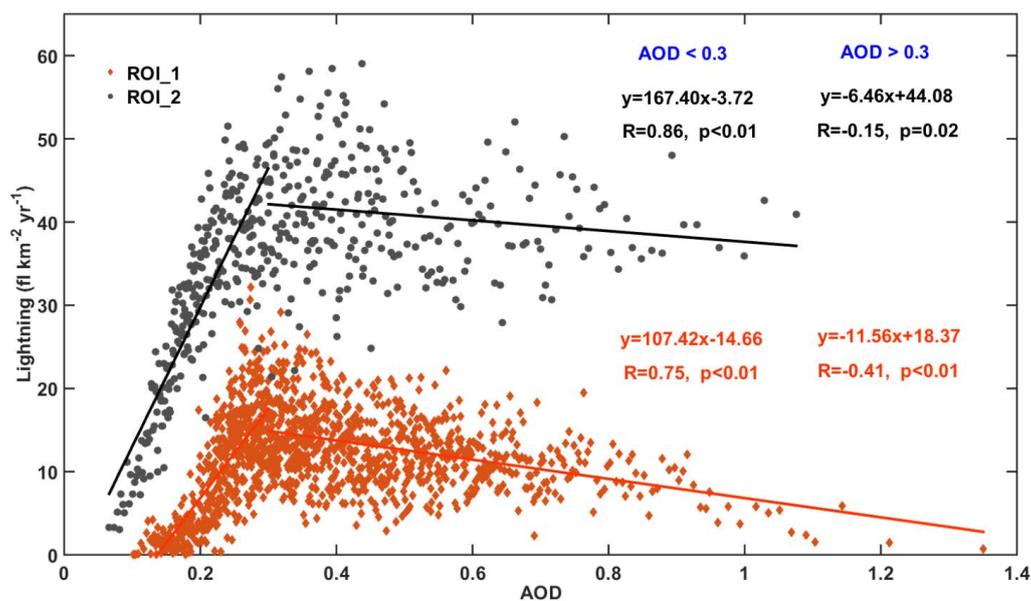

Figure 7. Scatter plot showing the response of lightning to dust or smoke aerosols in a boomerange shape in both ROI_1 and ROI_2. Turning points are around AOD=0.3. Regressions are calculated before and after the turning points in these two regions of interest. Regression equations, correlation coefficients (R), p values, and linear fitting curves are in black (orange) for ROI_1 (ROI_2). All data used here are processed with taking an average of 10 samples after ordering AOD from small to large to reduce the uncertainty caused by large dispersion of data .

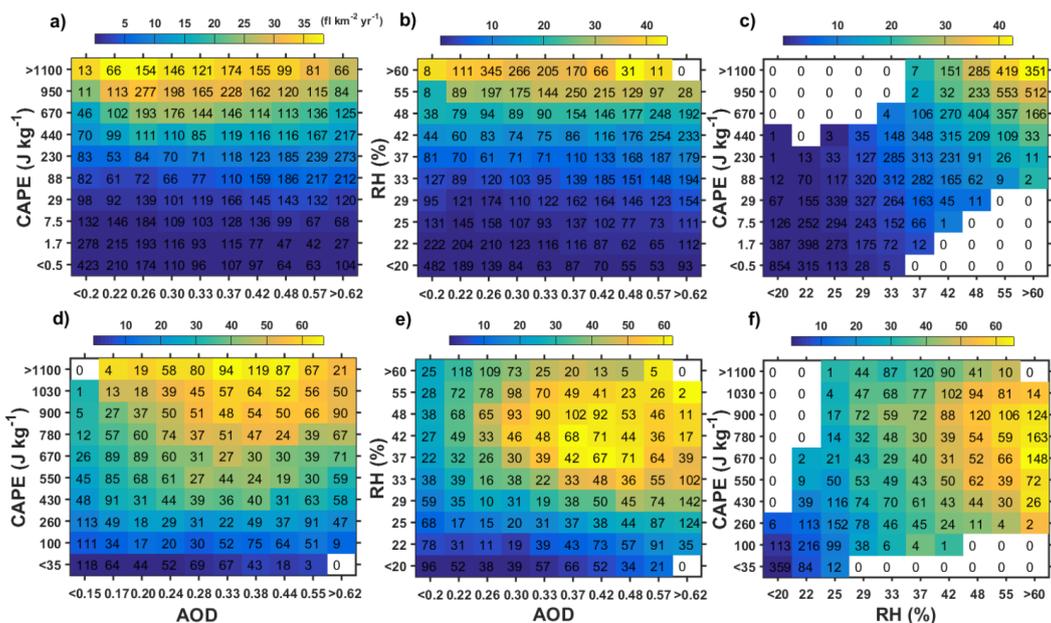

Figure 8. Joint dependence of lightning flashes on CAPE, RH, and AOD in both ROI_1 (a-c) and ROI_2 (d-f), respectively. Bold number in each cell indicate the number of samples in each cell. Colorbar denotes the number of lightning flashes averaged in each cell.

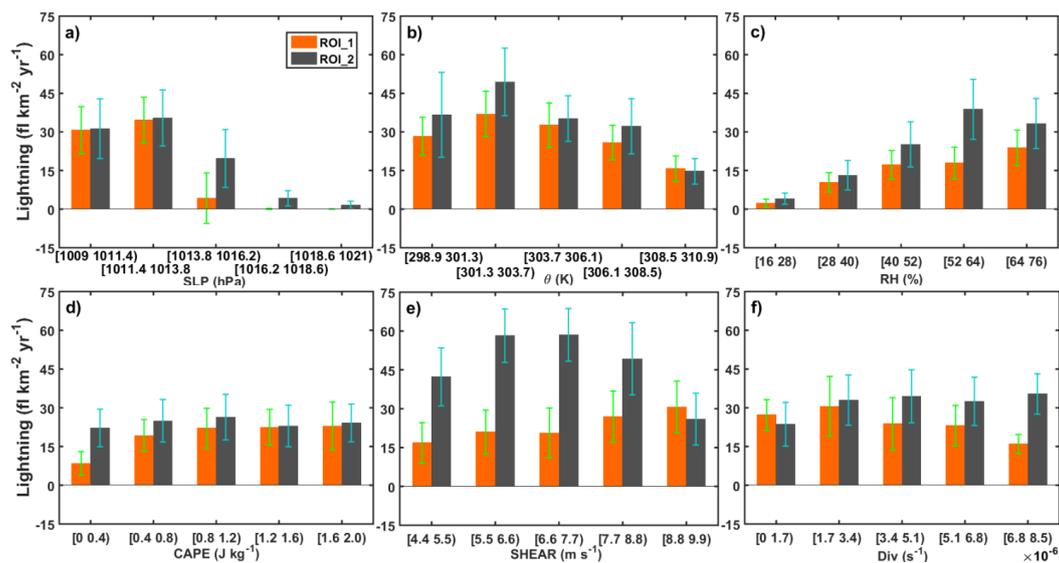

Figure 9. Differences (polluted minus clean subsets of data) of lightning flashes as a function of (a) sea level pressure (SLP), (b) potential temperature (θ), (c) mid-level relative humidity (RH), (d) convective available potential energy (CAPE), (e) vertical wind shear (SHEAR), (f) 200 hPa divergence (Div) in ROI_1 (in orange) and ROI_2 (in black). Note that, the top third of AOD is labeled as polluted case and the bottom third is labeled as clean case. Vertical error bars represent one standard deviation.

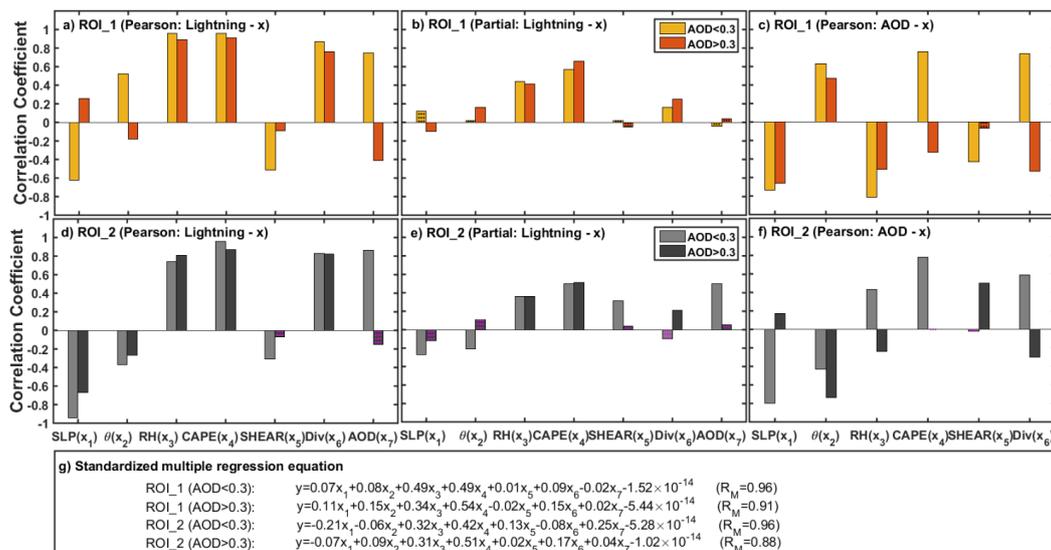

Figure 10. Correlations between AOD and meteorology, and between lightning and meteorology, AOD. (a,d) Pearson correlation coefficients between lightning and six meteorological variables and AOD (Pearson1). (b,e) Partial correlation coefficients between lightning and any influential factor (AOD or meteorological variable) while controlling the other variables (Partial). (c,f) Pearson correlation coefficients between AOD and any given meteorological variable (Pearson2). Those bars with black dots denote that they fail the statistical significance test at 95% confidence level. Also shown are standardized multiple regression equations of lightning (y) onto six meteorological variables (x₁-x₆) and AOD (x₇), and standardized multiple correlation coefficients (R_M). Six meteorological variables are SLP (x₁), θ (x₂), RH (x₃), CAPE (x₄), SHEAR (x₅), and Div (x₆).
