24 Abstract

25 Nighttime reaction of nitrate radicals (NO₃) with biogenic volatile organic compounds (BVOC)
26 has been proposed as a potentially important but also highly uncertain source of secondary
27 organic aerosol (SOA). The southeast United States has both high BVOC and nitrogen oxide
28 (NO_x) emissions, resulting in a large model-predicted NO₃-BVOC source of SOA. Coal-fired
29 power plants in this region constitute substantial NO_x emissions point sources into a nighttime
30 atmosphere characterized by high regionally widespread concentrations of isoprene. In this
31 paper, we exploit nighttime aircraft observations of these power plant plumes, in which NO₃
32 radicals rapidly remove isoprene, to obtain field-based estimates of the secondary organic
33 aerosol yield from NO₃ + isoprene. Observed in-plume increases in nitrate aerosol are
34 consistent with organic nitrate aerosol production from NO₃ + isoprene, and these are used to
35 determine molar SOA yields, for which the average over 9 plumes is 9%. Corresponding mass
36 yields depend on the assumed molecular formula for isoprene-NO₃-SOA, but the average over
37 9 plumes is 27%, larger than those previously measured in chamber studies (12 – 14% after
38 oxidation of both double bonds). Yields are larger for longer plume ages. This suggests that
39 ambient aging processes lead more effectively to condensable material than typical chamber
40 conditions allow. We discuss potential mechanistic explanations for this difference, including
41 ambient peroxy radical lifetimes and heterogeneous reactions of NO₃-isoprene gas phase
42 products. Future studies of aerosol composition from NO₃ radical + isoprene are needed to

43 better understand the oxidation chemistry producing this potentially important coupled
44 anthropogenic – biogenic source of SOA.

45 1 Introduction

46 Organic aerosol (OA) is increasingly recognized as a globally important component of the fine
47 particulate matter that exerts a large but uncertain negative radiative forcing on Earth's climate
48 (Myhre et al., 2013) and adversely affects human health around the world (Lelieveld et al.,
49 2015). This global importance is complicated by large regional differences in OA concentrations
50 relative to other sources of aerosol such as black carbon, sulfate, nitrate and sea salt. OA
51 comprises 20 – 50% of total fine aerosol mass at continental mid-latitudes, but more in urban
52 environments and biomass burning plumes, and up to 90% over tropical forests (Kanakidou et
53 al., 2005, Zhang et al., 2007). Outside of urban centers and fresh biomass burning plumes, the
54 majority of this OA is secondary organic aerosol (SOA) (Jimenez et al., 2009), produced by
55 oxidation of directly emitted volatile organic compounds followed by partitioning into the aerosol
56 phase. Forests are strong biogenic VOC emitters, in the form of isoprene (C_5H_8), monoterpenes
57 ($C_{10}H_{16}$), and sesquiterpenes ($C_{15}H_{24}$), all of which are readily oxidized by the three major
58 atmospheric oxidants, OH, NO_3 , and O_3 . The total global source of biogenic SOA from such
59 reactions remains highly uncertain, with a review estimating it at 90 ± 90 Tg C yr⁻¹ (Hallquist et
60 al., 2009), a large fraction of which may be anthropogenically controlled (Goldstein et al., 2009,
61 Carlton et al., 2010, Hoyle et al., 2011, Spracklen et al., 2011). As most NO_3 arises from
62 anthropogenic emissions, OA production from NO_3 + isoprene is one mechanism that could
63 allow for the anthropogenic control of biogenic SOA mass loading.

64
65 Isoprene constitutes nearly half of all global VOC emissions to the atmosphere, with a flux of
66 ~ 600 Tg yr⁻¹ (Guenther et al., 2006). As a result, accurate global biogenic SOA budgets depend
67 strongly on yields from isoprene oxidation. Recent global modeling efforts find that isoprene
68 SOA is produced at rates from 14 (Henze and Seinfeld 2006, Hoyle et al., 2007) to 19 TgC yr⁻¹
69 (Heald et al., 2008), which implies that it could constitute 27% (Hoyle et al., 2007) to 48%
70 (Henze and Seinfeld 2006) to 78% (Heald et al., 2008) of total SOA (based also on varying
71 estimates of total SOA burden in each study). More recent observational constraints on SOA
72 yield from isoprene find complex temperature-dependent mechanisms that could affect vertical
73 distributions (Worton et al., 2013) and suggest that isoprene SOA constitutes from 17% (Hu et
74 al., 2015) to 40% (Kim et al., 2015) up to 48% (Marais et al., 2016) of total OA in the
75 southeastern United States. This large significance comes despite isoprene's low SOA mass
76 yields – two recent observational studies estimated the total isoprene SOA mass yield to be
77 $\sim 3\%$ (Kim et al., 2015, Marais et al., 2016), and modeling studies typically estimate isoprene
78 SOA yields to be 4 to 10%, depending on the oxidant, in contrast to monoterpenes' yields of 10
79 to 20% and sesquiterpenes' yields of $>40\%$ (Pye et al., 2010). Furthermore, laboratory studies
80 of SOA mass yields may have a tendency to underestimate these yields, if they cannot access
81 the longer timescales of later-generation chemistry, or are otherwise run under conditions that
82 limit oxidative aging of first-generation products (Carlton et al., 2009).

83

84 Laboratory chamber studies of SOA mass yield at OA loadings of $\sim 10 \mu\text{g m}^{-3}$ from isoprene
85 have typically found low yields from O_3 (1% (Kleindienst et al., 2007)) and OH (2% at low NO_x to
86 5% at high NO_x (Kroll et al., 2006, Dommen et al., 2009); 1.3% at low NO_x and neutral seed
87 aerosol pH but rising to 29% in the presence of acidic sulfate seed aerosol due to reactive
88 uptake of epoxydiols of isoprene (IEPOX) (Surratt et al., 2010)). One recent chamber study on
89 OH-initiated isoprene SOA formation focused on the fate of second-generation RO_2 radical
90 found significantly higher yields, up to 15% at low NO_x (Liu et al., 2016), suggesting that omitting
91 later-generation oxidation chemistry could be an important limitation of early chamber
92 determinations of isoprene SOA yields. Another found an increase in SOA formed with
93 increasing HO_2 to RO_2 ratios, suggesting that RO_2 fate could also play a role in the variability of
94 previously reported SOA yields.

95
96 For NO_3 oxidation of isoprene, early chamber experiments already pointed to higher yields (e.g.,
97 12% (Ng et al., 2008)) than for OH oxidation. Ng et al. (Ng et al., 2008) also observed chemical
98 regime differences: SOA yields were approximately two times larger when chamber conditions
99 were tuned such that first-generation peroxy radical fate was RO_2+RO_2 dominated than when it
100 was RO_2+NO_3 dominated. In addition, Rollins et al. (Rollins et al., 2009) observed a significantly
101 higher SOA yield (14%) from second-generation NO_3 oxidation than that when only one double
102 bond was oxidized (0.7%). This points to the possibility that later-generation, RO_2+RO_2
103 dominated isoprene + NO_3 chemistry may be an even more substantial source of SOA than
104 what current chamber studies have captured. Schwantes et al. (Schwantes et al., 2015)
105 investigated the gas-phase products of NO_3 + isoprene in the RO_2+HO_2 dominated regime and
106 found the major product to be isoprene nitrooxy hydroperoxide (INP, 75-78% molar yield), which
107 can photochemically convert to isoprene nitrooxy hydroxyepoxide (INHE), a molecule that might
108 contribute to SOA formation via heterogeneous uptake similar to IEPOX. Here again, multiple
109 generations of chemistry are required to produce products that may contribute to SOA.

110
111 Because the SOA yield appears to be highest for NO_3 radical oxidation, and isoprene is such an
112 abundantly emitted BVOC, oxidation of isoprene by NO_3 may be an important source of OA in
113 areas with regional NO_x pollution. Since the SOA yield with neutral aerosol seed appears to be
114 an order of magnitude larger than that from other oxidants, even if only 10% of isoprene is
115 oxidized by NO_3 , it will produce comparable SOA to daytime photo-oxidation. For example,
116 Brown et al. (Brown et al., 2009) concluded that NO_3 contributed more SOA from isoprene than
117 OH over New England, where $> 20\%$ of isoprene emitted during the previous day was available
118 at sunset to undergo dark oxidation by either NO_3 or O_3 . The corresponding contribution to total
119 SOA mass loading was 1 – 17% based on laboratory yields (Ng et al., 2017). Rollins et al.
120 (Rollins et al., 2012) concluded that multi-generational NO_3 oxidation of biogenic precursors was
121 responsible for one-third of nighttime organic aerosol increases during the CalNex-2010
122 experiment in Bakersfield, CA. In an aircraft study near Houston, TX, Brown et al. (Brown et al.,
123 2013) observed elevated organic aerosol in the nighttime boundary layer, and correlated vertical
124 profiles of organic and nitrate aerosol in regions with rapid surface level NO_3 radical production
125 and BVOC emissions. From these observations, the authors estimated an SOA source from
126 NO_3 + BVOCs within the nocturnal boundary layer of $0.05 - 1 \mu\text{g m}^{-3} \text{h}^{-1}$. Carlton et al. (Carlton
127 et al., 2009) note the large scatter in chamber-measured SOA yields from isoprene

128 photooxidation and point throughout their review of SOA formation from isoprene to the likely
129 importance of poorly understood later generations of chemistry in explaining field observations.
130 We suggest that similar differences in multi-generational chemistry could explain the variation
131 among the (sparse) chamber and field observations of NO_3 + isoprene yields described in the
132 previous paragraph, and summarized in a recent review of NO_3 + BVOC oxidation mechanisms
133 and SOA formation (Ng et al., 2017).

134
135 The initial products of NO_3 + isoprene include organic nitrates, some of which will partially
136 partition to the aerosol phase. Organic nitrates in the particle phase (pRONO_2) are challenging
137 to quantify with online methods, due to both interferences and their often overall low
138 concentrations in ambient aerosol. Hence, field datasets to constrain modeled pRONO_2 are
139 sparse (Fisher et al., 2016, Ng et al., 2017). One of the most used methods in recent studies,
140 used also here, is quantification with the Aerodyne Aerosol Mass Spectrometer (AMS). Organic
141 nitrates thermally decompose in the AMS vaporizer and different approaches have been used to
142 apportion the organic fraction contributing to the total nitrate signal. Allan et al. (Allan et al.,
143 2004) first proposed the use of nitrate peaks at m/z 30 and 46 to distinguish various nitrate
144 species with the AMS. Marcolli et al. (Marcolli et al., 2006), in the first reported tentative
145 assignment of aerosol organic nitrate using AMS data, used cluster analysis to analyze data
146 from the 2002 New England Air Quality Study. In that study, cluster analysis identified two
147 categories with high m/z 30 contributions. One of these peaked in the morning when NO_x was
148 abundant and was more prevalent in plumes with lowest photochemical ages, potentially from
149 isoprene oxidation products. The second was observed throughout the diurnal cycle in both
150 fresh and aged plumes, and contained substantial m/z 44 contribution (highly oxidized OA). A
151 subsequent AMS laboratory and field study discussed and further developed methods for
152 separate quantification of organic nitrate (in contrast to inorganic nitrate) (Farmer et al., 2010). A
153 refined version of one of these separation methods, based on the differing $\text{NO}_2^+/\text{NO}^+$
154 fragmentation ratio for organic vs. inorganic nitrate, was later employed to quantify organic
155 nitrate aerosol at two forested rural field sites where strong biogenic VOC emissions and
156 relatively low NO_x combined to make substantial organic nitrate aerosol concentrations ((Fry et
157 al., 2013, Ayres et al., 2015)). Most recently, Kiendler-Scharr et al. (Kiendler-Scharr et al., 2016)
158 used a variant of this method to conclude that across Europe, organic nitrates comprise ~40%
159 of submicron organic aerosol. Modeling analysis concluded that a substantial fraction of this
160 organic nitrate aerosol is produced via NO_3 radical initiated chemistry. Chamber studies have
161 employed this fragmentation ratio method to quantify organic nitrates (Fry et al., 2009, Rollins et
162 al., 2009, Bruns et al., 2010, Fry et al., 2011, Boyd et al., 2015), providing the beginnings of a
163 database of typical organonitrate fragmentation ratios from various BVOC precursors.

164
165 Measurements conducted at the SOAS ground site in Centreville, Alabama in 2013 found
166 evidence of significant organonitrate contribution to SOA mass loading. Xu et al. (Xu et al.,
167 2015) reported that organic nitrates constituted 5 to 12% of total organic aerosol mass from
168 AMS data applying a variant of the $\text{NO}_2^+/\text{NO}^+$ ratio method. Xu et al. (Xu et al., 2015) identify a
169 nighttime-peaking “LO-OOA” AMS factor which they attribute to mostly NO_3 oxidation of BVOC
170 (in addition to O_3 + BVOC). They estimated that the NO_3 radical oxidizes 17% of isoprene, 20%
171 of α -pinene, and 38% of β -pinene in the nocturnal boundary layer at this site. However, applying

172 laboratory-based SOA yields to model the predicted increase in OA, Xu et al. predict only 0.7 $\mu\text{g m}^{-3}$
173 m^{-3} of SOA would be produced, a factor of three lower than the measured nighttime LO-OOA
174 production of 1.7 $\mu\text{g m}^{-3}$. The more recent analysis of Zhang et al. (Zhang et al., 2018) found a
175 strong correlation of monoterpene SOA with the fraction of monoterpene oxidation attributed to
176 NO_3 , even for non-nitrate containing aerosol, suggesting an influence of NO_3 even in pathways
177 that ultimately eliminate the nitrate functionality from the SOA, such as hydrolysis or NO_2
178 regeneration. Ayres et al. (Ayres et al., 2015) used a correlation of overnight organonitrate
179 aerosol buildup with calculated net NO_3 + monoterpene and isoprene reactions to estimate an
180 overall NO_3 + monoterpene SOA mass yield of 40 – 80%. The factor of two range in this
181 analysis was based on two different measurements of aerosol-phase organic nitrates. These
182 authors used similar correlations to identify specific CIMS-derived molecular formulae that are
183 likely to be NO_3 radical chemistry products of isoprene and monoterpenes, and found minimal
184 contribution of identified first-generation NO_3 + isoprene products to the aerosol phase (as
185 expected based on their volatility). Lee et al. (Lee et al., 2016) detected abundant highly
186 functionalized particle-phase organic nitrates at the same site, with apparent origin both from
187 isoprene and monoterpenes, and both daytime and nighttime oxidation, and estimated their
188 average contribution to submicron organic aerosol mass to be between 3 – 8 %. For the same
189 ground campaign, Romer et al. (Romer et al., 2016) found evidence of rapid conversion from
190 alkyl nitrates to HNO_3 , with total alkyl nitrates having an average daytime lifetime of 1.7 hours.
191

192 Xie et al. (Xie et al., 2013) used a model constrained by observed alkyl nitrate correlations with
193 O_3 from the INTEX-NA/ICARTT 2004 field campaign to determine a range of isoprene nitrate
194 lifetimes between 4 and 6 hours, with 40-50% of isoprene nitrates formed by NO_3 + isoprene
195 reactions. Laboratory studies show that not all organic nitrates hydrolyze to HNO_3 equally
196 rapidly: primary and secondary organic nitrates were found to be less prone to aqueous
197 hydrolysis than tertiary organic nitrates (Darer et al., 2011, Hu et al., 2011, Boyd et al., 2015,
198 Fisher et al., 2016). This suggests that field-based estimates of the contribution of organic
199 nitrates to SOA formation could be a lower limit, if they are based on measurement of those
200 aerosol-phase nitrates. This is because if hydrolysis is rapid, releasing HNO_3 but leaving behind
201 the organic fraction in the aerosol phase, then that organic mass would not be accurately
202 accounted for as arising from nitrate chemistry. This was addressed in a recent modeling study
203 of SOAS (Pye et al., 2015) in which modeled hydrolysis products of particulate organic nitrates
204 of up to 0.8 $\mu\text{g m}^{-3}$ additional aerosol mass loading in the southeast U.S. were included in the
205 estimate of change in OA due to changes in NO_x . Another recent GEOS-Chem modeling study
206 using of gas- and particle-phase organic nitrates observed during the SEAC⁴RS and SOAS
207 campaigns similarly finds RONO_2 to be a major sink of NO_x across the SEUS region (Fisher et
208 al., 2016, Lee et al., 2016).

209

210 Complementing these SOAS ground site measurements, the NOAA-led SENEX (Southeast
211 Nexus) aircraft campaign conducted 18 research flights focused in part on studying the
212 interactions between biogenic and anthropogenic emissions that form secondary pollutants
213 between 3 June and 10 July 2013 (Warneke et al., 2016). Flight instrumentation focused on
214 measurement of aerosol precursors and composition enable the present investigation of SOA
215 yields using this aircraft data set. Edwards et al. (Edwards et al., 2017) used data from the

216 SENEX night flights to evaluate the nighttime oxidation of BVOC, observing high nighttime
217 isoprene mixing ratios in the residual layer that can undergo rapid NO_3 oxidation when sufficient
218 NO_x is present. These authors suggest that past NO_x reductions may have been uncoupled
219 from OA trends due to NO_x not having been the limiting chemical species for OA production, but
220 that future reductions in NO_x may decrease OA if NO_3 oxidation of BVOC is a substantial
221 regional SOA source. Because isoprene is ubiquitous in the nighttime residual layer over the
222 southeastern United States and the NO_3 + isoprene reaction is rapid, NO_3 reaction will be
223 dominant relative to O_3 in places with anthropogenic inputs of NO_x (Edwards et al. (Edwards et
224 al., 2017) concludes that when $\text{NO}_2/\text{BVOC} > 0.5$, NO_3 oxidation will be dominant). Hence, a
225 modest NO_3 + isoprene SOA yield may constitute a regionally important OA source.

226
227 Several modeling studies have investigated the effects of changing NO_x on global and SEUS
228 SOA. Hoyle et al. (Hoyle et al., 2007) found an increase in global SOA production from 35 Tg yr⁻¹
229 to 53 Tg yr⁻¹ since preindustrial times, resulting in an increase in global annual mean SOA
230 mass loading of 51%, attributable in part to changing NO_x emissions. Zheng et al. (Zheng et al.,
231 2015) found only moderate SOA reductions from a 50% reduction in NO_x emissions: 0.9 – 5.6 %
232 for global NO_x or 6.4 – 12.0% for southeast US NO_x , which they attributed to buffering by
233 alternate chemical pathways and offsetting tendencies in the biogenic vs. anthropogenic SOA
234 components. In contrast, Pye et al. (Pye et al., 2015) find a 9% reduction in total organic aerosol
235 in Centreville, AL for only 25% reduction in NO_x emissions. A simple limiting-reagent analysis of
236 NO_3 + monoterpene SOA from power plant plumes across the United States found that between
237 2008 and 2011, based on EPA-reported NO_x emissions inventories, some American power
238 plants shifted to the NO_x -limited regime (from 3.5% to 11% of the power plants), and showed
239 that these newly NO_x -limited power plants were primarily in the southeastern United States (Fry
240 et al., 2015). The effect of changing NO_x on SOA burden is clearly still in need of further study.

241
242 Here, we present aircraft transects of spatially discrete NO_x plumes from electric generating
243 units (EGU), or power plants (PP), as a method to specifically isolate the influence of NO_3
244 oxidation. These plumes are concentrated and highly enriched in NO_x over a scale of only a
245 few km (Brown et al., 2012), and have nitrate radical production rates ($P(\text{NO}_3)$) 10 – 100 times
246 greater than those of background air. The rapid shift in $P(\text{NO}_3)$ allows direct comparison of air
247 masses with slow and rapid oxidation rates attributable to the nitrate radical, effectively isolating
248 the influence of this single chemical pathway in producing SOA and other oxidation products.
249 Changes in organic nitrate aerosol (pRONO_2) concentration and accompanying isoprene
250 titration enable a direct field determination of the SOA yield from NO_3 + isoprene.

251 **2 Field campaign and experimental and modeling methods**

252 The Southeast Nexus (SENEX: <http://esrl.noaa.gov/csd/projects/senex/>) campaign took place 3
253 June through 10 July 2013 as the NOAA WP-3D aircraft contribution to the larger Southeast
254 Atmospheric Study (SAS: http://www.eol.ucar.edu/field_projects/sas/), a large, coordinated
255 research effort focused on understanding natural and anthropogenic emissions, oxidation
256 chemistry and production of aerosol in the summertime atmosphere in the southeastern United
257 States. The NOAA WP-3D aircraft operated 18 research flights out of Smyrna, Tennessee,

258 carrying an instrument payload oriented towards elucidating emissions inventories and reactions
259 of atmospheric trace gases, and aerosol composition and optical properties (Warneke et al.,
260 2016). One of the major goals of the larger SAS study is to quantify the fraction of organic
261 aerosol that is anthropogenically controlled, with a particular focus on understanding how OA
262 may change in the future in response to changing anthropogenic emissions.

263
264 The subset of aircraft instrumentation employed for the present analysis of nighttime NO_3 +
265 isoprene initiated SOA production includes measurements used to determine NO_3 radical
266 production rate ($P(\text{NO}_3) = k_{\text{NO}_2+\text{O}_3}(\text{T}) [\text{NO}_2] [\text{O}_3]$), isoprene and monoterpene concentrations,
267 other trace gases for plume screening and identification, aerosol size distributions, and aerosol
268 composition. The details on the individual measurements and the overall aircraft deployment
269 goals and strategy are described in Warneke et al. (Warneke et al., 2016). Briefly, NO_2 was
270 measured by UV photolysis and gas-phase chemiluminescence (P-CL) and by cavity ringdown
271 spectroscopy, (CRDS), which agreed within 6%. O_3 was also measured by both gas-phase
272 chemiluminescence and CRDS and agreed within 8%, within the combined measurement
273 uncertainties of the instruments. Various volatile organic compounds were measured with
274 several techniques, including for the isoprene and monoterpenes of interest here, proton
275 reaction transfer mass spectrometry (PTR-MS) and canister whole air samples and post-flight
276 GC-MS analysis (iWAS/GCMS). A comparison of PTR-MS and iWAS/GCMS measurements of
277 isoprene during SENEX has high scatter due to imperfect time alignment and isoprene's high
278 variability in the boundary layer, but the slope of the intercomparison is 1.04 (Warneke et al.,
279 2016); for more details on the VOC intercomparisons, see also Lerner et al., (Lerner et al.,
280 2017)). Acetonitrile from the PTRMS was used to screen for the influence of biomass burning.
281 Sulfur dioxide (SO_2) was used to identify emissions from coal-fired power plants. All gas-phase
282 instruments used dedicated inlets, described in detail in the supplemental information for
283 Warneke et al. (Warneke et al., 2016).

284
285 Aerosol particles were sampled downstream of a low turbulence inlet (Wilson et al., 2004), after
286 which they were dried by ram heating, size-selected by an impactor with 1 μm aerodynamic
287 diameter size cut-off, and measured by various aerosol instruments (Warneke et al., 2016). An
288 ultra-high-sensitivity aerosol sizing spectrometer (UHSAS, Particle Metrics, Inc., Boulder, CO
289 (Cai et al., 2008, Brock et al., 2011)) was used to measure the dry submicron aerosol size
290 distribution down to about 70 nm. Data for the UHSAS are reported at 1 Hz whereas AMS data
291 were recorded roughly every 10 seconds. The ambient (wet) surface areas were calculated
292 according to the procedures described in Brock et al., 2016 (Brock et al., 2016). A pressure-
293 controlled inlet (Bahreini et al., 2008) was employed to ensure that a constant mass flow rate
294 was sampled by a compact time-of-flight aerosol mass spectrometer (C-ToF-AMS) which
295 measured the non-refractory aerosol composition (Drewnick et al., 2005). The aerosol volume
296 transmitted into the AMS was calculated by applying the measured AMS lens transmission
297 curve (Bahreini et al., 2008) to the measured particle volume distributions from the UHSAS. For
298 the entire SENEX study, the mean, calculated fraction of aerosol volume behind the 1 micron
299 impactor that was transmitted through the lens into the AMS instrument was 97% (with $\pm 4\%$
300 standard deviation), indicating that most of the submicron aerosol volume measured by the
301 sizing instruments was sampled by the AMS.

302

303 After applying calibrations and the composition-dependent collection efficiency following
304 Middlebrook et al. (Middlebrook et al., 2012), the limits of detection for the flight analyzed here
305 were $0.05 \mu\text{g m}^{-3}$ for nitrate, $0.26 \mu\text{g m}^{-3}$ for organic mass, $0.21 \mu\text{g m}^{-3}$ for ammonium, and 0.05
306 $\mu\text{g m}^{-3}$ for sulfate, determined as three times the standard deviation of 10-second filtered air
307 measurements obtained for 10 minutes during preflight and 10 minutes during postflight (110
308 datapoints). Note that the relative ionization efficiency for ammonium was 3.91 and 3.87 for the
309 two bracketing calibrations and an average value of 3.9 was used for the flight analyzed here.
310 An orthogonal distance regression (ODR-2) of the volume from composition data (AMS mass
311 plus refractory black carbon) using a mass weighted density as described by Bahreini et al.
312 (Bahreini et al., 2009) versus the volume based on the sizing instruments (after correcting for
313 AMS lens transmission as above) had a slope of 1.06 for the entire SENEX study and 72% of
314 the data points were within the measurements' combined uncertainties of $\pm 45\%$ (Bahreini et al.,
315 2008). For the flight analyzed here, however, the same regression slope was 1.58, which is
316 slightly higher than the combined uncertainties. It is unclear why the two types of volume
317 measurements disagree more for this flight, since other flights during this field project compared
318 better; this does not change the conclusions of this work, but is discussed further in the
319 Supplemental Information and comparisons are shown for the plumes of interest in Fig. S1.

320

321 The C-ToF-AMS is a unit mass resolution (UMR) instrument and the mass spectral signals that
322 are characteristic of aerosol nitrate at m/z 30 and 46 (NO^+ and NO_2^+) often contain interferences
323 from organic species such as CH_2O^+ and CH_2O_2^+ , respectively. Here, the m/z 30 and 46 signals
324 have been corrected for these interferences by using correlated organic signals at m/z 29, 42,
325 43, and 45 that were derived from high-resolution AMS measurements during the NASA
326 SEAC⁴RS campaign that took place in the same regions of the SE US shortly after SENEX (see
327 Supplemental Information and Fig. S2). The corrections were applied to the individual flight
328 analyzed here from July 2. All of the corrections were well correlated with each other for the
329 SEAC⁴RS dataset and we used the organic peak at m/z 29 (from CHO^+) and the peak at m/z 45
330 (from CHO_2^+), respectively, since those corrections were from peaks closest (in m/z) to those
331 being corrected. Once corrected, the nitrate mass concentrations in the final data archive for
332 this flight were reduced by $0\text{--}0.24 \mu\text{g sm}^{-3}$, an average reduction of $0.11 \mu\text{g sm}^{-3}$ or 32% from
333 the initial nitrate mass concentrations. The organic interferences removed from the m/z 30 and
334 m/z 46 signals are linearly correlated with the total organic mass concentrations, corresponding
335 to an average 1.3% increase in the total organic mass.

336

337 The ratio of the corrected $\text{NO}_2^+/\text{NO}^+$ signals was then used to calculate the fraction of aerosol
338 nitrate that was organic (pRONO₂) or inorganic (ammonium nitrate) based on the method
339 described first in Fry et al. [27]. Here we used an organic $\text{NO}_2^+/\text{NO}^+$ ratio that was equal to the
340 ammonium nitrate $\text{NO}_2^+/\text{NO}^+$ ratio from our calibrations divided by 2.8. This factor was
341 determined from multiple datasets compiled by Day et al (Day et al., 2017), who discuss the
342 uncertainties of this approach in detail. The ammonium nitrate $\text{NO}_2^+/\text{NO}^+$ ratio was obtained
343 from the two calibrations on 30 June and 7 July that bracketed the flight on 2 July, which is
344 analyzed here. It was 0.514 and 0.488, respectively, and for all of the data from both
345 calibrations it averaged 0.490. Hence, the organic nitrate $\text{NO}_2^+/\text{NO}^+$ ratio was estimated to be

346 0.175. This is the first time, to our knowledge, that UMR measurements of aerosol nitrate have
347 been corrected with HR correlations and used to apportion the corrected nitrate into inorganic or
348 organic nitrate species.

349

350 The time since emission of intercepted power plant plumes was estimated from the slope of a
351 plot of O₃ against NO₂. For nighttime emitted NO_x plumes that consist primarily of NO (Peischl
352 et al., 2010), O₃ is negatively correlated with NO₂ due to the rapid reaction of NO with O₃ that
353 produces NO₂ in a 1:1 ratio:

354

356

357 Reaction R1 goes rapidly (NO pseudo first order loss rate coefficient of 0.03 s⁻¹ at 60 ppb O₃) to
358 completion, so that all NO_x is present as NO₂, as long as the plume NO does not exceed
359 background O₃ after initial mixing of the plume into background air. Subsequent oxidation of
360 NO₂ via reaction (R2) leads to an increasingly negative slope of O₃ vs NO₂:

361

363

364 Equation (1) then gives plume age subsequent to the completion of (R1) in terms of the
365 observed slope, *m*, of O₃ vs NO₂ (Brown et al., 2006).

366

$$367 t_{\text{plume}} = \frac{\ln[1-S(m+1)]}{Sk_1\bar{O}_3} \quad (1)$$

368

369 Here *S* is a stoichiometric factor that is chosen for this analysis to be 1 based on agreement of
370 plume age with elapsed time in a box model run initialized with SENEX flight conditions (see
371 below); *k*₂ is the temperature dependent bimolecular rate constant for NO₂ + O₃ (R2) and \bar{O}_3 is
372 the average O₃ within the plume.

373

374 We calculate plume ages using both a stoichiometric factor of 1 (loss of NO₃ and N₂O₅
375 dominated by NO₃ reactions) and 2 (loss dominated by N₂O₅ reactions), although we note that
376 the chemical regime for NO₃+N₂O₅ loss may change over the lifetime of the plume, progressing
377 from 1 to 2 as the BVOC is consumed. We use *S*=1 values in the analysis that follows. Because
378 the more aged plumes are more likely to have *S* approach 2, this means that some of the older
379 plumes may have overestimated ages. Fig. S3 in the Supplemental Information shows the
380 plume age calculated by Eq. 1 using modeled NO_x, NO_y and O₃ concentrations for *S*=1 and
381 *S*=2, from nighttime simulations of plume evolution using an observationally constrained box
382 model. This confirms that for nighttime plumes, *S*=1 plume ages match modeled elapsed time
383 well. The model used for this calculation, and those used to assess peroxy radical lifetimes and
384 fates in Section 4.3, was the Dynamically Simple Model of Atmospheric Chemical Complexity
385 (DSMACC (Emmerson and Evans 2009)) containing the Master Chemical Mechanism v3.3.1
386 chemistry scheme (Jenkin et al., 2015). More details on the model approach are provided in the
387 SI.

388 3 Nighttime flight selection

389 There were three nighttime flights (takeoffs on the evenings of 19 June, 2 July, and 3 July,
390 2013, local time) conducted during SENEX, of which one (2 July) surveyed regions surrounding
391 Birmingham, Alabama, including multiple urban and power plant plume transects. As described
392 in the introduction, these plume transects are the focus of the current analysis since they
393 correspond to injections of concentrated NO (and subsequently high $P(\text{NO}_3)$) into the regionally
394 widespread residual layer isoprene. The nighttime flight on 3 July, over Missouri, Tennessee
395 and Arkansas sampled air more heavily influenced by biomass burning than biogenic emissions.
396 The 19 June night flight sampled earlier in the evening, in the few hours immediately after
397 sunset, and sampled more diffuse urban plume transects that had less contrast with background
398 air. Therefore, this paper uses data exclusively from the 2 July flight, in which 9 transects of
399 well-defined NO_x plumes from power plants emitted during darkness can be analyzed to obtain
400 independent yields measurements.

401
402 A map of the 2 July flight track is shown in Fig. 1a. After takeoff at 8:08 pm local Central
403 Daylight Time on 2 July, 2013 (1:08 am UTC 3 July, 2016), the flight proceeded towards the
404 southwest until due west of Montgomery, AL, after which it conducted a series of east-west
405 running tracks while working successively north toward Birmingham, AL. Toward the east of
406 Birmingham, the aircraft executed overlapping north-south tracks at six elevations to sample the
407 E. C. Gaston power plant. During the course of the flight, concentrated NO_x plumes from the
408 Gaston, Gorgas, Miller and Greene City power plants were sampled. Around 1:30 and 2:30 AM
409 Central Daylight Time (5:30 and 6:30 am UTC), two transects of the Birmingham, AL urban
410 plume were measured prior to returning to the Smyrna, TN airport base.

411
412 The flight track is shown colored by the nitrate radical production rate, $P(\text{NO}_3)$, to show the
413 points of urban and/or power plant plume influence:

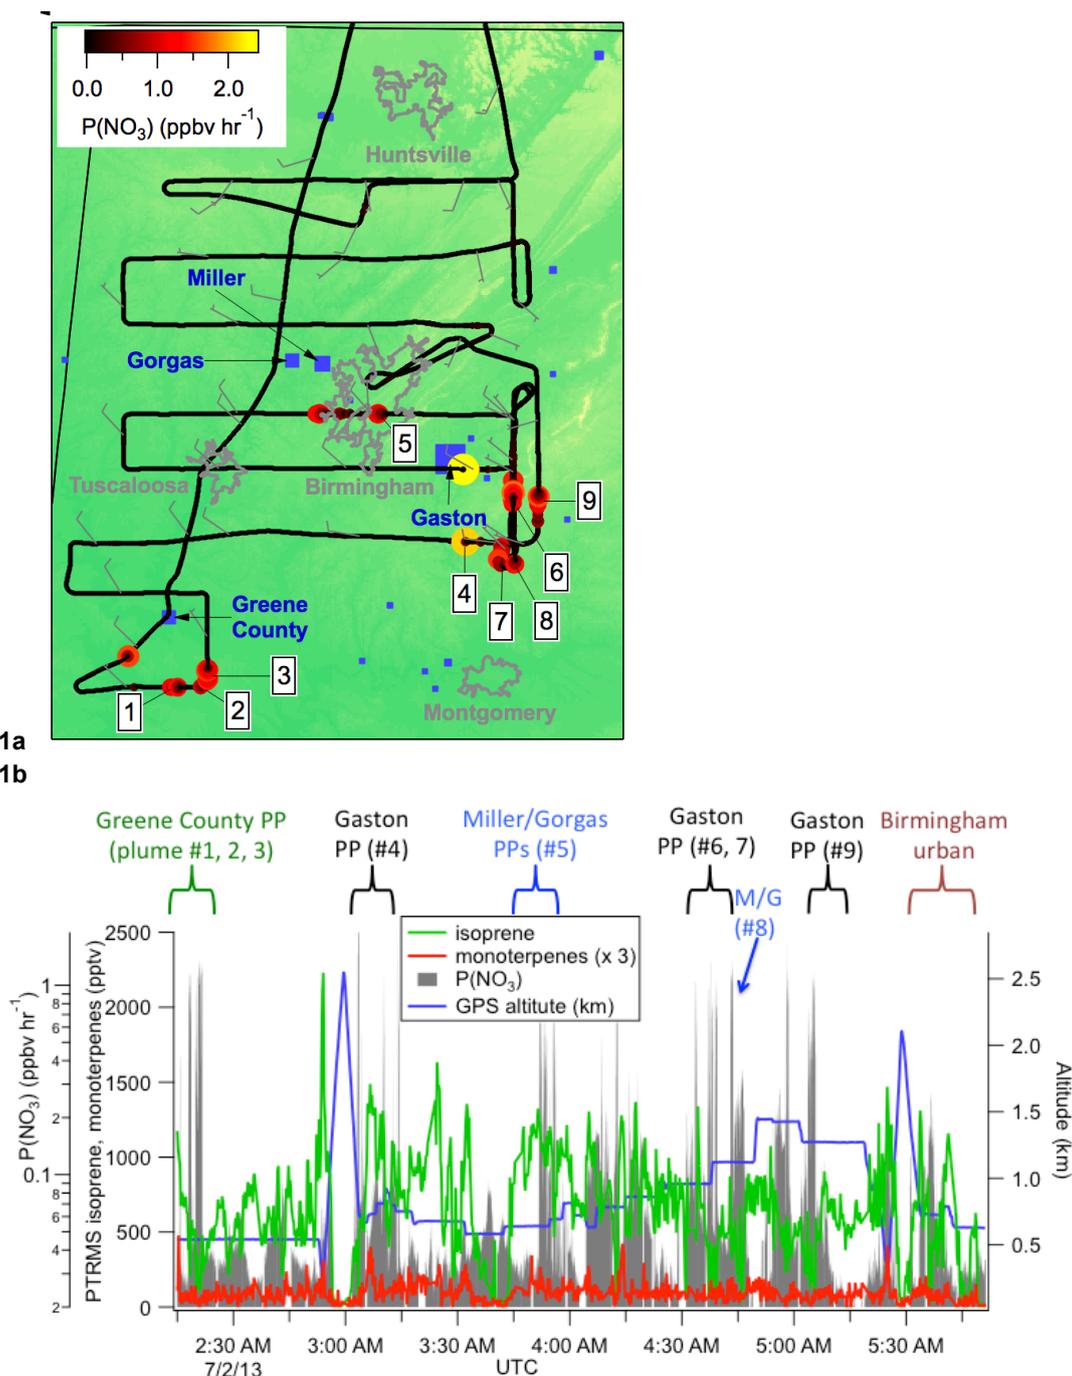

$$414 \quad 415 \quad P(\text{NO}_3) = k_2(T) [\text{NO}_2][\text{O}_3] \quad (2)$$

416
417 Here, k_2 is again the temperature-dependent rate coefficient for reaction of NO₂ + O₃ (Atkinson
418 et al., 2004), and the square brackets indicate number densities. Fig. 1b further illustrates the
419 selection of power plants plumes: sharp peaks in $P(\text{NO}_3)$ are indicative of power plant plume
420 transects, during which isoprene mixing ratios also are observed to drop from the typical
421 regional residual layer background values of ~ 1 ppb, indicative of loss by NO₃ oxidation (an
422 individual transect is shown in more detail below in Fig. 2). Also shown in Fig. 1b are measured
423 concentrations of isoprene and monoterpenes throughout the flight, showing substantial residual
424 layer isoprene and supporting the assumption that effectively all NO₃ reactivity is via isoprene
425 (see calculation in next section). Residual layer concentrations of other VOCs that could
426 produce SOA (e.g., aromatics) are always below 100 pptv, and their reaction rates with NO₃ are
427 slow. Edwards *et al.* (Edwards et al., 2017) have shown that NO₃ and isoprene mixing ratios for
428 this and other SENEX night flights exhibit a strong and characteristic anticorrelation that is
429 consistent with nighttime residual layer oxidation chemistry.

430

431 1a
 432 1b

433
 434 **Figure 1a.** Map of northern Alabama, showing the location of the flight track of the 2 July 2013
 435 night flight used in the present analysis, with plume numbers labeled and wind direction shown.
 436 Although the wind direction changed throughout the night, these measurements enable us to

437 attribute each plume to a power plant source (see labels in Figure 1b and Table 2). Color scale
438 shows $P(\text{NO}_3)$ based on aircraft-measured $[\text{NO}_2]$ and $[\text{O}_3]$, while power plants discussed in the
439 text are indicated in blue squares with marker size scaled to annual NO_x emissions for 2013
440 (scale not shown). Isoprene emissions are widespread in the region (Edwards et al., 2017).
441 **Figure 1b** shows time series data from the same flight, with plume origins and numbers labeled,
442 showing aircraft-measured isoprene and monoterpene concentrations, altitude, and $P(\text{NO}_3)$
443 determined according to Eq. 2 (log scale), showing that the isoprene was uniformly distributed
444 (mixing ratios often in excess of 1 ppbv), while the more reactive monoterpenes were present at
445 mixing ratios below 100 ppt except at the lowest few hundred meters above ground in the
446 vertical profiles (not used in the present analysis). Figure 1b also shows that sharp peaks in
447 nitrate radical production rate occur both at the lowest points of these vertical profiles, when the
448 aircraft approached the surface, but also frequently during periods of level flight in the residual
449 layer, which correspond to the power plant plume transects analyzed in this paper.

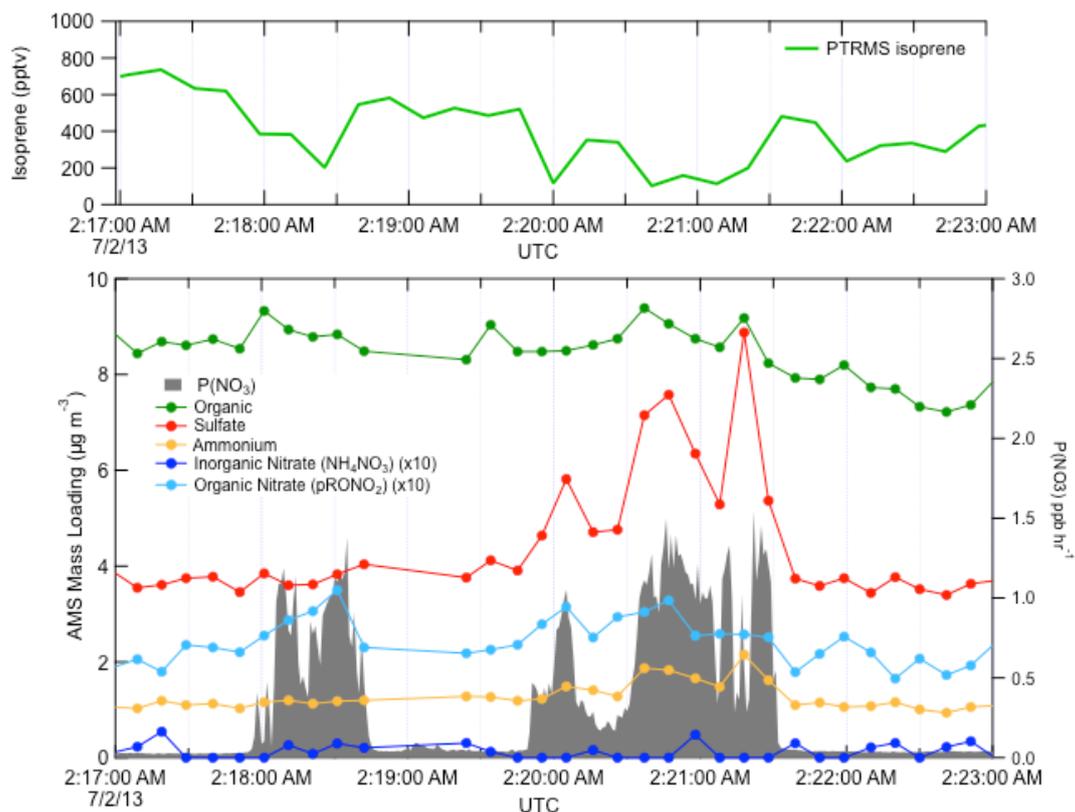

450 **4 Results**

451 **4.1 Selection of plumes**

452 Figure 2 shows a subset of the July 2 flight time series data, illustrating three NO_x plumes used
453 for analysis. The large NO_3 source and isoprene loss was accompanied by an increase in
454 organic nitrate aerosol mass, which we attribute to the $\text{NO}_3 + \text{isoprene}$ reaction based on prior
455 arguments. We observed each plume as a rapid and brief perturbation to background
456 conditions, of order 10 – 50 sec., or 1 – 5 km in spatial scale. Each plume's perturbed
457 conditions can correspond to different plume ages, depending on how far downwind of the
458 power plant the plume transect occurred.

459

460

461

Figure 2. Three representative plume transect observations from the 2 July 2013 flight (plumes are identified by the peaks in $P(\text{NO}_3)$, listed in Table 1 at times 02:18, 02:20, and 02:21 UTC).

462

Note the difference in sulfate enhancement in the three plumes, which is largest in the third

463

plume, and is accompanied by increases in ammonium. In all three cases, the isoprene

464

concentration drops in the plumes, accompanied by a clear increase in organic nitrate, no

465

changes in the inorganic nitrate, and a modest changes in organic aerosol mass concentrations.

466

467

468

Candidate plumes were initially identified by scanning the time series flight data for any period

469

where the production rate of nitrate radical ($P(\text{NO}_3)$) rose above 0.5 ppbv hr^{-1} . For each such

470

period, a first screening removed any of these candidate plumes that occurred during missed

471

approaches or other periods where radar altitude above ground level (AGL) was changing,

472

because in the stratified nighttime boundary layer structure, variations in altitude may result in

473

sampling different air-masses, rendering the adjacent out of plume background not necessarily

474

comparable to in-plume conditions. A second criterion for rejection of a plume was missing

475

isoprene or AMS data during brief plume intercepts. No selected plumes on July 2 showed

476

enhanced acetonitrile or refractory black carbon, indicating no significant biomass burning

477

influence. Finally, two plumes downwind of the Gaston power plant (at 03:10 and 03:14) were

478

removed from the present analysis, because (03:10) the background isoprene was changing

479 rapidly, preventing a good baseline measurement, and (03:14) there was no observed decrease
480 in isoprene concentration in-plume (as well as no increase in nitrate aerosol). The 03:14 plume
481 was apparently too recently emitted to have undergone significant nighttime reaction; its O_3/NO_2
482 slope was unity to within the combined measurement error of O_3 and NO_2 (Eq. 1). After this
483 filtering, there are 9 individual plume observations for determination of NO_3 + isoprene SOA
484 yields (see Table 1). The rapid increases in $P(NO_3)$ appeared simultaneously with significant
485 decreases in isoprene and increases in aerosol nitrate. The aerosol and isoprene
486 measurements (taken at data acquisition rates < 1 Hz) were not exactly coincident in time which
487 leads to some uncertainty in the yield analysis below.

488
489 Derivation of SOA yields from observed changes in isoprene and aerosol mass in plumes
490 depends on two conditions, and has several caveats that will be discussed in the text that
491 follows (see Table 3 below for a summary of these caveats). The two conditions are: (1) that the
492 majority of VOC mass consumed by NO_3 in plumes is isoprene (rather than monoterpenes or
493 other VOC), and then either or both (2a) that the change in aerosol organic mass concentration
494 during these plumes is due to NO_3 + isoprene reactions, and/or (2b) that the change in aerosol
495 nitrate mass concentration is due to NO_3 + isoprene reactions. There are separate
496 considerations for each of these conditions.

497
498 For the first condition, we note that the isoprene to monoterpenes ratio just outside each plume
499 transect was always high (a factor of 10 to 70, on average 26). With the 298 K NO_3 rate
500 constants of $\sim 5 \times 10^{-12} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ for monoterpenes and $6.5 \times 10^{-13} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ for
501 isoprene (Calvert et al., 2000), isoprene (~ 2 ppb) will always react faster with nitrate than
502 monoterpenes (~ 0.04 ppbv). At these relative concentrations, even if all of the monoterpene is
503 oxidized, the mass of hydrocarbon conversion will be much larger for isoprene. Contribution to
504 aerosol by N_2O_5 uptake is also not important in these plumes. Edwards et al. (Edwards et al.,
505 2017) calculated the sum of NO_3 and N_2O_5 loss throughout this flight and showed that it is
506 consistently NO_3 +BVOC dominated (Fig. S4 of that paper). As isoprene depletes, N_2O_5 uptake
507 will increasingly contribute to NO_3 loss, but as shown below, we are able to rule out a
508 substantial source of inorganic nitrate for most plumes. We also know that despite increased
509 OH production in-plume, the isoprene loss is still overwhelming dominated by NO_3 (Fig. S5 in
510 Edwards, et al. (Edwards et al., 2017)) .

511
512 The second condition requires that we can find an aerosol signal that is attributable exclusively
513 to NO_3 + isoprene reaction products, whether it be organic aerosol (OA) or organic nitrate
514 aerosol ($pRONO_2$) mass loading, or both. We note that the ratio of in-plume aerosol organic
515 mass increase to $pRONO_2$ mass increase is noisy (see discussion below at Fig. 6), but indicates
516 an average in-plume ΔOA to $\Delta pRONO_2$ ratio of about 5. The large variability is primarily due to
517 the fact that the variability in organic aerosol mass between successive 10-second data points
518 for the entire flight is quite large (of order $0.75 \mu\text{g m}^{-3}$) and comparable to many of the individual
519 plume ΔOA increases, far exceeding the expected organonitrate driven increases in OA, which
520 are roughly twice the $pRONO_2$ mass increases. It is also possible that in these plumes, where
521 total aerosol mass is elevated, semivolatile organic compounds may re-partition to the aerosol
522 phase, contributing a non- $pRONO_2$ driven variability in ΔOA . For example, if some gas phase

523 IEPOX is present in the residual layer, it may be taken up into the highly acidic aerosol from the
524 power plants. Alternatively, very polar gas-phase compounds could partition further into the
525 higher liquid water associated with the sulfate in the plume. Therefore, in-plume organic aerosol
526 increases cannot be attributed clearly to NO_3 + isoprene SOA production, so we do not use
527 them in the SOA yield calculations.

528

529 This leaves consideration 2b, whether all increase in nitrate mass is due to NO_3 + isoprene
530 reactions. Here we must evaluate the possibility of inorganic nitrate aerosol production in these
531 high- NO_x plumes. Fine-mode aerosol inorganic nitrate can be formed by the (reversible)
532 dissolution of $\text{HNO}_{3(\text{g})}$ into aqueous aerosol. In dry aerosol samples, inorganic nitrate is typically
533 in the form of ammonium nitrate (NH_4NO_3), when excess ammonium is available after
534 neutralization of sulfate as $(\text{NH}_4)_2\text{SO}_4$ and $\text{NH}_4(\text{HSO}_4)$. Because of the greater stability of
535 ammonium sulfate salt relative to ammonium nitrate, in high-sulfate plumes with limited
536 ammonium, inorganic nitrate aerosol will typically evaporate as $\text{HNO}_{3(\text{g})}$ (Guo et al., 2015)
537 (reaction R3):

538

540

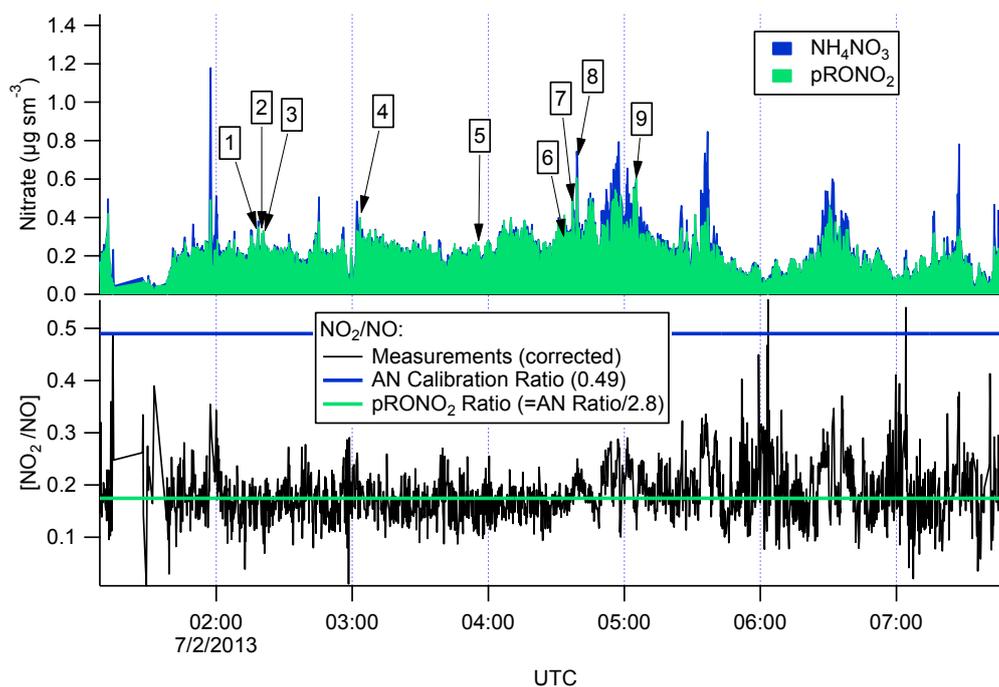

541 Inorganic nitrate can also form when crustal dust (e.g. CaCO_3) or seasalt (NaCl) are available.
542 Uptake of HNO_3 is rendered favorable by the higher stability of nitrate mineral salts, evaporating
543 CO_2 or HCl .

544

545 There are several lines of evidence that the observed nitrate aerosol is organic and not
546 inorganic. First, examination of the $\text{NO}_2^+/\text{NO}^+$ (interference-corrected m/z 46: m/z 30) ratio
547 measured by the aircraft AMS (Fig. 3) shows a ratio throughout the July 2 flight, including the
548 selected plumes, that is substantially lower than that from the bracketing ammonium nitrate
549 calibrations. This lower AMS measured $\text{NO}_2^+/\text{NO}^+$ ratio has been observed for organic nitrates
550 (Farmer et al., 2010), and some mineral nitrates (e.g. $\text{Ca}(\text{NO}_3)_2$ and NaNO_3 , (Hayes et al.,
551 2013)), which are not important in this case because aerosol was dominantly submicron. As
552 described above, we can separate the observed AMS nitrate signal into pRONO₂ and inorganic
553 nitrate contributions. These mass loadings are also shown in Fig. 3, indicating dominance of
554 pRONO₂ throughout the flight.

555

556

557 **Figure 3.** For the flight under consideration, the estimated relative contributions of ammonium
558 and organic nitrate to the total corrected nitrate signal (top panel) was calculated from the ratios
559 of the corrected peaks at m/z 30 and 46 (lower panel). Each of the plumes is identified here by
560 plume number. The ratios of $\text{NO}_2^+/\text{NO}^+$ (black data in the lower panel) from the corrected peaks
561 at m/z 46 and 30, respectively, are compared to the ratios expected for ammonium nitrate (AN
562 Calibration Ratio, blue horizontal line at 0.49) or organic nitrate (pRONO₂ Ratio, green
563 horizontal line at 0.175 which is estimated from the AN calibration ratio using multiple data sets
564 by Day *et al.* (Day *et al.*, 2017)). The measured ratio for most of the flight is more characteristic
565 of organic nitrate than ammonium nitrate.

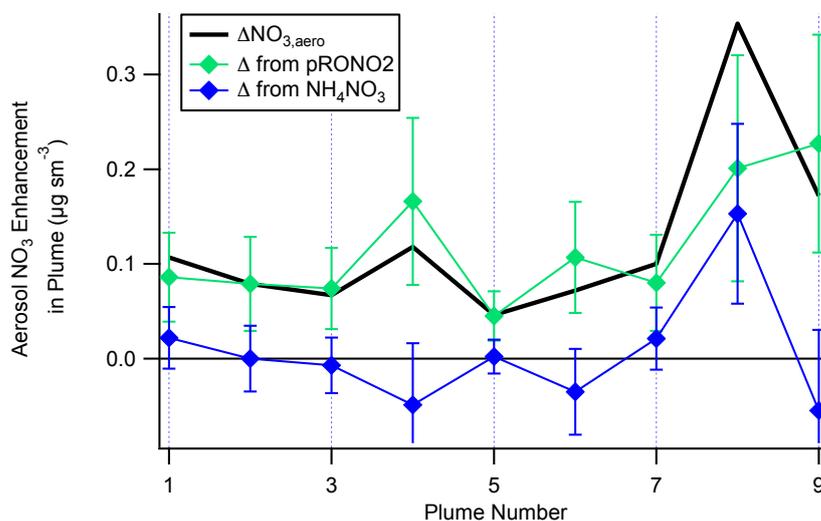

566

567 We can also employ the comparison of other AMS-measured aerosol components during the
568 individual plumes to assess the possibility of an inorganic nitrate contribution to total measured
569 nitrate. Fig. S5 shows that the in-plume increases in sulfate are correlated with increases in
570 ammonium with an R^2 of 0.4. The observed slope of 5.4 is characteristic of primarily $(\text{NH}_4)\text{HSO}_4$,
571 which indicates that the sulfate mass is not fully neutralized by ammonium. We note, however,
572 that if the largest observed aerosol nitrate increase is due solely to ammonium nitrate, the
573 ammonium increase would be only $0.11 \mu\text{g m}^{-3}$, which would be difficult to discern from the NH_4
574 variability of order $0.11 \mu\text{g m}^{-3}$. However, the slope is consistent with incomplete neutralization
575 of the sulfate by ammonium, which would make $\text{HNO}_{3(g)}$ the more thermodynamically favorable
576 form of inorganic nitrate. Thus, NH_4NO_3 is unlikely to be stable in the aerosol phase under the
577 conditions of these plumes, consistent with the AMS observations.

578

579 A plot of the calculated plume enhancements from the derived apportionment into organic
580 (pRONO₂) and inorganic (ammonium) nitrate is shown in Fig. 4. The increases in aerosol nitrate
581 for nearly all of the plumes appear to be mostly due to enhancements in pRONO₂. Based on
582 these considerations, we conclude that in-plume pRONO₂ mass increases are a consequence
583 (and thus a robust measure) of organic nitrate aerosol produced from NO₃ + isoprene. Since
584 each isoprene molecule condensing will have one nitrate group, the ratio of these increases to
585 isoprene loss is a direct measure of the molar organic aerosol yield from NO₃-isoprene
586 oxidation.

587

588

589 **Figure 4** The contribution of each species to the nitrate enhancements in each of the plumes,
590 showing that the enhancements in most of the plumes are mainly due to enhancements in
591 organic nitrate, with the exception of Plume 8 which had enhancements in both organic and
592 ammonium nitrate. Error bars are estimated from the measurement variability, the UMR
593 corrections to the nitrate signals, apportionment between organic and inorganic nitrate, and the
594 total nitrate uncertainty (see Supplemental Information)

595

596 Table 1 shows the selected plumes to be used for yield analysis. Wherever possible, multiple
597 points have been averaged for in-plume and background isoprene and nitrate aerosol
598 concentrations; in each case the number of points used is indicated and the corresponding
599 standard deviations are reported. In two cases (2:20 and 3:03 plumes), the plumes were so
600 narrow that only a single point was measured in-plume at the 10 s time resolution of the PTR-
601 MS and AMS; for these “single-point” plumes it is not possible to calculate error bars. Error bars
602 were determined using the standard deviations calculated for in-plume and background
603 isoprene and nitrate aerosol concentrations, and propagated through the yield formula detailed
604 in the following section.

605

606 **Table 1.** List of plumes used in this NO₃ + isoprene SOA yield analysis. For each plume, the
 607 delta-values listed indicate the difference between in-plume and outside-plume background in
 608 average observed concentration, and the standard deviations (SD) are the propagated error
 609 from this subtraction. After each plume number, the numbers of points averaged for isoprene
 610 (10 s resolution) and AMS (10 s resolution), respectively, are listed. Because the isoprene data
 611 were reported at a lower frequency, these numbers are typically lower to cover the same period
 612 of time. Plume numbers annotated with * indicate brief plumes for which only single-point
 613 measurements of in-plume aerosol composition were possible. Additional AMS and auxiliary
 614 data from each plume is included in the Supplemental Information, Table S3.

plume number [#isop/#AMS]	7/2/13 plume time (UTC)	Δ ISOP (ppt) [\pm SD]	Δ NO _{3,aero} ($\mu\text{g m}^{-3}$) [\pm SD]	Δ NO ₃ from pRONO ₂ ($\mu\text{g m}^{-3}$) [\pm SD]	Δ NO ₃ from NH ₄ NO ₃ ($\mu\text{g m}^{-3}$) [\pm SD]
Typical variability ($\mu\text{g m}^{-3}$):			0.05	0.05	0.05
1 [2/3]	2:18	-335 [128]	0.107 [0.039]	0.086 [0.033]	0.022 [0.012]

615 **Plume 5 has the smallest Δ NO_{3,aero} and may be affected by background pRONO₂ variability.

616 ***Plume 8 has a measurable increase in inorganic nitrate as well as organic.

617 4.2 SOA yield analysis

618 A **molar** SOA yield refers to the number of molecules of aerosol organic nitrate produced per
 619 molecule of isoprene consumed. In order to determine molar SOA yields from the data
 620 presented in Table 1, we convert the aerosol organic nitrate mass loading differences to mixing
 621 ratio differences (ppt) using the NO₃ molecular weight of 62 g mol⁻¹. At standard conditions of
 622 273 K and 1 atm (all aerosol data are reported with this STP definition), 1000 ppt NO₃ = 2.77 $\mu\text{g m}^{-3}$
 623 m⁻³, so each ΔM_{pRONO_2} is multiplied by 361 ppt ($\mu\text{g m}^{-3}$)⁻¹ to determine this molar yield:

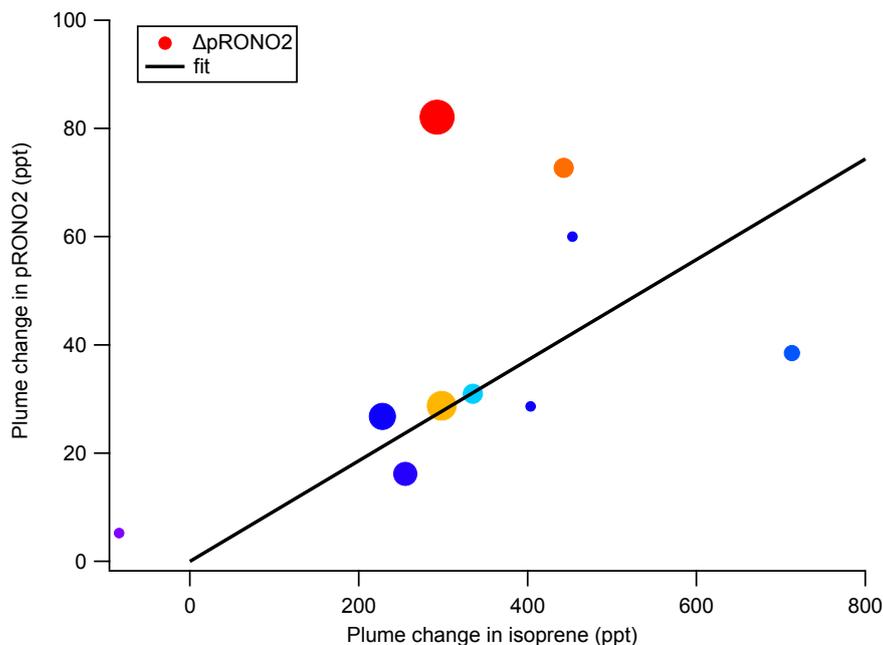

624

$$Y_{SOA,molar} = \frac{(pRONO_2_{plume} \pm SD_{pRONO_2plume}) - (pRONO_2_{bkg} \pm SD_{pRONO_2bkg})}{-[(isop_{plume} \pm SD_{isopplume}) - (isop_{bkg} \pm SD_{isopbkg})]} \times \frac{361 \text{ ppt } NO_3}{\mu g \text{ m}^{-3}} \quad (3)$$

626

627 The SOA molar yields resulting from this calculation are shown in Table 2, spanning a range of
 628 5-28%, with uncertainties indicated based on the SDs in measured AMS and isoprene
 629 concentrations. In addition to this uncertainty based on measurement precision and ambient
 630 variability, there is an uncertainty of 50% in the AMS derived-organic nitrate mass loadings (see
 631 SI) and 25% in the PTR-MS isoprene concentrations (Warneke et al., 2016). The average molar
 632 pRONO₂ yield across all plumes, with each point weighed by the inverse of its standard
 633 deviation and assuming SD = 0.1 for single point plumes, is 9%. (As noted below, the yield
 634 appears to increase with plume age, so this average obscures that trend.) An alternate
 635 graphical analysis of molar SOA yield from all nine plumes plus one 'null' plume (03:14, in which
 636 no isoprene had yet reacted and thus not included in Tables 1 and 2) obtains the same average
 637 molar yield of 9% (Fig. 5). Here, the molar yield is the slope of a plot of plume change in
 638 pRONO₂ vs plume change in isoprene. The slope is determined by a linear fit with points
 639 weighted by the square root of the number of AMS data points used to determine in-plume
 640 pRONO₂ in each case.

641

642

643 **Figure 5.** SOA molar yield can be determined as the slope of $\Delta pRONO_2$ vs. $\Delta isoprene$, both in
 644 mixing ratio units. The linear fit is weighted by square root of number of points to determine
 645 each in-plume pRONO₂, with intercept held at zero. The slope coefficient \pm one standard
 646 deviation is 0.09298 ± 0.00113 . Points are colored by plume age (red = longest), and size
 647 scaled by square root of number of points (the point weight used in linear fit). This plot and fit

648 includes the nine plumes listed in Tables 1 and 2, as well as the 03:14 “unreacted” plume (at
 649 Δisoprene = -84 ppt.

650

651 To estimate SOA **mass** yields, we need to make some assumption about the mass of the
 652 organic molecules containing the nitrate groups that lead to the observed nitrate aerosol mass
 653 increase. The observed changes in organic aerosol are too variable to be simply interpreted as
 654 the organic portion of the aerosol organic nitrate molecules. We conservatively assume the
 655 organic mass to be approximately double the nitrate mass (62 g mol^{-1}), based on an “average”
 656 molecular structure of an isoprene nitrate with 3 additional oxygens: e.g. a tri-hydroxynitrate
 657 ($\text{C}_5\text{H}_{11}\text{O}_3$, 119 g mol^{-1}), consistent with 2nd-generation oxidation product structures suggested in
 658 Schwantes, et al. (Schwantes et al., 2015). Based on this assumed organic to nitrate ratio, all
 659 plumes’ expected organic mass increases would be less than the typical variability in organic of
 660 $0.75 \mu\text{g m}^{-3}$. This assumed structure is consistent with oxidation of both double bonds, which
 661 appears to be necessary for substantial condensation of isoprene products, and which
 662 structures would have calculated vapor pressures sufficiently low to partition to the aerosol
 663 phase (Rollins et al., 2009). However, it is difficult to understand how the second double bond
 664 would be oxidized unless by another nitrate radical, which would halve these organic to nitrate
 665 ratios (assuming the nitrate is retained in the molecules). On the other hand, any organic nitrate
 666 aerosol may lose the NO_3 moiety, increasing the organic to nitrate ratio. Given these
 667 uncertainties, we use the assumed “average” structure above to guess an associated organic
 668 mass of double the nitrate mass. Thus, to estimate SOA mass yield, we multiply the increase in
 669 organic nitrate aerosol mass concentration by three (i.e., $2 \times \Delta M_{p\text{RONO}_2} + \Delta M_{p\text{RONO}_2}$), and divide
 670 by the observed decrease in isoprene, converted to $\mu\text{g m}^{-3}$ by multiplying by $329 \text{ ppt} (\mu\text{g m}^{-3})^{-1}$,
 671 the conversion factor based on isoprene’s molecular weight of 68.12 g mol^{-1} .

672

$$673 \quad Y_{\text{SOA, mass}} = \frac{(p\text{RONO}_2\text{plume} \pm SD_{p\text{RONO}_2\text{plume}}) - (p\text{RONO}_2\text{bkg} \pm SD_{p\text{RONO}_2\text{bkg}})}{-(isop\text{plume} \pm SD_{isop\text{plume}}) - (isop\text{bkg} \pm SD_{isop\text{bkg}})} \times 3 \times \frac{329 \text{ ppt}}{\mu\text{g m}^{-3}} \quad (4)$$

674

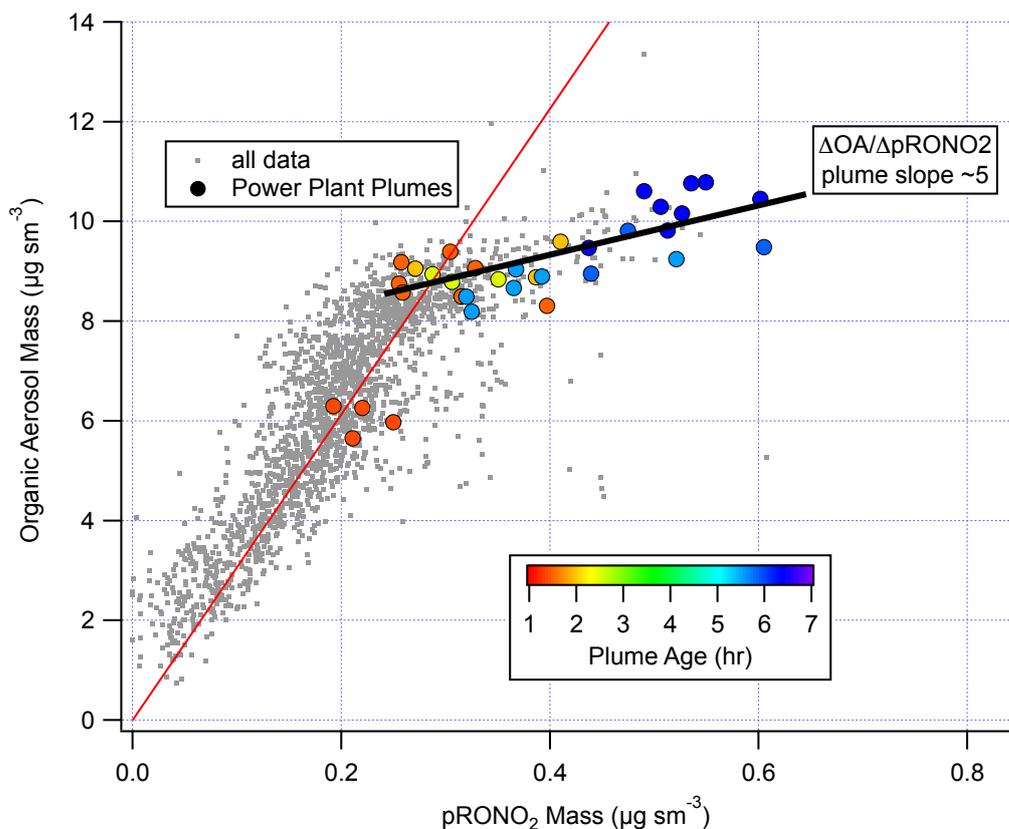

675 Note that the SOA mass yield reported here is based on the (assumed) mass of organic aerosol
 676 plus the (organo)nitrate aerosol formed in each plume. If instead the yield were calculated using
 677 only the assumed increase in **organic** mass (i.e., $2 \times \Delta M_{p\text{RONO}_2}$ instead of $3 \times \Delta M_{p\text{RONO}_2}$), which
 678 would be consistent with the method used in Rollins, et al. (Rollins et al., 2009) and Brown et al.
 679 (Brown et al., 2009), the mass yields would be 2/3 the values reported here. However, since
 680 SOA mass yield is typically defined based on the total increase in aerosol mass, we use the
 681 definition with the sum of the organic and nitrate mass here.

682

683 We note also that correlation of in-plume increases in OA with $p\text{RONO}_2$ (Fig. 6) point to a
 684 substantially larger 5:1 organic-to-nitrate ratio; if this were interpreted as indicating that the
 685 average molecular formula of the condensing organic nitrate has 5 times the organic mass as
 686 nitrate, this would increase the SOA mass yields reported here. However, due to the
 687 aforementioned possibility of additional sources of co-condensing organic aerosol, which led us
 688 to avoid using ΔOA in determining SOA yields, we do not consider this to be a direct indication
 689 of the molecular formula of the condensing organic nitrate. Including OA in the SOA yield

690 determination, based on this 5:1 slope rather than the assumed 2:1 OA:pRONO₂, would give
691 2.5 times larger SOA mass yields than reported here.
692

693

694 **Figure 6.** Correlation of organic aerosol mass concentration with pRONO₂ mass concentration
695 for the full 2 July flight (grey points and red fit line, fitted slope and thus average OA/pRONO₂
696 mass ratio of ~30) and for the points during the selected plumes (colored points, colored by
697 plume age, average OA/pRONO₂ mass ratio of ~ 5).

698

699

700 **Table 2.** SOA Yields for each plume observation, estimated plume age, and likely origin. See
 701 text for description of uncertainty estimates. For the mass yields, the calculated SOA mass
 702 increase includes both the organic and (organo)nitrate aerosol mass; the measurements for OA
 703 increases shown in Figure 6 do not include the nitrate mass.

plume number	plume time (UTC)	SOA molar yield (fraction) [± SD]	SOA mass yield (fraction) [± SD]	plume age from O ₃ / NO ₂ clock assuming S=1 (hours)	Likely NO _x origin & altitude (m)
1	7/2/13 2:18	0.09 [0.05]	0.25 [0.14]	2.5	Greene County @ 540 m
2	7/2/13 2:20	0.07	0.21	1.5	<i>ibid</i>

704

705

706 **Table 3.** Several caveats to the present SOA yields analysis are listed below, alongside the
 707 expected direction each would adjust the estimated yields. Because we do not know whether or
 708 how much each process may have occurred in the studied plumes, we cannot quantitatively
 709 assess the resulting uncertainties, so we simply list them here. See text above for more detailed
 710 discussion.

Process	Effect on determined SOA yield
Organic nitrate aerosol loses NO ₃ functional group	Larger, because the non-nitrate OA would not be counted in this analysis
Both double bonds in isoprene are oxidized by NO ₃ : two nitrates per condensing molecule	Smaller, because the assumed organic to nitrate mass ratio assumes one nitrate per molecule
NO ₃ oxidizes daytime isoprene oxidation products (e.g. ISOPOOH) to make new aerosol	Smaller, because this would produce organic nitrate aerosol without corresponding decrease in isoprene, so that some of existing SOA production is mis-attributed to isoprene + NO ₃
Assumed organic to nitrate mass ratio is incorrect	Unknown direction of effect, depends on whether assumed ratio is high or low
Daytime-produced IEPOX uptake onto acidic particles	No effect (only changes ΔOA, not nitrate)
Suppression of O ₃ + monoterpene or O ₃ + isoprene SOA in plumes	No effect (only changes ΔOA, not nitrate)

711
 712 Finally, the large range in observed yields can be interpreted by examining the relationship to
 713 estimated plume age. Using the slope of O₃ to NO₂ (Eq. 1) to estimate plume age as described
 714 above, a weak positive correlation is observed (Table 2, Fig. S4), suggesting that as the plume
 715 ages, later-generation chemistry results in greater partitioning to the condensed phase of NO₃ +
 716 isoprene organonitrate aerosol products. This is consistent with the observation by Rollins et al.
 717 (Rollins et al., 2009) that 2nd-generation oxidation produced substantially higher SOA yields
 718 than the oxidation of the first double bond alone, but we note that these mass yields (averaging
 719 27%, would be 18% using the organic mass only) are higher than even the largest yield found in
 720 that chamber study (14%, used organic mass only).

721
 722 We observe increasing SOA yield, from a molar yield of around 10% at 1.5 hours up to 30% at 6
 723 hours of aging. The lowest yields observed are found in the most recently emitted plumes,
 724 suggesting the interpretation of the higher yields as a consequence of longer aging timescales
 725 in the atmosphere.

726 4.3 Mechanistic considerations

727
 728 These larger SOA mass yields from field determinations (average 27%) relative to chamber
 729 work (12 – 14%, see introduction) may arise for several reasons. We first assess the volatility of
 730 assumed first- and second-generation products using group contribution theory in order to
 731 predict partitioning. After a single oxidation step, with a representative product assumed to be a

732 C₅ hydroperoxynitrate, the saturation vapor pressure estimated by group contribution theory
733 (Pankow and Asher 2008) at 283 K would be 2.10×10^{-3} Torr ($C^* = 1.7 \times 10^4 \mu\text{g m}^{-3}$ for MW =
734 147 g mol^{-1}), while a double-oxidized isoprene molecule (assuming a C₅ dihydroxy dinitrate) has
735 an estimated vapor pressure of 7.95×10^{-8} Torr ($C^* = 1.01 \mu\text{g m}^{-3}$ for MW = 226 g mol^{-1}). This
736 supports the conclusion that while the first oxidation step produces compounds too volatile to
737 contribute appreciably to aerosol formation, oxidizing both double bonds of the isoprene
738 molecule is sufficient to produce substantial partitioning, consistent with Rollins et al. (Rollins et
739 al., 2009). This is also true if the second double bond is not oxidized by nitrate (group
740 contribution estimate P_{vap} for a C₅ tri-hydroxy nitrate is 7.7×10^{-8} Torr, $C^* = 0.79 \mu\text{g m}^{-3}$ for MW =
741 181 g mol^{-1}). These C^* saturation concentration values suggest that no dimer formation or
742 oligomerization is *required* to produce low-enough volatility products to condense to the aerosol
743 phase; however, such oligomerization would result in more efficient condensation. The fact that
744 Rollins et al. (Rollins et al., 2009) did not observe larger mass yields may indicate that it takes
745 longer than a typical chamber experiment timescale to reach equilibrium, or that this absorptive
746 partitioning model did not accurately capture those experiments, or that substantial loss of
747 semivolatiles to the chamber walls (e.g. (Krechmer et al., 2016)) suppressed apparent yields.

748

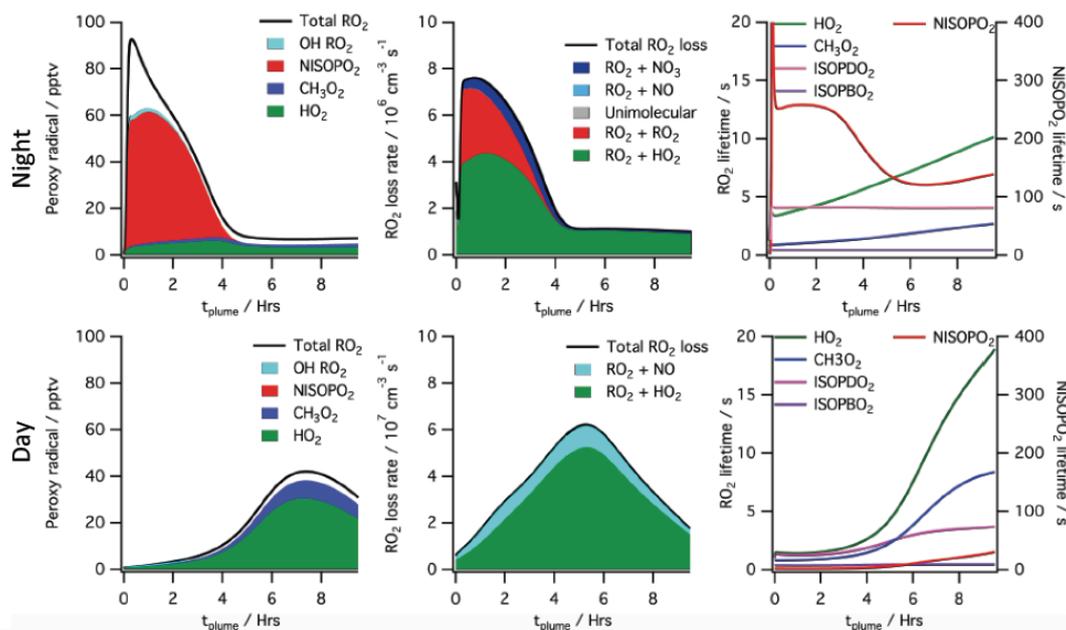

749 Determination of yields from ambient atmospheric data differs from chamber determinations in
750 several additional respects. First, ambient measurements do not suffer from wall loss effects,
751 such that no corrections are necessary for loss of aerosol or semi-volatile gases (Matsunaga
752 and Ziemann ‡ 2010, Krechmer et al., 2016). Second, ambient measurements take place on
753 the aging time scale of the atmosphere rather than a time scale imposed by the characteristics
754 of the chamber or the choice of oxidant addition. Third, the typical lifetime of the initially
755 produced nitrooxy-isoprene-RO₂ radical is more representative of the ambient atmosphere
756 rather than a chamber. The unique conditions of a high NO_x power plant plume affect lifetime
757 and fates of peroxy radicals, as described below.

758

759 To help interpret these in-plume peroxy radical lifetimes, a box model calculation using the
760 MCM v3.3.1 chemistry scheme was run (see details in Supplemental Information). This box
761 model shows substantially longer peroxy radical lifetimes during nighttime than daytime,
762 initializing with identical plume-observed conditions. These long peroxy radical lifetimes may
763 have consequences for comparison to chamber experiments: for example, in Schwantes'
764 (Schwantes et al., 2015) chamber experiment on the NO₃ + isoprene reaction mechanism, the
765 HO₂-limited nitrooxy-RO₂ lifetime was at maximum 30 s. In the plumes investigated in this study,
766 peroxy radical lifetimes are predicted to be substantially longer (>200 s early in the night, see
767 Fig. 7), allowing for the possibility of different bimolecular fates, or of unimolecular
768 transformations of the peroxy radicals that may result in lower-volatility products (e.g., auto-
769 oxidation to form highly oxidized molecules (Ehn et al., 2014)).

770

771

772

773

774 **Figure 7.** Simulated peroxy radical concentration (left), loss rates (middle), and lifetime (right),

775 using the MCM v3.3.1 chemical mechanism, for conditions typical of a nighttime intercepted

776 power plant plume (top) and the same plume initial conditions run for daytime simulation

777 (bottom, local noon occurs at 5 hrs). Included are total peroxy radical concentration and losses,

778 as well as the highlighted subclasses HO₂, CH₃O₂, total nitrooxy-isoprene-RO₂, and the total779 hydroxy-isoprene-RO₂ produced from OH oxidation. The righthand panels show HO₂, CH₃O₂780 and the dominant hydroxy-isoprene-RO₂ ISOPBO₂ and ISOPDO₂ (β -hydroxy-peroxy radicals

781 from OH attack at carbons 1 and 4 respectively) lifetime on the left axis and nitrooxy-isoprene-

782 RO₂ on the right axis, showing nighttime lifetimes an order of magnitude longer than daytime for783 this NO₃ + isoprene derived RO₂ radical (NISOPO₂).

784

785 The typically assumed major fate of nighttime RO₂ in the atmosphere is reaction with HO₂ to786 yield a hydroperoxide, NO₃-ROOH. This is shown in the model output above as the green787 reaction, and is responsible for half of early RO₂ losses in the MCM modeled plume. Schwantes788 *et al.* (Schwantes *et al.*, 2015) proposed reaction of these nighttime derived hydroperoxides with

789 OH during the following day as a route to epoxides, which in turn can form SOA via reaction

790 with acidic aerosol. Reaction of hydroperoxides with nighttime generated OH may similarly

791 provide a route to SOA through epoxides, albeit more slowly than that due to photochemically

792 generated OH.

793

794 The predicted longer nighttime peroxy radical lifetimes may enable unique chemistry. For

795 example, if nitrooxy-isoprene-RO₂ self-reactions are substantially faster than assumed in the796 MCM, as suggested by Schwantes *et al.* (Schwantes *et al.*, 2015), RO₂+RO₂ reactions may797 compete with the HO₂ reaction even more than shown in Fig. 7, and dimer formation may be

798 favored at night, yielding lower volatility products. The 5:1 AMS Organic:Nitrate ratio observed in

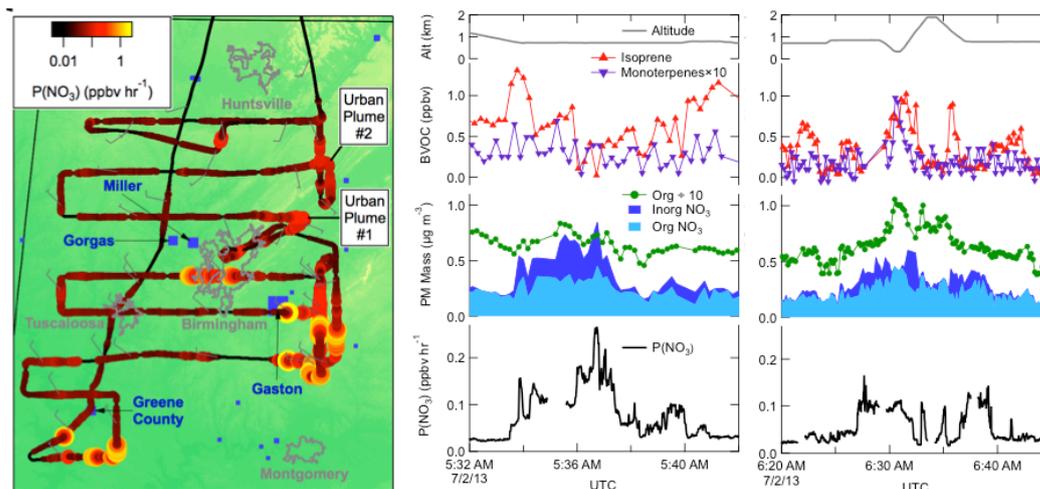

798 the SOA formed in Rollins et al. (Rollins et al., 2009) , and consistent with aggregated
799 observations reported here, may suggest that in some isoprene units the nitrate is re-released
800 as NO₂ in such oligomerization reactions. We note that this larger organic to nitrate ratio would
801 mean higher SOA mass yields than estimated in Table 2.

802
803 Alternatively, longer nighttime peroxy radical lifetimes may allow sufficient time for
804 intramolecular reactions to produce condensable products. This unimolecular isomerization
805 (auto-oxidation) of initially formed peroxy radicals is a potentially efficient route to low-volatility,
806 highly functionalized products that could result in high aerosol yields. For OH-initiated oxidation
807 of isoprene, laboratory relative rate experiments found the fastest 1,6-H-shift isomerization
808 reaction to occur for the hydroxy-isoprene-RO₂ radical at a rate of 0.002 s⁻¹ (Crouse et al.,
809 2011), meaning that peroxy radicals must have an ambient lifetime of >500 s for this process to
810 be dominant. As shown in Fig. 7, the simulated power plant plume peroxy radical lifetimes are
811 long (>200 s), so an isomerization reaction at this rate may play a significant role. However, a
812 recent study has demonstrated that OH-initiated and NO₃-initiated RO₂ radicals from the same
813 precursor VOC can have very different unimolecular reactive fates due to highly structurally
814 sensitive varying rates of reactions of different product channels (Kurtén et al., 2017). A similar
815 theoretical study on the rate of unimolecular autooxidation reactions of nitrooxy-isoprene-RO₂
816 radicals would be valuable to help determine under what conditions such reactions might occur,
817 and this knowledge could be applied to comparing chamber and field SOA yields.

818 **4.4 Two urban plume case studies**

819
820 In addition to the nine power plant plumes analyzed above to determine the NO₃ + isoprene
821 SOA molar yield, towards the end of the July 2 flight, the Birmingham urban plume was
822 intercepted twice (around 5:36 am and 6:37 am UTC, Fig. 8). These downwind urban plumes
823 are among the most aged plumes (estimated at 5.2 and 5.8 hours, respectively), but are also
824 substantially more diffuse than the narrow power plant plume intercepts and have lower peak
825 $P(\text{NO}_3)$. Nevertheless, we note that these two plumes contain periods of apparent anti-
826 correlation of isoprene and organic nitrate aerosol time series and high apparent SOA molar
827 yields (23%, 19%) and mass yields (62%, 51%), if calculated by the same method as above and
828 omitting the period of vertical profiling in the second plume. Potentially complicating these urban
829 SOA yield determinations is the fact that the inorganic fraction of nitrate was much larger than in
830 the power plant plumes (see Fig. 8). The background isoprene is also somewhat lower in these
831 urban plumes, potentially shifting the NO₃/N₂O₅ fate to reactions other than NO₃ + isoprene (see
832 Fig. S4 in Edwards et al. (Edwards et al., 2017)). The aerosol surface area is not noticeably
833 higher in these urban plumes, which one might expect to lead to a larger contribution of N₂O₅
834 uptake and hydrolysis. In the more complex mix of gases characteristic of an urban plume, we
835 hesitate to attribute these apparent yields exclusively to the NO₃ + isoprene reaction.
836

837
838 **Figure 8.** Flight map and time series of two urban plume intercepts, showing anticorrelation of
839 organic nitrate and isoprene. These more diffuse plumes, with lower $P(\text{NO}_3)$ and larger
840 inorganic nitrate contribution, make yield determination more uncertain, so we do not include
841 them in the overall yield determination. However, using the same methodology as for the power
842 plant plumes would give similarly high yields for these very aged plumes.
843

844 **4.5 Atmospheric implications and needs for future work**

845 Because this paper proposes higher SOA yield for the $\text{NO}_3 + \text{isoprene}$ reaction than measured
846 in chamber studies, we conclude with some discussion of the implications for regional aerosol
847 burdens, and further needs for investigation in the $\text{NO}_3 + \text{isoprene}$ system.
848

849 Using an isoprene + NO_3 yield parameterization that gave a 12% SOA mass yield at $10 \mu\text{g m}^{-3}$,
850 Pye et al. (2010) found that adding the $\text{NO}_3 + \text{isoprene}$ oxidation pathway increased isoprene
851 SOA mass concentrations in the southeastern United States by about 30%, increases of 0.4 to
852 $0.6 \mu\text{g m}^{-3}$. The larger $\text{NO}_3 + \text{isoprene}$ SOA mass yields suggested in this paper, with average
853 value of 30%, could double this expected NO_3 radical enhancement of SOA production.

854 Edwards et al. (2017) concluded that the southeast U.S. is currently in transition between NO_x -
855 independent and NO_x -controlled nighttime BVOC oxidation regime. If NO_3 -isoprene oxidation is
856 a larger aerosol source than currently understood, and if future NO_x reductions lead to a
857 stronger sensitivity in nighttime BVOC oxidation rates, regional SOA loadings could decrease by
858 a substantial fraction from the typical regional summertime OA loadings of $5 \pm 3 \mu\text{g m}^{-3}$ (Saha
859 et al., 2017).
860

861 Analysis of the degree of oxidation and chemical composition of $\text{NO}_3 + \text{isoprene}$ SOA would
862 help to elucidate mechanistic reasons for the different field and lab SOA yields. For example,
863 the potential contribution of the uptake of morning-after OH + NISOPOOH produced epoxides,
864 discussed above in section 4.3, onto existing (acidic) aerosol could be quantified by
865 measurement of these intermediates or their products in the aerosol phase. Assessment of

866 degree of oxidation could help determine whether auto-oxidation mechanisms are active.
867 Because of the potentially large effect on predicted SOA loading in regions of high isoprene
868 emissions, a better mechanistic understanding of these observed yields is crucial.
