8 **Abstract**

9 Aerosol acidity plays a key role in secondary aerosol formation. The high-temporal resolution  
10  $PM_{2.5}$  pH and size-resolved aerosol pH in Beijing were calculated with ISORROPIA-II. In 2016-  
11 2017, the mean  $PM_{2.5}$  pH (at relative humidity (RH) > 30%) over four seasons was  $4.5\pm 0.7$  (winter) >  
12  $4.4\pm 1.2$  (spring) >  $4.3\pm 0.8$  (autumn) >  $3.8\pm 1.2$  (summer), showing moderate acidity. In coarse-mode  
13 aerosols,  $Ca^{2+}$  played an important role in aerosol pH. Under heavily polluted conditions, more  
14 secondary ions accumulated in the coarse mode, leading to the acidity of the coarse mode aerosols  
15 shifted from neutral to weakly acidic. Sensitivity tests also demonstrated the significant contribution  
16 of crustal ions to  $PM_{2.5}$  pH. In the North China Plain (NCP), the common driving factors affecting  
17  $PM_{2.5}$  pH variation in all four seasons were  $SO_4^{2-}$ ,  $TNH_3$  (total ammonium (gas+aerosol)), and  
18 temperature, while the unique factors were  $Ca^{2+}$  in spring and RH in summer. The decreasing  $SO_4^{2-}$   
19 and increasing  $NO_3^-$  mass fractions in  $PM_{2.5}$  as well as excessive  $NH_3$  in the atmosphere in the NCP  
20 in recent years are the reasons why aerosol acidity in China is lower than that in Europe and the  
21 United States. The nonlinear relationship between  $PM_{2.5}$  pH and  $TNH_3$  indicated that although  $NH_3$   
22 in the NCP was abundant, the  $PM_{2.5}$  pH was still acidic because of the thermodynamic equilibrium  
23 between  $NH_4^+$  and  $NH_3$ . To reduce nitrate by controlling ammonia, the amount of ammonia must be  
24 greatly reduced below excessive quantities.

26

## 27 **1. Introduction**

28 Aerosol acidity has a significant effect on secondary aerosol formation through the gas-aerosol  
29 partitioning of semi-volatile and volatile species (Eddingsaas et al., 2010; Surratt et al., 2010; Pathak  
30 et al., 2011; Guo et al., 2016). Studies have shown that aerosol acidity can promote the generation  
31 of secondary organic aerosols by affecting aerosol acid-catalysed reactions (Rengarajan et al., 2011).  
32 Moreover, metals can become soluble by acid dissociation under low aerosol pH (Shi et al., 2011;  
33 Meskhidze et al., 2003; Fang et al., 2017) or by forming ligands with organic species, such as oxalate,  
34 at higher pH (Schwertmann et al., 1991). The investigation of aerosol acidity is conducive to better  
35 understanding the important role of aerosols in acid deposition and atmospheric chemical reactions.

36 Aerosol acidity is frequently estimated by the charge balance of measurable cations and anions.  
37 Nevertheless, not all ions (even trace ones) are well constrained in the observations and the  
38 dissociation state of multivalent ions are unclear, ion balance and other similar proxies fail to  
39 represent the in situ aerosol pH because such metrics cannot accurately predict the  $H^+$  concentration  
40 in the aerosol liquid phase (Guo et al., 2015; Hennigan et al., 2015). To better understand the in situ  
41 aerosol pH, the aerosol liquid water content (ALWC) and hydrogen ion concentration per volume  
42 air ( $H_{air}^+$ ) should be determined (Guo et al., 2015).

43 Most inorganic ions and some organic acids in aerosols are water soluble (Peng, 2001; Wang et  
44 al., 2017). Since the deliquescence relative humidity (DRH) and the efflorescence relative humidity  
45 (ERH) of mixed salts are lower than that of any single component, ambient aerosols are generally  
46 in the form of droplets containing liquid water (Seinfeld and Pandis, 2016). ALWC can be derived  
47 from hygroscopic growth factors or calculated by thermodynamic models, and good consistencies  
48 in ALWC have been found among these methods (Engelhart et al., 2011; Bian et al., 2014; Guo et  
49 al., 2015). However,  $H_{air}^+$  can only be obtained by thermodynamic models, which offer a more  
50 precise approach to determine aerosol pH (Nowak et al., 2006; Fountoukis et al., 2009; Weber et al.,  
51 2016; Fang et al., 2017). Among these thermodynamic models, ISORROPIA-II is widely used  
52 owing to its rigorous calculation, performance, and computational speed (Guo et al., 2015; Fang et  
53 al., 2017; Liu et al., 2017; Galon-Negru et al., 2018).

54 The North China Plain (NCP) is the region with the most severe aerosol pollution in China.  
55 Nitrate and sulfate are the major contributors to haze, and their secondary formation processes are  
56 determined in large part by aerosol pH (Zou et al., 2018; Huang et al., 2017; Gao et al., 2018).  
57 Therefore, understanding the aerosol pH level in this region is extremely important and has recently  
58 become a trending topic. Fine aerosol pH reported in the NCP (Liu et al., 2017; Song et al., 2018;  
59 Shi et al., 2017; Shi et al., 2019) was higher than that found in the United States or Europe, where  
60 aerosols are often highly acidic with a pH lower than 3.0 (Guo et al., 2015, 2016; Bougiatioti et al.,  
61 2016; Weber et al., 2016; Young et al., 2013). The differences in aerosol pH in the NCP arise from  
62 1) different methods or different model settings, 2) variations in  $PM_{2.5}$  chemical composition in the  
63 NCP in recent years, 3) the levels of gas precursors of the main water-soluble ions ( $NH_3$ ,  $HNO_3$ ,  
64 and HCl), and 4) differences in ambient temperature and RH. Studies demonstrated that pH diurnal

65 variations are largely driven by meteorological conditions (Guo et al., 2015, 2016; Bougiatioti et al.,  
66 2016). In the NCP, a comprehensive understanding of the impacts of these factors on aerosol pH is  
67 still poor.

68 Additionally, most studies on aerosol pH focus on  $PM_1$  or  $PM_{2.5}$ . Knowledge regarding size-  
69 resolved aerosol pH is still rare (Fang et al., 2017; Craig et al., 2018). Aerosol chemical  
70 compositions are different among multiple size ranges. Among inorganic ions,  $SO_4^{2-}$ ,  $NO_3^-$ ,  $Cl^-$ ,  $K^+$ ,  
71 and  $NH_4^+$  are mainly concentrated in the fine mode except on dusty days (Meier et al., 2009; Pan et  
72 al., 2009; Tian et al., 2014), whereas  $Mg^{2+}$  and  $Ca^{2+}$  are abundant in the coarse mode (Zhao et al.,  
73 2017). Aerosol pH can be expected to be diverse among different particle sizes; pH levels at different  
74 sizes may be associated with different formation pathways of secondary aerosols.

75 To better understand the driving factors of aerosol acidity, in this work, the thermodynamic model  
76 ISORROPIA-II was utilized to predict aerosol pH in Beijing based on a long-term online high-  
77 temporal resolution dataset and a size-resolved offline dataset. The hourly measured  $PM_{2.5}$  inorganic  
78 ions and precursor gases in four seasons from 2016 to 2017 were used to analyse the seasonal and  
79 diurnal variations in aerosol acidity; samples collected by multi-stage cascade impactors (MOUDI-  
80 120) were used to estimate the pH variations among 10 different size ranges. Additionally, a  
81 sensitivity analysis was conducted to identify the key factors affecting aerosol pH and gas-particle  
82 partitioning. The main purposes of this work are to 1) obtain the  $PM_{2.5}$  pH level based on an online  
83 measurement, contributing towards a global pH dataset; 2) investigate the size-resolved aerosol pH,  
84 providing useful information for understanding the formation processes of secondary aerosols; and  
85 3) explore the main factors affecting aerosol pH and gas-particle partitioning, which can help  
86 explain the possible reasons for pH divergence in different works and provide a basis for controlling  
87 secondary aerosol generation.

## 88 **2. Data Collection and Methods**

### 89 **2.1 Site**

90 The measurements were performed at the Institute of Urban Meteorology in the Haidian district  
91 of Beijing (39°56'N, 116°17'E). The site is located next to a high-density residential area, without  
92 significant nearby air pollution emissions. Therefore, the observation data represent the air quality  
93 levels of the urban area of Beijing.

### 94 **2.2 Online data collection**

95 Water-soluble ions ( $SO_4^{2-}$ ,  $NO_3^-$ ,  $Cl^-$ ,  $NH_4^+$ ,  $Na^+$ ,  $K^+$ ,  $Mg^{2+}$ , and  $Ca^{2+}$ ) in  $PM_{2.5}$  and gaseous  
96 precursors (HCl,  $HNO_3$ ,  $HNO_2$ ,  $SO_2$ , and  $NH_3$ ) in ambient air were measured by an online analyser  
97 (MARGA) with hourly temporal resolution during spring (April and May 2016), winter (February  
98 2017), summer (July and August 2017), and autumn (September and October 2017). More details  
99 about MARGA can be found in Rumsey et al. (2014) and Chen et al. (2017). The  $PM_{2.5}$  and  $PM_{10}$   
100 mass concentrations (TEOM 1405DF), hourly ambient temperature and RH were also  
101 synchronously obtained. The hourly concentrations of  $PM_{2.5}$ ,  $PM_{10}$ , and major secondary ions ( $SO_4^{2-}$ ,  
102  $NO_3^-$ , and  $NH_4^+$ ) in  $PM_{2.5}$ , as well as meteorological parameters during the observations, are shown

103 in Figure 1. In the spring, two dust events occurred (April 21 and May 6). In the following pH  
104 analysis based on MARGA data, it was assumed that the particles were internally mixed; hence,  
105 these two dust events were excluded from this analysis.

### 106 **Figure 1**

#### 107 **2.3 Size-resolved chemical composition**

108 A micro-orifice uniform deposit impactor (MOUDI-120) was used to collect size-resolved aerosol  
109 samples with calibrated 50% cut sizes of 0.056, 0.10, 0.18, 0.32, 0.56, 1.0, 1.8, 3.1, 6.2, 9.9 and 18  
110  $\mu\text{m}$ . Size-resolved sampling was conducted July 12-18, 2013; January 13-19, 2014; July 3-5, 2014;  
111 October 9-20, 2014; and January 26-28, 2015. Fifteen, fourteen, and eighteen sets of samples were  
112 obtained in summer, autumn, and winter, respectively. Except for two sets of samples, all the  
113 samples were collected in daytime (from 08:00 to 19:00) and nighttime (from 20:00 to 7:00 the next  
114 day). One hour of preparation time was allowed for filter changing and washing the nozzle plate  
115 with ethanol. The water-soluble ions in the samples were analysed by using ion chromatography  
116 (DIONEX ICS-1000). Detailed information about the features of MOUDI-120 and the procedures  
117 of sampling, pre-treatment, and laboratory chemical analysis (including quality assurance & quality  
118 control) were described in our previous papers (Zhao et al., 2017; Su et al., 2018).

#### 119 **2.4 Aerosol pH prediction**

120 Aerosol pH can be predicted by thermodynamic models such as AIM and ISORROPIA (Clegg et  
121 al., 1998; Nenes et al., 1998). AIM is considered an accurate benchmark model, while ISORROPIA  
122 has been optimized for use in chemical transport models. Currently, ISORROPIA-II, with the  
123 addition of  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$  (Fountoukis and Nenes, 2007), can calculate the equilibrium  $\text{H}_{\text{air}}^+$   
124 and ALWC with reasonable accuracy by using the water-soluble ion mass concentration,  
125 temperature (T), and RH as input.  $\text{H}_{\text{air}}^+$  and ALWC were then used to predict aerosol pH by Eq. (1).

$$126 \quad \text{pH} = -\log_{10} \text{H}_{\text{aq}}^+ \cong -\log_{10} \frac{1000 \text{H}_{\text{air}}^+}{\text{ALWC}_i} \quad (1)$$

127 where  $\text{H}_{\text{aq}}^+$  ( $\text{mole L}^{-1}$ ) is the hydronium ion concentration in the ambient particle liquid water.  $\text{H}_{\text{aq}}^+$   
128 can also be calculated as  $\text{H}_{\text{air}}^+$  ( $\mu\text{g m}^{-3}$ ) divided by the concentration of ALWC associated with  
129 inorganic species,  $\text{ALWC}_i$  ( $\mu\text{g m}^{-3}$ ). Both the inorganic species and part of the organic species in  
130 particles are hygroscopic. However, pH prediction is not highly sensitive to water uptake by organic  
131 species ( $\text{ALWC}_o$ ) (Guo et al., 2015, 2016). In recent years, the fraction of organic matter in  $\text{PM}_{2.5}$  in  
132 the NCP was 20%~25%, which is much lower than that in the United States (Guo et al., 2015). In  
133 contrast, approximately 50% of  $\text{PM}_{2.5}$  in the NCP is inorganic ions (Huang et al., 2017; Zhang et al.,  
134 2018; Zhang et al., 2019). The results obtained by Liu et al. (2017) in Beijing showed that the mass  
135 fraction of organic matter-induced particle water accounted for only 5% of total ALWC, indicating  
136 a negligible contribution to aerosol pH. Hence, aerosol pH can be fairly well predicted by  
137 ISORROPIA-II with only measurements of inorganic species in most cases. However, potential  
138 errors can be incurred by ignoring  $\text{ALWC}_o$  in regions where hygroscopic organic species have a  
139 relatively high contribution to fine particles.

140 In ISORROPIA-II, forward and reverse modes are provided to predict ALWC and  $H_{\text{air}}^+$ . In  
141 forward mode, T, RH, and the total (*i.e.*, gas+aerosol) concentrations of  $\text{NH}_3$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HCl}$ , and  
142  $\text{HNO}_3$  need to be input. In reverse mode, equilibrium partitioning is calculated given only the  
143 concentrations of aerosol components, RH, and T as input. In this work, the online ion  
144 chromatography system MARGA was used to measure both inorganic ions in  $\text{PM}_{2.5}$  and gaseous  
145 precursors. Moreover, the forward mode has been reported to be less sensitive to measurement error  
146 than the reverse mode (Hennigan et al., 2015; Song et al., 2018). Hence, ISORROPIA-II was run in  
147 forward mode for aerosols in the metastable conditions in this study.

148 When using ISORROPIA-II to calculate the  $\text{PM}_{2.5}$  acidity, all particles were assumed to be  
149 internally mixed, and the bulk properties were used without considering the variability in chemical  
150 composition at a given particle size. In the ambient atmosphere, the aerosol chemical composition  
151 is complicated; hence, the deliquescence relative humidity (DRH) of aerosols is generally low  
152 (Seinfeld and Pandis, 2016). Once the particles are deliquescent, crystallization only occurs at a  
153 very low RH, which is called hysteresis phenomenon. The efflorescence RH (ERH) of a salt cannot  
154 be calculated from thermodynamic principles; rather, it must be measured in the laboratory. For a  
155 particle consisting of approximately 1:1  $(\text{NH}_4)_2\text{SO}_4 : \text{NH}_4\text{NO}_3$ , the ERH is around 20%, while for a  
156 1:2 molar ratio it decreases to around 10%. (Shaw and Rood 1990). Recently,  $\text{NO}_3^-$  dominates the  
157 particles in the NCP (Zhao et al., 2013, 2017; Huang et al., 2017; Ma et al., 2017); therefore, we  
158 assumed that the particles are in a liquid state (metastable condition). Assumption that particles are  
159 in metastable were adopted by numerous studies in the NCP (Liu et al., 2017; Guo et al., 2017; Shi  
160 et al., 2017; Shi et al., 2019). Figure 2 and Figure S1-S4 show comparisons between the predicted  
161 and measured  $\text{NH}_3$ ,  $\text{HNO}_3$ ,  $\text{HCl}$ ,  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ,  $\text{Cl}^-$ ,  $\varepsilon(\text{NH}_4^+)$  ( $\text{NH}_4^+ / (\text{NH}_3 + \text{NH}_4^+)$ , mol/mol),  $\varepsilon(\text{NO}_3^-)$   
162 ( $\text{NO}_3^- / (\text{HNO}_3 + \text{NO}_3^-)$ , mol/mol), and  $\varepsilon(\text{Cl}^-)$  ( $\text{Cl}^- / (\text{HCl} + \text{Cl}^-)$ , mol/mol) based on real-time ion  
163 chromatography data; all results are coloured with the corresponding RH. The predicted and  
164 measured  $\text{NH}_3$ ,  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and  $\text{Cl}^-$  values are in good agreement: the  $R^2$  values of linear regressions  
165 are all higher than 0.94, and the slopes are approximately 1. Moreover, the agreement between the  
166 predicted and measured  $\varepsilon(\text{NH}_4^+)$  is better than those of  $\varepsilon(\text{NO}_3^-)$  and  $\varepsilon(\text{Cl}^-)$ . The slope of the linear  
167 regression between the predicted and measured  $\varepsilon(\text{NH}_4^+)$  was 0.93, 0.91, 0.95, and 0.96 and  $R^2$  was  
168 0.87, 0.93, 0.89, and 0.97 in spring, winter, summer, and autumn, respectively. However, the  
169 measured and predicted partitioning of  $\text{HNO}_3$  and  $\text{HCl}$  show significant discrepancies ( $R^2$  values of  
170 0.28 and 0.18, respectively), which may be attributed to the much lower gas concentrations than  
171 particle concentrations, as well as the  $\text{HNO}_3$  and  $\text{HCl}$  measurement uncertainties from MARGA  
172 (Rumsey et al., 2014). Clearly, more scatter points deviate from the 1:1 line when ISORROPIA-II  
173 is operated at  $\text{RH} \leq 30\%$ , which is highly evident in winter and spring. It should be noted that when  
174 RH is low, ALWC becomes very small,  $\text{PM}_{2.5}$  pH is subject to considerably more uncertain. Guo et  
175 al. (2017) suggest that the lower RH limit is about 40%. In this work, due to the overall good  
176 agreement between predictions and measurements when RH was high than 30%, we only determined  
177 the  $\text{PM}_{2.5}$  pH for data with RH higher than 30%.

## Figure 2

Running ISORROPIA-II in the forward mode with only aerosol component concentrations as input may result in a bias in predicted pH due to repartitioning of ammonia in the model, leading to a lower predicted pH when gas-phase data are not available (Hennigan et al., 2015). In this work, no synchronous gas phase was available during the MOUDI sampling periods, the gas-phase measurements that were taken by the MARGA in 2017 were therefore applied. Even if the periods are not perfectly aligned, the order of magnitude of  $\text{NH}_3$ ,  $\text{HNO}_3$  and  $\text{HCl}$  during a certain period does not change drastically. Guo et al. (2017) found that even if there is some error in  $\text{NH}_3$ , pH is less sensitive to it, a factor of 10 change in  $\text{NH}_3$  is required to change pH by one unit. Averaged  $\text{NH}_3$ ,  $\text{HNO}_3$ , and  $\text{HCl}$  measured by MARGA matched to  $\text{PM}_{2.5}$  mass concentration levels during the MOUDI sampling periods, together with ion concentrations of samples collected by MOUDI as well as the average RH and T during each sampling period were used to determine the aerosol pH for different size ranges. Similar to calculating the  $\text{PM}_{2.5}$  pH, it was assumed that all the particles in each size bin were internally mixed and had the same pH.

Comparisons of the measured and predicted  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{Cl}^-$  for MOUDI samples are shown in Figure 3. The measured and predicted  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{Cl}^-$  agreed very well in fine-mode particles, the slopes are approximately 1. In the coarse-mode, the predicted  $\text{NH}_4^+$  was lower than the measured  $\text{NH}_4^+$  due to the impact of crustal ions.

## Figure 3

### 2.5 Sensitivity of $\text{PM}_{2.5}$ pH to $\text{SO}_4^{2-}$ , $\text{TNO}_3$ , $\text{TNH}_3$ , $\text{Ca}^{2+}$ , RH, and T

To explore the major influencing factors on aerosol pH, sensitivity tests were performed. In the sensitivity analysis,  $\text{SO}_4^{2-}$ ,  $\text{TNO}_3$  (total nitrate (gas+aerosol) expressed as equivalent  $\text{HNO}_3$ ),  $\text{TNH}_3$  (total ammonium (gas+aerosol) expressed as equivalent  $\text{NH}_3$ ),  $\text{Ca}^{2+}$ , RH, and T were selected as the variables since  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  are major anions in aerosols,  $\text{NH}_4^+$  and  $\text{Ca}^{2+}$  are major cations in aerosols, and  $\text{Ca}^{2+}$  is generally considered representative of crustal ions. To assess how a variable affects  $\text{PM}_{2.5}$  pH, the real-time measured values of this variable and the average values of other species (K, Na, Mg, and total chloride (gas+aerosol) were also included) in each season were input into ISORROPIA-II. The magnitude of the relative standard deviation (RSD) of the calculated aerosol pH can reflect the impact of variable variations on aerosol acidity. The higher the RSD is, the greater the impact, and vice versa. The average value and variation range for each variable in the four seasons are listed in Table S1.

The sensitivity analysis in this work was only aimed at  $\text{PM}_{2.5}$  (*i.e.*, fine particles) since the MARGA system equipped with a  $\text{PM}_{2.5}$  inlet had a high temporal resolution (1 h). In addition, the data set had a wide range, covering different levels of haze events. The sensitivity analysis in this work only reflected the characteristics during the observation periods, and further work is needed to determine whether the sensitivity analysis is valid in other environments.

## 3. Results and Discussion

### 3.1 Overall summary of $\text{PM}_{2.5}$ pH over four seasons

216 The average mass concentrations of PM<sub>2.5</sub> and major inorganic ions in the four seasons are shown  
217 in Table 1. Among all the ions measured, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and NH<sub>4</sub><sup>+</sup> were the three most dominant  
218 species, accounting for 83% ~ 87% of the total ion content. The average concentrations of primary  
219 inorganic ions (Cl<sup>-</sup>, Na<sup>+</sup>, K<sup>+</sup>, Mg<sup>2+</sup>, and Ca<sup>2+</sup>) were higher in spring than in other seasons. PM<sub>2.5</sub> in  
220 Beijing showed moderate acidity, with PM<sub>2.5</sub> pH values of 4.4±1.2, 4.5±0.7, 3.8±1.2, and 4.3±0.8  
221 for spring, winter, summer, and autumn observations, respectively (data at RH ≤30% were excluded).  
222 The overall winter PM<sub>2.5</sub> pH was comparable to the result (4.2) found in Beijing by Liu et al. (2017)  
223 and that (4.5) found by Guo et al. (2017), but lower than that (4.9, winter and spring) in Tianjin (Shi  
224 et al., 2017), another mega city approximately 120 km away from Beijing. The PM<sub>2.5</sub> pH in summer  
225 was lowest among all four seasons. The seasonal variation in PM<sub>2.5</sub> pH in this work was similar to  
226 the results in Tan et al. (2018), except for spring, and followed the trend winter (4.11 ± 1.37) >  
227 autumn (3.13 ± 1.20) > spring (2.12 ± 0.72) > summer (1.82 ± 0.53).

228 **Table 1**

229 To further investigate the PM<sub>2.5</sub> pH level under different pollution conditions over four seasons,  
230 the PM<sub>2.5</sub> concentrations were classified into three groups: 0~75 μg m<sup>-3</sup>, 75~150 μg m<sup>-3</sup>, and >150  
231 μg m<sup>-3</sup>, representing clean, polluted, and heavily polluted conditions, respectively. The relationship  
232 between PM<sub>2.5</sub> concentration and pH is shown in Figure S5. The PM<sub>2.5</sub> pH under clean conditions  
233 spanned 2~7, while those under polluted and heavily polluted conditions was mostly concentrated  
234 from 3~5. Table 1 shows that as the air quality deteriorated, the aerosol component concentration,  
235 as well as ALWC and H<sub>air</sub><sup>+</sup>, all increased in each season. The average PM<sub>2.5</sub> pH under clean  
236 conditions was the highest (Table 1), followed by polluted and heavily polluted conditions in spring,  
237 summer, and autumn. In winter, however, the average pH under polluted conditions (4.8±1.0) was  
238 the highest.

239 On clean days, some higher PM<sub>2.5</sub> pH values (>6) appeared and were generally accompanied by  
240 higher mass fraction of crustal ions (Mg<sup>2+</sup> and Ca<sup>2+</sup>). In contrast, lower PM<sub>2.5</sub> pH (<3) was often  
241 accompanied by a higher mass fraction of SO<sub>4</sub><sup>2-</sup> and lower mass fraction of crustal ions, such  
242 conditions were most obvious in summer (Figure 4). Under polluted and heavily polluted conditions,  
243 the mass fractions of major chemical components were similar, and the difference in PM<sub>2.5</sub> pH  
244 between these two conditions was also small. All of these results indicated that the aerosol chemical  
245 composition should be an essential factor that drives aerosol acidity. The impact of aerosol  
246 composition on PM<sub>2.5</sub> pH is discussed in Section 3.4.

247 **Figure 4**

248 In spring, summer, and autumn, the pH of PM<sub>2.5</sub> from the northern direction was generally higher  
249 than that from the southwest direction, and the higher pH in summer also occurred with strong  
250 southwest winds (wind speed >3 m s<sup>-1</sup>) (Figure 5). Generally, northern winds occur with cold-front  
251 systems, which can sweep away air pollutants but raise dust in which the crustal ion species (Ca<sup>2+</sup>,  
252 Mg<sup>2+</sup>) are higher. In winter, the PM<sub>2.5</sub> pH was distributed relatively evenly in all wind directions,  
253 but we surprisingly found that the pH in northerly winds on clean days could be as low as 3~4,

254 which was consistent with the high mass fraction of  $\text{SO}_4^{2-}$ .

### 255 **Figure 5**

### 256 **3.2 Diurnal variation in ALWC, $\text{H}_{\text{air}}^+$ , and $\text{PM}_{2.5}$ pH**

257 Obvious diurnal variation was observed based on the long-term online dataset, as shown in Figure  
258 6. To understand the factors that can drive changes in  $\text{PM}_{2.5}$  pH, the diurnal variations of  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  
259 ALWC, and  $\text{H}_{\text{air}}^+$  were investigated and are exhibited in Figure 6. Generally, ALWC was higher  
260 during nighttime than daytime and reached a peak near 04:00 ~ 06:00 (local time). After sunrise,  
261 the increasing temperature resulted in a rapid drop in RH, leading to a clear loss of particle water,  
262 and ALWC reached the lowest level in the afternoon.  $\text{H}_{\text{air}}^+$  was highest in the afternoon, followed  
263 by nighttime, and  $\text{H}_{\text{air}}^+$  was relatively low in the morning. The low ALWC and high  $\text{H}_{\text{air}}^+$  values in  
264 the afternoon resulted in the minimum  $\text{PM}_{2.5}$  pH. The average nighttime pH was 0.3~0.4 units higher  
265 than that during daytime. From the above discussion, we found that both  $\text{H}_{\text{air}}^+$  and ALWC had  
266 significant diurnal variations, which means that besides chemical composition, the  $\text{PM}_{2.5}$  pH diurnal  
267 variation was also affected by meteorological conditions. This trend is slightly different from the  
268 situation from the US: Guo et al. (2015) found that the ALWC diurnal variation was significant and  
269 the diurnal pattern in pH was mainly driven by the dilution of aerosol water.

270 The correlation between  $\text{NO}_3^-$  concentration and  $\text{PM}_{2.5}$  pH was weakly positive at low ALWC,  
271 and  $\text{PM}_{2.5}$  pH was almost independent of the  $\text{NO}_3^-$  mass concentration at higher ALWC values  
272 (Figure S6). In contrast, at a low ALWC level, increasing  $\text{SO}_4^{2-}$  decreased the pH; at a high ALWC  
273 level, a negative correlation still existed between  $\text{SO}_4^{2-}$  mass concentration and  $\text{PM}_{2.5}$  pH.  $\text{SO}_4^{2-}$  had  
274 a greater effect than  $\text{NO}_3^-$  on  $\text{PM}_{2.5}$  pH.

### 275 **Figure 6**

### 276 **3.3 Factors affecting $\text{PM}_{2.5}$ pH**

277 In this work, the effects of  $\text{SO}_4^{2-}$ ,  $\text{TNO}_3$ ,  $\text{TNH}_3$ ,  $\text{Ca}^{2+}$ , RH, and T on  $\text{PM}_{2.5}$  pH were determined  
278 through a four-season sensitivity analysis. The common important driving factors affecting  $\text{PM}_{2.5}$   
279 pH variations in all four seasons were  $\text{SO}_4^{2-}$ ,  $\text{TNH}_3$ , and T (Table 2), while the unique influencing  
280 factors were  $\text{Ca}^{2+}$  in spring and RH in summer. For ALWC, the most important factor was RH,  
281 followed by  $\text{SO}_4^{2-}$  or  $\text{NO}_3^-$ . Figure 7 and Figure S7-S14 show how these factors affect the  $\text{PM}_{2.5}$  pH,  
282 ALWC, and  $\text{H}_{\text{air}}^+$  over all four seasons.

### 283 **Table 2**

284  $\text{H}_2\text{SO}_4$  can be completely dissolved in ALWC and in the form of sulfate. As shown in Table 3,  
285  $\text{HNO}_3$  also had a high conversion rate to nitrate when  $\text{RH}>30\%$ . Under rich-ammonia conditions  
286 (defined and explained in Figure S15), sulfate and nitrate mostly exist in aerosol phase with  
287 ammonium. The thermodynamic equilibrium between  $\text{NH}_4^+$  and  $\text{NH}_3$  makes aerosol acidic (Weber  
288 et al., 2016). In the sensitivity tests, we found that elevated  $\text{SO}_4^{2-}$  is crucial in the increase of  $\text{H}_{\text{air}}^+$   
289 (Figure S7, S9, S12) and ALWC (Figure S8, S10, S13), and has a key role in aerosol acidity (Figure  
290 7, S11, S14). However, only the  $\text{PM}_{2.5}$  pH in winter and autumn decreased significantly with  
291 elevated  $\text{TNO}_3$  (Figure 7, S14). In spring and summer,  $\text{PM}_{2.5}$  pH changed little with elevated  $\text{TNO}_3$ .

292 Moreover, when the TNO<sub>3</sub> concentration was low, PM<sub>2.5</sub> pH even increased with elevated TNO<sub>3</sub>  
293 (Figure 7, S11). The effect of TNO<sub>3</sub> on H<sub>air</sub><sup>+</sup> and ALWC is similar to that of SO<sub>4</sub><sup>2-</sup>, that is, the  
294 elevated TNO<sub>3</sub> will also result in the increase of H<sub>air</sub><sup>+</sup> and ALWC. The difference is that SO<sub>4</sub><sup>2-</sup> can  
295 lead to much higher concentration of H<sub>air</sub><sup>+</sup> than TNO<sub>3</sub> due to its low volatility (Figure S7, S9, S12).  
296 Thus, the sensitivity of PM<sub>2.5</sub> pH to TNO<sub>3</sub> is less than that to SO<sub>4</sub><sup>2-</sup>. Moreover, in spring and summer,  
297 more excessive NH<sub>3</sub> could continuously react with the increasing TNO<sub>3</sub> (Table S1), leading to the  
298 minimal changes in PM<sub>2.5</sub> pH with elevated TNO<sub>3</sub>. Differently, TNH<sub>3</sub> mass concentration was lower  
299 in winter and TNO<sub>3</sub> was higher in autumn (Table S1), which made TNH<sub>3</sub> was not excessive enough  
300 and resulted in the decreased PM<sub>2.5</sub> pH with elevated TNO<sub>3</sub>.

301 In the process of increasing NH<sub>3</sub> concentration in the ammonia–nitric acid–sulfuric acid–water  
302 system, NH<sub>3</sub> first reacts with sulfuric acid and consumes a large amount of H<sup>+</sup>, and then reacts with  
303 HNO<sub>3</sub> to produce ammonium nitrate (Seinfeld and Pandis, 2016). After most nitric acid is converted  
304 to ammonium nitrate, it is difficult to dissolve more ammonia into aerosol droplet. The sensitivity  
305 tests well describe this mechanism. Changes in TNH<sub>3</sub> in the lower concentration range had a  
306 significant impact on H<sub>air</sub><sup>+</sup> and PM<sub>2.5</sub> pH, and variations in TNH<sub>3</sub> at higher concentrations could  
307 only generate limited pH changes (Figure 7, S11, S14). The nonlinear relationship between PM<sub>2.5</sub>  
308 pH and TNH<sub>3</sub> indicates that although NH<sub>3</sub> in the NCP was abundant, the PM<sub>2.5</sub> pH was far from  
309 neutral.

310

311

### Figure 7

312 In this work, PM<sub>2.5</sub> pH was lowest in summer but highest in winter, which was consistent with  
313 the SO<sub>4</sub><sup>2-</sup> mass fraction with respect to the total ion content. The SO<sub>4</sub><sup>2-</sup> mass fraction was highest in  
314 summer among the four seasons, with a value of 32.4%±11.1%, but lowest in winter, with a value  
315 of 20.9%±4.4%. In recent years, the SO<sub>4</sub><sup>2-</sup> mass fraction in PM<sub>2.5</sub> in Beijing has decreased  
316 significantly due to the strict emission control measures for SO<sub>2</sub>; in most cases, NO<sub>3</sub><sup>-</sup> dominates the  
317 inorganic ions (Zhao et al., 2013, 2017; Huang et al., 2017; Ma et al., 2017), which could reduce  
318 aerosol acidity. A study in the Pearl River Delta of China showed that the in situ acidity of PM<sub>2.5</sub>  
319 significantly decreased from 2007-2012; the variation in acidity was mainly caused by the decrease  
320 in sulfate (Fu et al., 2015). The excessive NH<sub>3</sub> in the atmosphere and the high NO<sub>3</sub><sup>-</sup> mass fraction in  
321 PM<sub>2.5</sub> is the reason why the aerosol acidity in China is lower than that in Europe and the United  
322 States (Guo et al., 2017).

323 Ca<sup>2+</sup> is an important crustal ion; in the output of ISORROPIA-II, Ca exists mainly as CaSO<sub>4</sub>  
324 (slightly soluble). Elevated Ca<sup>2+</sup> concentrations can increase PM<sub>2.5</sub> pH by decreasing H<sub>air</sub><sup>+</sup> and  
325 ALWC (Figure 7 and Figure S7-S14). As discussed in Section 3.1, on clean days, PM<sub>2.5</sub> pH reached  
326 6~7 when the mass fraction of Ca<sup>2+</sup> was high; hence, the role of crustal ions on PM<sub>2.5</sub> pH cannot be  
327 ignored in areas or seasons (such as spring) in which mineral dust is an important particle source.  
328 Due to the strict control measures for road dust, construction sites, and other bare ground, the crustal  
329 ions in PM<sub>2.5</sub> decreased significantly in the NCP, especially on polluted days.

330 In addition to the particle chemical composition, meteorological conditions also have important  
331 impacts on aerosol acidity. RH had different impacts on PM<sub>2.5</sub> pH in different seasons (Figure 7,  
332 S11, S14). In winter, elevated RH could reduce PM<sub>2.5</sub> pH. However, an opposite tendency was  
333 observed in summer. In spring and autumn, RH had little impact on PM<sub>2.5</sub> pH. Elevated RH can  
334 enhance water uptake and promote gas-to-particle conversion, resulting in the increased H<sub>air</sub><sup>+</sup> and  
335 ALWC synchronously for all four seasons. Therefore, the effect of RH on PM<sub>2.5</sub> pH depends on the  
336 differences in the degree of RH's effect on H<sub>air</sub><sup>+</sup> and RH's effect on ALWC. Temperature can alter  
337 the PM<sub>2.5</sub> pH by affecting gas-particle partitioning. At higher ambient temperatures, ε(NH<sub>4</sub><sup>+</sup>),  
338 ε(NO<sub>3</sub><sup>-</sup>), and ε(Cl<sup>-</sup>) all showed a decreased tendency (Figure 8, S16). The volatilization of  
339 ammonium nitrate and ammonium chloride can result in a net increase in particle H<sup>+</sup> and lower pH  
340 (Guo et al., 2018). Moreover, a higher ambient temperature tends to lower ALWC, which can further  
341 decrease PM<sub>2.5</sub> pH.

### 342 **Figure 8**

#### 343 **3.4 Size-resolved aerosol pH**

344 Inorganic ions in particles present clear size distributions, and the size-resolved chemical  
345 composition can change at different pollution levels (Zhao et al., 2017; Ding et al., 2017; Ding et  
346 al., 2018), which may result in variations in aerosol pH. Thus, we further investigated the size-  
347 resolved aerosol pH at different pollution levels. According to the average PM<sub>2.5</sub> concentration  
348 during each sampling period, all the samples were also classified into three groups (clean, polluted,  
349 and heavily polluted) according to the rules described in Section 3.1. A severe haze episode occurred  
350 during the autumn sampling period; hence, there were more heavily polluted samples in autumn  
351 than in other seasons. Figure 9 shows the average size distributions of PM components and pH under  
352 clean, polluted, and heavily polluted conditions in summer, autumn, and winter. NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NH<sub>4</sub><sup>+</sup>,  
353 Cl<sup>-</sup>, K<sup>+</sup>, OC, and EC were mainly concentrated in the size range of 0.32~3.1 μm, while Mg<sup>2+</sup> and  
354 Ca<sup>2+</sup> were predominantly distributed in the coarse mode (>3.1 μm). During haze episodes, the  
355 sulfate and nitrate in the fine mode increased significantly. However, the increases in Mg<sup>2+</sup> and Ca<sup>2+</sup>  
356 in the coarse mode were not as substantial as the increases in NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and NH<sub>4</sub><sup>+</sup>, and the low  
357 wind speed made it difficult to raise dust during heavily polluted periods. More detailed information  
358 about the size distributions for all analysed species during the three seasons is given in Zhao et al.  
359 (2017) and Su et al. (2018).

### 360 **Figure 9**

361 The aerosol pH in both fine mode and coarse mode was lowest in summer among the three  
362 seasons, followed by autumn and winter. The seasonal variation in aerosol pH derived from MOUDI  
363 data was consistent with that derived from the real-time PM<sub>2.5</sub> dataset. In summer, the predominance  
364 of sulfate in fine mode and high ambient temperature resulted in a low pH, ranging from 3.2 to 3.9.  
365 The fine-mode aerosol pH in autumn and winter was in the range of 3.9 ~ 5.2 and 4.7 ~ 5.7,  
366 respectively. The fine-mode aerosol pH was overall comparable to the PM<sub>2.5</sub> pH. Moreover, in the  
367 fine mode, the difference in aerosol pH among size bins was not significant because the aerosol is

368 in thermodynamic equilibrium with the gas phase (Fang et al., 2017). Additionally, the size  
369 distributions of aerosol pH in the daytime and nighttime were explored and are illustrated in Figure  
370 S17. In summer and autumn, the pH in the daytime was lower than that in the nighttime, while in  
371 winter, the pH was higher in the daytime. During the winter sampling periods,  $\text{SO}_4^{2-}$  mass fraction  
372 were obviously higher in the nighttime and led to abundant  $\text{H}_{\text{air}}^+$ .

373 The abundance of  $\text{Ca}^{2+}$  in the coarse mode led to a predicted aerosol pH approximately at or  
374 higher than 7 in autumn and winter. Even if the coarse mode  $\text{Ca}^{2+}$  mass concentration in the summer  
375 was low, the coarse mode aerosol pH was still more than 1 unit higher than the fine mode aerosol  
376 pH. The difference in aerosol pH (with and without  $\text{Ca}^{2+}$ ) increased with increasing particle size  
377 above 1  $\mu\text{m}$  (Figure S18). Moreover, the coarse-mode aerosols during severely hazy days shifted  
378 from neutral to weakly acidic, especially in autumn and winter. As shown in Figure 9, the pH in  
379 stage 3 (3.1-6.2  $\mu\text{m}$ ) declined from 7.4 (clean) to 5.0 (heavily polluted) in winter. The significant  
380 decrease in the mass ratio of  $\text{Ca}^{2+}$  in the coarse mode particles on heavily polluted days resulted in  
381 the loss of acid-buffering capacity. Furthermore, the different size-resolved aerosol acidity levels  
382 may be associated with different generation pathways of secondary aerosols. According to Cheng  
383 et al. (2017) and Wang et al. (2017), the aqueous oxidation of  $\text{SO}_2$  by  $\text{NO}_2$  is key in sulfate formation  
384 under a high RH and neutral conditions. However, it is speculated that dissolved metals or HONO  
385 may be more important for secondary aerosol formation under acidic conditions.

### 386 **3.5 Factors affecting gas-particle partitioning**

387 Gas-particle partitioning can be directly affected by the concentration levels of gaseous precursors  
388 and meteorological conditions. In this work, sensitivity tests showed that decreasing  $\text{TNO}_3$  lowered  
389  $\epsilon(\text{NH}_4^+)$  effectively, which helped maintain  $\text{NH}_3$  in the gas phase. Elevated  $\text{TNH}_3$  can increase  
390  $\epsilon(\text{NO}_3^-)$  when  $\text{TNO}_3$  is fixed, which means that the elevated  $\text{TNH}_3$  altered the gas-particle  
391 partitioning and shifted more  $\text{TNO}_3$  into the particle phase, leading to an increase in nitrate (Figure  
392 8 and S16). Controlling the emissions of both  $\text{NO}_x$  (gaseous precursor of  $\text{NO}_3^-$ ) and  $\text{NH}_3$  are efficient  
393 ways to reduce  $\text{NO}_3^-$ . However, the relationship between  $\text{TNH}_3$  and  $\epsilon(\text{NO}_3^-)$  in the sensitivity tests  
394 (Figure 8 and S16) showed that the  $\epsilon(\text{NO}_3^-)$  response to  $\text{TNH}_3$  control was highly nonlinear, which  
395 means that a decrease in nitrate would happen only when  $\text{TNH}_3$  is greatly reduced. The same result  
396 was also obtained from a study by Guo et al. (2018). The main sources of  $\text{NH}_3$  emission are  
397 agricultural fertilization, livestock, and other agricultural activities, which are all associated with  
398 people's livelihoods. Therefore, in terms of controlling the generation of nitrate, a reduction in  $\text{NO}_x$   
399 emissions is more feasible than a reduction in  $\text{NH}_3$  emissions.

400 RH and temperature can also alter gas-particle partitioning. The equilibrium constants for  
401 solutions of ammonium nitrate or ammonium chloride are functions of T and RH. The measurement  
402 data also showed that lower T and higher RH contribute to the conversion of more  $\text{TNH}_3$ ,  $\text{TNO}_3$ ,  
403 and TCl into the particle phase (Table 3). When the RH exceeded 60%, more than 90% of  $\text{TNO}_3$   
404 was in the particle phase for all four seasons. In summer and autumn, more than half of the  $\text{TNO}_3$   
405 and TCl were partitioned into the gaseous phase at lower RH conditions ( $\leq 30\%$ ). In winter, low

406 temperatures favoured the existence of  $\text{NO}_3^-$  and  $\text{Cl}^-$  in aerosol phase, and  $\epsilon(\text{NO}_3^-)$  and  $\epsilon(\text{Cl}^-)$  were  
407 higher than 75%, even at low RH.  $\epsilon(\text{NH}_4^+)$  was lower than  $\epsilon(\text{NO}_3^-)$  and  $\epsilon(\text{Cl}^-)$ . In spring, summer,  
408 and autumn, the average  $\epsilon(\text{NH}_4^+)$  was still lower than 0.3 even when the RH was >60%; this trend  
409 was associated with excess  $\text{NH}_3$  in the NCP. Higher RH and lower temperature are typical  
410 meteorological characteristics of haze events in the NCP (Figure 1), which are favourable conditions  
411 for the formation of secondary particles.

412 **Table 3.**

## 413 **5. Summary and Conclusions**

414 Long-term high-temporal resolution  $\text{PM}_{2.5}$  pH and size-resolved aerosol pH in Beijing were  
415 calculated with ISORROPIA-II. In 2016-2017 in Beijing, the mean  $\text{PM}_{2.5}$  pH (RH>30%) over four  
416 seasons was  $4.5 \pm 0.7$  (winter) >  $4.4 \pm 1.2$  (spring) >  $4.3 \pm 0.8$  (autumn) >  $3.8 \pm 1.2$  (summer), showing  
417 moderate acidity. In this work, both  $\text{H}_{\text{air}}^+$  and ALWC had significant diurnal variations, indicating  
418 that aerosol acidity in the NCP was driven by both aerosol composition and meteorological  
419 conditions. The average  $\text{PM}_{2.5}$  nighttime pH was 0.3~0.4 units higher than that in the daytime. The  
420  $\text{PM}_{2.5}$  pH in northerly wind was generally higher than that in wind from the southwest. Size-resolved  
421 aerosol pH analysis showed that the coarse-mode aerosol pH was approximately equal to or even  
422 higher than 7 in winter and autumn, which was considerably higher than the fine mode aerosol pH.  
423 The presence of  $\text{Ca}^{2+}$  had a crucial effect on coarse-mode aerosol pH. Under heavily polluted  
424 conditions, the mass fractions of  $\text{Ca}^{2+}$  in coarse particles decreased significantly, resulting in an  
425 evident increase in the coarse mode aerosol acidity. The  $\text{PM}_{2.5}$  pH sensitivity tests also showed that  
426 when evaluating aerosol acidity, the role of crustal ions cannot be ignored in areas or seasons (such  
427 as spring) where mineral dust is an important particle source. In northern China, dust can effectively  
428 buffer aerosol acidity .

429 The sensitivity tests in this work showed that the common important driving factors affecting  
430  $\text{PM}_{2.5}$  pH are  $\text{SO}_4^{2-}$ ,  $\text{TNH}_3$ , and T, while unique influencing factors were  $\text{Ca}^{2+}$  in spring and RH in  
431 summer. Owing to the significantly rich  $\text{NH}_3$  in the atmosphere, the change in  $\text{PM}_{2.5}$  pH was not  
432 significant with the elevated  $\text{TNO}_3$ , especially in spring and summer. Excess  $\text{NH}_3$  in the atmosphere  
433 and a high  $\text{NO}_3^-$  mass fraction in  $\text{PM}_{2.5}$  is the reason why aerosol acidity in China is lower than that  
434 in Europe and the United States. Notably,  $\text{TNH}_3$  had a great influence on aerosol acidity at lower  
435 concentrations but had a limited influence on  $\text{PM}_{2.5}$  pH when present in excess. The nonlinear  
436 relationship between  $\text{PM}_{2.5}$  pH and  $\text{TNH}_3$  indicated that although  $\text{NH}_3$  in the NCP was abundant,  
437 the  $\text{PM}_{2.5}$  pH was still acidic due to the thermodynamic equilibrium between aerosol droplet and  
438 precursor gases. Higher ambient temperature could reduce the  $\text{PM}_{2.5}$  pH by increasing ammonium  
439 evaporation and decreasing ALWC. RH had different impacts on  $\text{PM}_{2.5}$  pH in different seasons,  
440 which depends on the differences in the degree of RH's effects on  $\text{H}_{\text{air}}^+$  and RH's effects on ALWC.

441 In recent years, nitrates have dominated  $\text{PM}_{2.5}$  in the NCP, especially on heavily polluted days.  
442 Sensitivity tests showed that decreasing  $\text{TNO}_3$  and  $\text{TNH}_3$  could lower  $\epsilon(\text{NH}_4^+)$  and  $\epsilon(\text{NO}_3^-)$ , helping  
443 to reduce nitrate production. However, the  $\epsilon(\text{NO}_3^-)$  response to  $\text{TNH}_3$  control was highly nonlinear.

444 Given that ammonia was excessive in most cases, a decrease in nitrate would occur only if TNH<sub>3</sub>  
445 were greatly reduced. Therefore, in terms of controlling the generation of nitrate, a reduction in NO<sub>x</sub>  
446 emissions is more feasible than a reduction in NH<sub>3</sub> emissions.

646 **Figure captions**

647 **Figure 1.** Time series of relative humidity (RH) and temperature (T) (a, e, i, m); PM<sub>2.5</sub>, PM<sub>10</sub>, and  
648 NH<sub>3</sub> (b, f, g, n); dominant water-soluble ions: NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and NH<sub>4</sub><sup>+</sup> (c, g, k, o); and PM<sub>2.5</sub> pH  
649 coloured by PM<sub>2.5</sub> concentration (d, h, l, p) over four seasons.

650 **Figure 2.** Comparisons of predicted and measured NH<sub>3</sub>, HNO<sub>3</sub>, HCl, NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, Cl<sup>-</sup>, ε(NH<sub>4</sub><sup>+</sup>),  
651 ε(NO<sub>3</sub><sup>-</sup>), and ε(Cl<sup>-</sup>) coloured by RH. In this figure, the data from all four seasons were combined;  
652 comparisons of individual seasons are shown in Figure S1-S4.

653 **Figure 3.** Comparisons of predicted and measured NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, Cl<sup>-</sup> coloured by particle size. In this  
654 figure, all MOUDI data were combined.

655 **Figure 4.** Time series of mass fractions of NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NH<sub>4</sub><sup>+</sup>, Cl<sup>-</sup>, Mg<sup>2+</sup>, and Ca<sup>2+</sup> with respect to  
656 the total ion content, as well as PM<sub>2.5</sub> pH in all four seasons (PM<sub>2.5</sub> pH values at RH≤30% were  
657 excluded).

658 **Figure 5.** Wind-dependence map of PM<sub>2.5</sub> pH over four seasons. In each picture, the shaded contour  
659 indicates the mean value of PM<sub>2.5</sub> pH for varying wind speeds (radial direction) and wind directions  
660 (transverse direction) (data at RH≤30% were excluded).

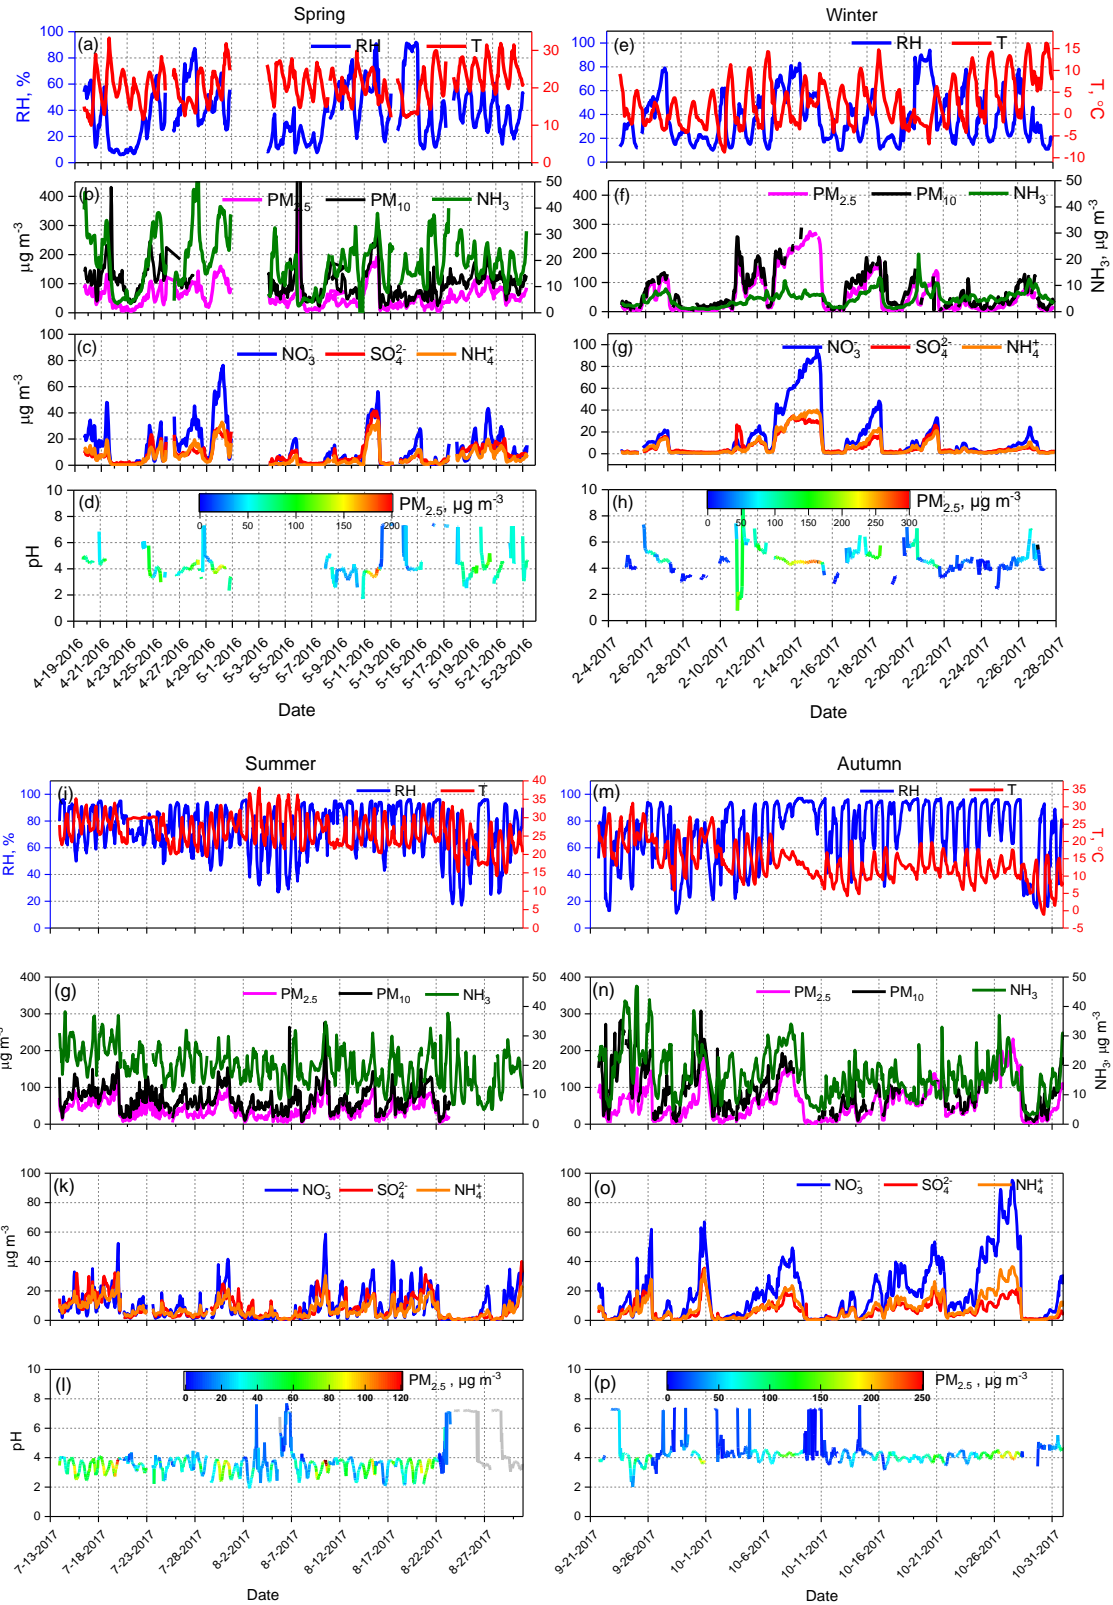

661 **Figure 6.** Diurnal patterns of mass concentrations of NO<sub>3</sub><sup>-</sup> and SO<sub>4</sub><sup>2-</sup> in PM<sub>2.5</sub>, predicted aerosol  
662 liquid water content (ALWC), H<sub>air</sub><sup>+</sup>, and PM<sub>2.5</sub> pH over four seasons. Mean and median values are  
663 shown, together with 25% and 75% quantiles. Data at RH≤30% were excluded, and the shaded area  
664 represents the time period when most RH values were lower than 30%.

665 **Figure 7.** Sensitivity tests of PM<sub>2.5</sub> pH to SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub>, TNH<sub>3</sub>, Ca<sup>2+</sup>, and meteorological parameters  
666 (RH and T) in summer (S) and winter (W).

667 **Figure 8.** Sensitivity tests of ε(NH<sub>4</sub><sup>+</sup>), ε(NO<sub>3</sub><sup>-</sup>) to TNO<sub>3</sub>, TNH<sub>3</sub>, RH and T coloured by PM<sub>2.5</sub> pH in  
668 summer (S) and winter (W).

669 **Figure 9.** Size distributions of aerosol pH and all analysed chemical components under clean (a, d,  
670 g), polluted (b, e, h), and heavily polluted conditions (c, f, i) in summer, autumn, and winter.
