9 Abstract

10 Acidity (pH) plays a key role in the physical and chemical behavior of aerosol and cannot be
11 measured directly. In this work, aerosol liquid water content (ALWC) and size-resolved pH are
12 predicted by thermodynamic model (ISORROPIA-II) in 2017 of Beijing. The mean aerosol pH over
13 four seasons is 4.3 ± 1.6 (spring), 4.5 ± 1.1 (winter), 3.9 ± 1.3 (summer), 4.1 ± 1.0 (autumn), respectively,
14 showing the moderate aerosol acidity. The aerosol pH in fine mode is in the range of 1.8 ~ 3.9, 2.4
15 ~ 6.3 and 3.5 ~ 6.5 for summer, autumn and winter, respectively. And coarse particles are generally
16 neutral or alkaline. Diurnal variation of aerosol pH follows both aerosol components (especially the
17 sulfate) and ALWC. For spring, summer and autumn, the averaged nighttime pH is 0.3~0.4 unit
18 higher than that on daytime. Whereas in winter, the aerosol pH is relatively low at night and higher
19 at sunset. SO_4^{2-} and RH are two crucial factors affecting aerosol pH. For spring, winter and autumn,
20 the effect of SO_4^{2-} on aerosol pH is greater than RH, and it is comparable with RH in summer. The
21 aerosol pH decreases with elevated SO_4^{2-} concentration. As the NO_3^- concentration increases, the
22 aerosol pH firstly increases and then decreases. Sulfate-dominant aerosols are more acidic with pH
23 lower than 4, whereas nitrate-dominated aerosols are weak in acidity with pH ranges 3~5. In recent
24 years, the dominance of NO_3^- in inorganic ions may be another reason responsible for the
25 moderately acidic aerosol. ALWC has a different effect on aerosol pH in different seasons. In winter,
26 the increasing RH could reduce the aerosol pH whereas it shows a totally reverse tendency in
27 summer, and the elevated RH has little effect on aerosol pH in spring and autumn when the RH is
28 between 30% and 80%. The dilution effect of ALWC on H_{air}^+ is only obvious in summer. The
29 elevated NH_3 and NH_4^+ could reduce aerosol acidity by decreasing H_{air}^+ concentration exponentially.

30 **Key words:** Aerosol pH, Size distribution, Influencing factors, Beijing

31

32 1. Introduction

33 Acidity or pH, which drives many processes related to particle composition, gas-aerosol
34 partitioning and aerosol secondary formation, is an important aerosol property (Jang et al., 2002;
35 Eddingsaas et al., 2010; Surratt et al., 2010). The aerosol acidity has a significant effect on the
36 aerosol secondary formation through the gas-aerosol partitioning of semi-volatile and volatile
37 species (Pathak et al., 2011a; Guo et al., 2016). Recent studies have shown that aerosol acidity
38 could promote the generation of secondary organic aerosol by affecting the aerosol acid-catalyzed
39 reactions (Rengarajan et al., 2011;). Moreover, metals can become soluble by acid dissociation
40 under lower pH conditions (Shi et al., 2011; Meskhidze et al., 2003) or by forming a ligand with
41 organic species, such as oxalate at higher pH (Schwertmann et al., 1991). In addition, higher aerosol
42 acidity could lower the acidification buffer capacity and affect the formation of acid rain. The
43 investigation in aerosol acidity is conducive to better understand the important role of aerosols in
44 acid deposition and atmospheric chemical reactions.

45 The hygroscopic components in the aerosols include water-soluble inorganic ions and part of
46 organic acid (Peng, 2001; Wang et al., 2017). The deliquescence relative humidity for the mixed-
47 salt is lower than that of any one component (Seinfeld and Pandis, 2016), hence the ambient aerosols
48 are generally droplets containing liquid water. The aerosol pH actually is the pH of the aerosol liquid
49 water. The aerosol acidity is usually estimated by the charge balance of measurable cations and
50 anions. A net negative balance correlated with an acidic aerosol and vice versa (Zhang et al., 2007;
51 Pathak et al., 2011b; Zhao et al., 2017). Generally, a larger value of the ion balance implies a stronger
52 acidity or stronger alkaline. Nevertheless, an ion balance or other similar proxies fail to represent
53 the true aerosol pH because the aerosol acidity estimated by this way is measured through the aerosol
54 water extract, which poorly predicts the concentration of hydronium ion in the aerosol liquid water
55 (Guo et al., 2015; Hennigan et al., 2015). Moreover, due to the large amounts of water is used for
56 extraction, the results cannot reflect the characteristics of the in-situ aerosol acidity, and it cannot
57 be applied to study the influence of aerosol acidity on gas-particle conversion. In-situ aerosol acidity,
58 defined as the free H^+ concentration in the liquid phase of a particle, is an important parameter that
59 actually affects the chemical behavior of the particle, which could be calculated by hydrogen ion
60 concentration and the aerosol liquid water content (ALWC).

61 It is critical to obtain the ALWC in calculating aerosol acidity. One way to calculate the ALWC
62 is based upon the assumption that the volume of ALWC is equal to subtracting the volume of dry
63 aerosol particles from that of wet particles (Guo et al., 2015; Bian et al. 2014; Engelhart et al. 2011).
64 Under this assumption, ALWC could be calculated by the size-resolved hygroscopic growth factors
65 ($g(D, RH)$) combining particle size distribution (PNSDs) or by the hygroscopic growth factor of
66 aerosol scattering coefficient ($f(RH)$) (Bian et al. 2014; Guo et al., 2015; Kuang et al., 2017a). The
67 $g(D, RH)$, defined as the ratio of the diameter of the wet particle at a certain relative humidity to the
68 corresponding diameter at dry conditions, could be measured by H-TDMA (Hygroscopic Tandem
69 Differential Mobility Analyzer) (Liu et al., 1978; Swietlicki et al., 2008; Liu et al., 2011). And the
70 $f(RH)$ could be observed by the wet & dry nephelometer system (Covert et al., 1972; Rood et al.
71 1985; Yan et al., 2009; Kuang et al., 2016, 2017b).

72 Another way to calculate the ALWC is based on the aerosol chemical components with
73 thermodynamic models, such as ISORROPIA-II, AIM, ADDEM etc. (Nenes et al., 1998;
74 Fountoukis and Nenes, 2007, Clegg et al., 1998, Topping et al., 2005a, b). Based on the aerosol
75 chemical components as well as temperature and relative humidity, the aerosol thermodynamic
76 models could output both ALWC and concentration of the hydronium ion in air (moles H^+ per
77 volume of air, denoted hereafter as H_{air}^+), which offers a more precise approach to acquire aerosol
78 pH (Pye et al., 2013). Among these thermodynamic models, ISORROPIA and ISORROPIA-II are
79 most widely used owing to its rigorous calculation and performance on computational speed.
80 ISORROPIA simulates the gas-particle partitioning in the H_2SO_4 , NH_3 , HNO_3 , HCl , Na^+ , H_2O
81 system, while its second version, ISORROPIA-II, adds Ca^{2+} , K^+ , Mg^{2+} and the corresponding salts
82 to the simulated particle components in thermodynamic equilibrium with water vapor and gas-phase
83 precursors.

84 Comparisons were made in some studies to investigate the consistency of calculated ALWC
85 derived from the above methods. In the North China Plain, Bian et al. (2014) found that the ALWC
86 calculated using size-resolved hygroscopic growth factors and the PNSD agreed well with that
87 calculated using ISORROPIA II at higher relative humidity (>60%). Relatively good consistency
88 was also found in the study of Engelhart et al. (2011) in USA based on the similar method. Guo et
89 al. (2015) compared the ALWC calculated by $f(RH)$ with the total predicted water by organics and

90 inorganics. The total predicted water was highly correlated and on average within 10 % of the $f(\text{RH})$
91 measured water. Though good consistencies in ALWC were found among these methods, the H_{air}^+
92 could only be obtained by thermodynamic models, which have been applied to predict aerosol
93 acidity in many studies (Nowak et al., 2006; Fountoukis et al., 2009; Weber et al., 2016; Fang et al.,
94 2017).

95 When calculating aerosol acidity with thermodynamic models, the aerosol is assumed internally
96 mixed and the bulk properties of aerosol are used, without considering variability of chemical
97 compositions with particle size. However, the size-resolved characteristics of aerosol chemical
98 components are obviously different. Among inorganic ions, SO_4^{2-} , NO_3^- , Cl^- , K^+ , NH_4^+ are mainly
99 concentrated in fine mode, whereas Mg^{2+} , Ca^{2+} are abundant in coarse mode (Zhao et al., 2017). The
100 aerosol acidity is the result of the balance between the soluble acidic (SO_4^{2-} , NO_3^- , Cl^- and some
101 soluble organic acids) and alkaline (NH_4^+ , Na^+ , K^+ , Mg^{2+} , Ca^{2+}) component in the aerosol. The gas
102 precursor NH_3 , HNO_3 , and HCl for main water-soluble ions as well as ambient temperature and
103 relative humidity are also important factors affecting the aerosol acidity. In some countries where
104 PM concentration is very low, the pH diurnal variation was mainly driven by meteorological
105 conditions (Guo et al., 2015, 2016; Bougiatioti et al., 2016). In China, however, the annual average
106 $\text{PM}_{2.5}$ concentration in some mega cities was ~ 2 times higher than the national standard value (35
107 $\mu\text{g m}^{-3}$) and the inorganic ions account for 40%~50% to $\text{PM}_{2.5}$, especially in the North China Plain
108 (Zou et al., 2018; Huang et al., 2017; Gao et al., 2018). Hence it can be expected that the aerosol
109 composition is also a crucial factor on pH, which cannot be ignored.

110 The North China Plain is the region with the most severe aerosol pollution in China. Nevertheless,
111 few studies have focused on aerosol pH at this region. Cheng et al. (2016) estimated the averaged
112 pH by ISORROPIA-II, and Wang et al. (2016) derived the particle pH by using a molar ratio
113 approach in Beijing, their results show that the aerosol acidity was close to neutral. However, Liu
114 et al. (2017) and Shi et al. (2017) found that fine particles in the North China Plain were moderately
115 acidic based on the hourly measured particulate water-soluble ions and precursor gases along with
116 ISORROPIA-II, with an average pH of 4.2 in winter of Beijing and 4.9 in Tianjin. These results are
117 all significantly higher than that in the United States or Europe, where aerosols are often highly
118 acidic with a pH lower than 3.0 (Guo et al., 2015, 2016; Bougiatioti et al., 2016; Weber et al., 2016;

119 Young et al., 2013). The differences in aerosol pH in the North China Plain mainly result from the
120 different calculated methods (ion balance & thermodynamic equilibrium models). Several studies
121 have shown that the ion balance and reverse-mode calculations of thermodynamic equilibrium
122 models are not applicable to interpret the aerosol acidity (Hennigan et al., 2015; Liu et al. 2017;
123 Song et al., 2018). Moreover, the change of the chemical composition of PM_{2.5} in the North China
124 Plain in recent years also contributed to the differences in aerosol pH. The observations in previous
125 studies exploring aerosol acidity in the North China Plain were almost conducted before 2015. In
126 the recent three years, the chemical composition of PM_{2.5} in Beijing has undergone tremendous
127 changes. Nitrate has replaced sulfate and is dominant in inorganic ions in most cases (Zhao et al.,
128 2017; Huang et al., 2017; Ma et al., 2017). Moreover, studies about seasonal variation of aerosol
129 pH and size-resolved aerosol pH are rare in the North China Plain, and the key factors affecting
130 aerosol acidity are still not well understood.

131 In this work, thermodynamic model ISORROPIA-II with forward mode is utilized to predict
132 ALWC and aerosol pH in Beijing. The hourly measured PM_{2.5} inorganic ions and precursor gases
133 in four seasons during 2016 to 2017 are used to analyze the seasonal and diurnal variation of aerosol
134 acidity, and the sensitivity analysis is conducted to identify the key factors that affecting the aerosol
135 pH. In our previous studies, the multi-stage cascade impactors (MOUDI-122) were used for size-
136 resolved aerosol sampling during 2013 to 2015. The actual relative humidity inside the impactors
137 was calculated, and the size distribution of water-soluble ions, organic carbon, and elemental carbon
138 in three seasons were discussed (Zhao et al., 2017; Su et al., 2018). Based on these size-resolved
139 results, the pH for aerosol in different size ranges could also be modeled, which can help to evaluate
140 whether it is appropriate to calculate the overall pH of PM_{2.5} ignoring the differences in particle size.

141 **2. Data Collection and Methods**

142 **2.1 Site**

143 The measurements were performed at the Institute of Urban Meteorology in Haidian district of
144 Beijing (39°56'N, 116°17'E). The sampling site was located next to a high-density residential area,
145 without significant air pollution emissions around the site. Therefore, the observation data could
146 represent the air quality levels of the urban area of Beijing.

147 **2.2 Online data collection**

148 Water-soluble ions (SO_4^{2-} , NO_3^- , Cl^- , NH_4^+ , Na^+ , K^+ , Mg^{2+} , Ca^{2+}) of $\text{PM}_{2.5}$ and trace gases (HCl,
149 HNO_3 , HNO_2 , SO_2 , NH_3) in the ambient air were measured by an online analyzer (MARGA) at
150 hourly temporal resolution during the spring (April and May in 2016), winter (February in 2017),
151 summer (July and August in 2017) and autumn (September and October in 2017). The more details
152 about MARGA can be found at ten Brink et al. (2007). The $\text{PM}_{2.5}$ and PM_{10} mass concentrations
153 (TEOM 1405DF), the hourly ambient temperature and relative humidity were also synchronously
154 attained.

155 Hourly concentrations of $\text{PM}_{2.5}$, PM_{10} , and water-soluble ions in $\text{PM}_{2.5}$, as well as meteorological
156 parameters during the observation, are shown in Figure 1. In spring, two dust events occurred (21-
157 22, April and 5-6, May). During the first dust event, the wind came predominantly from the north
158 with mean wind speed 3.5 m s^{-1} . And the PM_{10} concentration reached $425 \mu\text{g m}^{-3}$ while the $\text{PM}_{2.5}$
159 concentration was only $46 \mu\text{g m}^{-3}$ on the peak hour. Similarly, the second dust event was resulted
160 from the strong wind come from the northwest direction. In the following pH analysis based on
161 MARGA data, it is assumed that the particles were internally mixed, and the chemical compositions
162 were the same for particles of different sizes in $\text{PM}_{2.5}$. Hence, these two dust events were excluded
163 from this analysis.

164 **2.3 size-resolved chemical compositions**

165 A Micro-Orifice Uniform Deposit Impactor (MOUDI-120) was used to collect size-resolved
166 aerosol samples with the calibrated 50% cut sizes of 0.056, 0.10, 0.18, 0.32, 0.56, 1.0, 1.8, 3.1, 6.2,
167 9.9 and $18 \mu\text{m}$. Size-resolved sampling was conducted during July 12-18, 2013; January 13-19,
168 2014; July 3-5, 2014; October 9-20, 2014; and January 26-28, 2015. Fifteen, fourteen, and eighteen
169 sets of samples were obtained for the summer, autumn and winter, respectively. Except for two sets
170 of samples, all the samples were collected in daytime (from 08:00 to 19:00) and nighttime (from
171 20:00 to 7:00 the next day), respectively. One hour of preparation time was set for filter changing
172 and nozzle plate washing with ethanol. The water-soluble ions were analyzed from the samples by
173 using an ion chromatography (DIONEX ICS-1000). The detailed information about the features of
174 MOUDI-120, the procedures of sampling, pre-treatment, and laboratory chemical analysis
175 (including the quality assurance & quality control) were described in our previous papers (Zhao et
176 al., 2017; Su et al., 2018).

177 **2.4 Aerosol pH prediction**

178 As mentioned in the Introduction, pH of ambient aerosols could be predicted by the
179 thermodynamic model such as AIM and ISORROPIA, AIM is considered an accurate benchmark
180 model while ISORROPIA has been optimized for use in chemical transport models. Currently,
181 ISORROPIA-II, adds K^+ , Mg^{2+} , Ca^{2+} (Fountoukis and Nenes, 2007), could calculate the equilibrium
182 H_{air}^+ (particle hydronium ion concentration per volume air) and ALWC with reasonable accuracy
183 by taking water-soluble ions mass concentration, temperature and relative humidity as input. The
184 H_{air}^+ and ALWC were then used to predict aerosol pH by the Eq. (1).

$$185 \quad pH = -\log_{10} H_{aq}^+ \cong -\log_{10} \frac{1000 H_{air}^+}{ALWC_i} \quad (1)$$

186 Where H_{aq}^+ (mole L^{-1}) is the hydronium ion concentration in the ambient particle liquid water. H_{aq}^+
187 can also be deemed to be the H_{air}^+ ($\mu g m^{-3}$) divided by the concentration of ALWC associated with
188 inorganic species, $ALWC_i$ ($\mu g m^{-3}$). Both inorganic and part of organic species in particles are
189 hygroscopic. However, the pH prediction is not highly sensitive to the water uptake by organic
190 species ($ALWC_o$), unless the $ALWC_o$ mass fraction to the total particle water is close to 1 (Guo et al.,
191 2015, 2016). And similar result was also found in Beijing in Liu et al. (2017). Hence the aerosol pH
192 could be fairly predicted by ISORROPIA-II with just measurements of inorganic species in most
193 cases.

194 In ISORROPIA-II, forward and reverse mode are provided to predict ALWC and H_{air}^+ . In forward
195 mode, known quantities are T, RH and the total (i.e. gas+aerosol) concentrations of NH_3 , H_2SO_4 ,
196 HCl and HNO_3 . Reverse mode calculates the equilibrium partitioning given the concentration of
197 only aerosol composition together with RH and T as input. In this work, the online ion
198 chromatography MARGA was used to measure both inorganic ions of $PM_{2.5}$ and precursor gases,
199 hence ISORROPIA-II was run in the “forward mode” for aerosols in metastable condition.
200 Moreover, the forward mode was reported less sensitive to measurement error than the reverse mode
201 (Hennigan et al., 2015; Song et al., 2018).

202 Running ISORROPIA-II in the forward mode with only aerosol concentrations as input may
203 result in a bias in predicted pH due to repartitioning of ammonia in the model, leading to a lower
204 predicted pH when gas-phase data are not available (Hennigan et al., 2015). In this work, no $NH_{3(g)}$

205 was available for the size-resolved pH prediction. We determined aerosol pH in the fine mode
206 through an iteration procedure that used the measured particulate species and ISORROPIA-II to
207 predict gas species, detailed information could be found in Fang et al. (2017) and Guo et al. (2017).
208 As for coarse mode particles, equilibrium is not considered between the gas and particles due to
209 kinetic limitations (Dassios et al., 1999; Cruz et al., 2000), the pH was determined by ignoring the
210 gas phase and ISORROPIA-II was run in forward mode with zero gas concentrations.

211 The accuracy of the aerosol pH prediction is primarily assessed by the reproduction of
212 semivolatile components partitioning between gas and particle phases. A comparison between
213 predicted NO_3^- , NH_4^+ and measured values colored by RH is shown in Figure 2. Overall, the model
214 captures the measured NO_3^- , NH_4^+ , and the predicted NO_3^- , NH_4^+ are on average within $\pm 20\%$ of
215 the measurements, with $R^2 > 0.9$, and best agreement is observed at RH above 60%.

216

217 **Figure 1**

218

219 3. Results and Discussion

220 3.1 Overall summary of aerosol pH over four seasons

221 The averaged $\text{PM}_{2.5}$ concentration is 62 ± 36 , 60 ± 69 , 39 ± 24 , 59 ± 48 $\mu\text{g m}^{-3}$ in spring, winter,
222 summer and autumn observation, respectively. Among all ions measured, NO_3^- , SO_4^{2-} , NH_4^+ are
223 three dominant species, accounting for 83% ~ 87%. Compared with other seasons, the averaged
224 concentration of primary inorganic ions (Cl^- , Na^+ , K^+ , Mg^{2+} , Ca^{2+}) was higher in spring. The aerosol
225 in Beijing showed the moderate acidity with aerosol pH was 4.3 ± 1.6 , 4.5 ± 1.1 , 3.9 ± 1.3 and 4.1 ± 1.0
226 in spring, winter, summer and autumn observation, respectively. The overall winter aerosol pH is
227 comparable to the result found in Beijing (4.2, winter) from Liu et al. (2017) and lower than that
228 (4.9, winter and spring) in Tianjin (Shi et al., 2017), another mega city about 120 km away from
229 Beijing. The summer aerosol pH was lowest among all four seasons, implying the higher aerosol
230 acidity. The seasonal variation of aerosol pH in this work was similar to the result from Tan et al.
231 (2018) except for spring, which was winter (4.11 ± 1.37) > autumn (3.13 ± 1.20) > spring ($2.12 \pm$
232 0.72) > summer (1.82 ± 0.53). Noted that the observation in Tan et al. (2018) was conducted in 2014
233 of Beijing, the distinction in aerosol composition may be responsible for the lower aerosol pH in

234 their work.

235 The acid liquid surface has a catalytic effect on the gas-liquid reaction process, and the presence
236 of the oxidant can significantly increase the reaction rate and promote the formation of secondary
237 aerosols (Liu et al., 2012). How the moderate acidity of aerosol in the North China Plain affect the
238 formation of secondary aerosols needs to be further investigated.

239 **Figure 2**

240 Wind dependence of $\text{PM}_{2.5}$, NO_3^- , SO_4^{2-} , NH_4^+ , Ca^{2+} concentration and the averaged pH are shown
241 in Figure 3 and Fig. S1. In spring and summer, the high aerosol pH occurs with both NW and SW
242 strong winds (wind speed $>3 \text{ m s}^{-1}$) while the low aerosol pH occurs with calm winds (wind speed
243 $<2 \text{ m s}^{-1}$) and SW winds with wind speed lower than 3 m s^{-1} . For winter, we surprisingly found that
244 the high aerosol pH is mainly concentrated in the SSW direction, while the aerosol pH in northerly
245 winds is as low as 3~4. In autumn, the aerosol pH accompanied by NW winds is much higher than
246 that accompanied by souther winds. Generally, the northerly winds usually occur with cold front
247 systems and high wind speeds, which could sweep away air pollutants but raise dust in which the
248 crustal species (Ca^{2+} , Mg^{2+}) content are higher.

249 Haze episodes usually occur with SW and SE winds and calm winds in Beijing, the air pollutants
250 are transported to Beijing from other cities located in SW and SE directions, leading to the
251 accumulation of pollutants. Beijing is surrounded by mountains on three sides, and south Beijing is
252 plain. The industry is mainly concentrated in the south of Beijing, and there are plenty of emission
253 sources in these two major transport pathways from southwest and southeast directions, leading to
254 the higher $\text{PM}_{2.5}$ concentration. We find that the aerosol pH is negatively correlated with $\text{PM}_{2.5}$
255 concentration in spring, summer, and autumn whereas it shows the positive relationship in winter.

256 To further investigate the aerosol pH performance under different pollution level over four
257 seasons, the $\text{PM}_{2.5}$ concentration is classified into three groups with $0\sim75 \mu\text{g m}^{-3}$, $75\sim150 \mu\text{g m}^{-3}$
258 and $>150 \mu\text{g m}^{-3}$, representing clean, polluted and heavily polluted days, respectively. Overall, as
259 the air quality deteriorates, ALWC and H_{air}^+ all increased, but the aerosol acidity performs differently.
260 In spring, summer, and autumn, the pH on clean days is the highest (Table 1), then followed by
261 polluted days and heavily polluted days. In winter, however, the averaged pH on polluted days
262 (5.4 ± 1.0) is the highest, then followed by heavily polluted days (4.4 ± 0.9) and clean days (4.3 ± 1.1).

263 **Figure 3**

264 **Table 1**

265

266 **3.2 Diurnal variation of aerosol pH, ALWC, and H_{air}^+**

267 The diurnal variation for ALWC is similar over four seasons, but distinctions are found in H_{air}^+
268 and pH diurnal variations (Figure 4). Generally, nighttime mean ALWC is higher than daytime and
269 reached a peak at near 04:00 ~ 06:00 (local time). After sunrise, the increasing temperatures resulted
270 in a rapid drop in RH, leading to the obvious loss of particle water, ALWC reached the lowest level
271 in the afternoon. For spring, summer, and autumn, the significant H_{air}^+ peak starting at roughly 12:00
272 and reaching a maximum between 16:00 and 18:00, the low ALWC and high H_{air}^+ resulted in the
273 minimum pH in the afternoon. The averaged nighttime pH is 0.3~0.4 unit higher than that on
274 daytime for spring, summer, and autumn, respectively. However, for winter, H_{air}^+ in the nighttime
275 is slightly higher than that in the daytime, and the aerosol pH is relatively low at night and higher at
276 sunset. Noted that the diurnal variation of aerosol pH is all consistent with the diurnal variation of
277 SO_4^{2-} over four seasons, it seems that the SO_4^{2-} is a key factor affecting aerosol pH.

278 **Figure 4**

279 The distinguishing diurnal patterns of aerosol pH over four seasons indicate that aerosol
280 composition is a key factor for the diurnal variation of aerosol pH, which is very different from what
281 Guo et al. (2015) found in the southeastern United States: the pH diurnal variation is largely driven
282 by meteorological conditions due to the dilution of ALWC to H_{air}^+ , not aerosol composition. The
283 biggest reason for the discrepancy is that the hygroscopic components in particles such as
284 $(NH_4)_2SO_4$ and NH_4NO_3 in Beijing are much higher than that in the southeastern United States
285 (lower than $5 \mu g m^{-3}$) while the mean RH is lower. Thus the influence of aerosol composition on pH
286 cannot be ignored in Beijing.

287 **3.3 Factors affecting ALWC, H_{air}^+ and aerosol pH**

288 As mentioned above, the aerosol chemical composition has a non-negligible effect on aerosol pH.
289 In this work, the effects of aerosol chemical components (NO_3^- , SO_4^{2-} , NH_4^+ , Ca^{2+}) and precursor
290 gases (NH_3 , HNO_3), as well as meteorological parameters (RH, T) on aerosol pH are performed

291 through a sensitivity analysis over four seasons. When assessing how a factor affects aerosol acidity,
292 ALWC, or H_{air}^+ , the real-time measured values of an evaluated factor and the averaged values for
293 other factors in each season are input in ISORROPIA-II. For example, the magnitude of the
294 deviation for calculated aerosol pH can reflect the effect of an evaluated factor on the aerosol acidity.
295 The higher the deviation, the greater the effect, vice versa. Noted that the sensitivity analysis in this
296 work only reflects the characteristics during the observation period, further work is needed to
297 determine whether the sensitivity analysis is valid in other environments. And the sensitivity
298 analysis in this paper only focused on single factor variations, however, in reality, changes in one
299 factor could alter other factors and made it more complicated.

300 As show in Table 2, for ALWC, the largest deviation is observed when RH is taken as the
301 evaluated factor, then followed by SO_4^{2-} and NO_3^- (NO_3^- and SO_4^{2-} in autumn), which means that the
302 RH affect ALWC most and SO_4^{2-} and NO_3^- are major hygroscopic components in the aerosol. SO_4^{2-}
303 is the most influential factor for H_{air}^+ , and RH, NO_3^- , and NH_3 are also important factors affecting
304 H_{air}^+ . Synthetically, SO_4^{2-} and RH are two crucial factors affecting aerosol pH. For spring, winter
305 and autumn, the effect of SO_4^{2-} on aerosol pH is greater than the RH, and it is comparable with RH
306 in summer. Figure 4-6 and S2-S7 show how these factors affecting the aerosol acidity, ALWC and
307 H_{air}^+ in detail over four seasons. The sensitivity analysis for ALWC and H_{air}^+ are similar over four
308 seasons, while the sensitivity analysis of RH on aerosol pH in summer is different from the other
309 three seasons. In this study, the sensitivity analysis in winter and summer are chosen for detailed
310 description since winter is of a lot of concern due to the poor air quality while the photochemical
311 reactions are strongest in summer.

312 **Table 2**

313 The positive linear relationships between SO_4^{2-} , NO_3^- , HNO_3 concentration and ALWC as well
314 as negative linear relationship between Ca^{2+} concentration and ALWC are observed in the sensitive
315 analysis. Exponential relationships between RH and ALWC are observed, and the ALWC increased
316 rapidly with increasing RH, especially when the RH higher than 80%. Elevated NH_4^+ and NH_3
317 concentration could increase ALWC slightly. As for temperature, ALWC decreased with the
318 increasing temperature nonlinearly. High temperature could affect gas-aerosol partitioning, shifts the
319 equilibrium from NO_3^- to HNO_3 , underpredicted the NO_3^- and NH_4^+ concentration, thus decreasing

320 the ALWC. In addition, the higher temperature could also decrease RH and results in low ALWC in
321 the real atmosphere.

322 **Figure 5**

323 As mentioned above, SO_4^{2-} and RH are the most important factors on H_{air}^+ . An exponential
324 growth of H_{air}^+ with elevated SO_4^{2-} , RH, NO_3^- , and T are found, whereas an exponential decrease
325 of H_{air}^+ with elevated NH_3 and NH_4^+ are found. Though H_{air}^+ concentration decreased linearly with
326 the augment of Ca^{2+} concentration, Ca^{2+} concentration is generally lower than $3 \mu\text{g m}^{-3}$ and generates
327 a little variation in H_{air}^+ compared to other factors. It should be noted that a “U” shape between NO_3^-
328 and H_{air}^+ are found in spring (Fig.S2), H_{air}^+ drops with the increasing NO_3^- concentration within ~ 20
329 $\mu\text{g m}^{-3}$ and then starts to grow with the increasing NO_3^- concentration. The addition of NH_3 or NH_4^+
330 has a much more obvious effect on H_{air}^+ than ALWC. The higher the NH_3 concentration in the
331 atmosphere, the more NH_3 will dissolve in the aerosol liquid water and balance the H_{air}^+ partially.
332 Increasing temperature or RH alone will increase H_{air}^+ when other influencing factors were fixed,
333 which is consistent over four seasons.

334 **Figure 6**

335 The effects of all these factors on aerosol pH is actually a superposition of the effects on ALWC
336 and H_{air}^+ . Synthetically, the effect of chemical components (NO_3^- , SO_4^{2-} , NH_4^+ , Ca^{2+}) and precursor
337 gases (NH_3 , HNO_3), as well as meteorological parameters (RH, T) on aerosol pH is shown in Figure
338 7. The most important influencing factor on aerosol acidity is SO_4^{2-} . The aerosol pH decreases about
339 2.8 (5 to 2.2), 6.0 (6 to 0), 1.0 (3.8 to 2.8), and 1.1 (4 to 2.9) unit with SO_4^{2-} concentration goes up
340 from 0 to $40 \mu\text{g m}^{-3}$ in spring, winter, summer, and autumn, respectively. In spring and winter, the
341 ALWC is low, the variation of SO_4^{2-} concentration could generate dramatic changes in aerosol pH.
342 In section 3.1, the aerosol pH shows an obvious seasonal variation, the aerosol pH is generally low
343 in summer whereas highest in winter, which is consistent with the SO_4^{2-} mass fraction in total ions.
344 The SO_4^{2-} mass fraction in total ions in summer is highest among four seasons with $32.4\% \pm 11.1\%$,
345 whereas it is lowest in winter with $20.9\% \pm 4.4\%$. Similarly, the low aerosol pH on clean days in
346 winter also relates to the leading position of SO_4^{2-} (Table 1).

347 The second important factor on aerosol acidity is RH. In the North China Plain, the severe haze
348 episodes usually occur with very high RH at a stable weather condition, resulting in the considerable
349 ALWC. In this work, except for summer, the increasing RH could reduce the aerosol pH
350 significantly when RH lower than ~30%, and then the aerosol pH decreases slowly or keeps almost
351 a constant at ~4 when the RH is between 30~80%, and the aerosol pH starts to increase with the
352 further increasing RH. However, the aerosol pH increases continuously ~1.5 unit (2.5 to 4) when
353 RH goes up from 20% to 96% in summer. The PM_{2.5} concentration is lowest in summer, while the
354 RH is relatively high, the high ALWC tends to dilute H_{air}⁺ and increase aerosol pH. The sensitivity
355 analysis suggests that ALWC has a different effect on aerosol pH in different seasons, the dilution
356 effect of ALWC on H_{air}⁺ is obvious only in summer.

357

Figure 7

358 Different from SO₄²⁻, the effect of NO₃⁻ on aerosol pH is not always same. In winter, summer and
359 autumn, the aerosol pH increases first and then starts to decrease when NO₃⁻ concentration is larger
360 than ~30 μg m⁻³. There seems to be a threshold for the effect of NO₃⁻ on aerosol acidity. From a
361 mathematical point of view, the H_{air}⁺ concentration increased exponentially with elevated NO₃⁻
362 concentration, especially at higher NO₃⁻ concentrations, whereas the ALWC increase linearly with
363 elevated NO₃⁻ concentration. When NO₃⁻ concentration is less than the threshold, ALWC plays a
364 dominant role, while when the NO₃⁻ concentration is greater than the threshold, the H_{air}⁺ has a
365 greater effect and the aerosol acidity begins to increase.

366 Moreover, in spring, the aerosol pH increases continuously with the addition of NO₃⁻, which is
367 not consistent with the previous thought that addition of anion could reduce the aerosol pH. Same
368 results are found in Guo et al. (2017): at a constant ALWC, more NO₃⁻ is measured at higher pH.
369 Based on the measured NO₃⁻/2SO₄²⁻ ratio (mole mole⁻¹) of this work, we find that aerosol pH is
370 generally between 3~5 when the aerosol anionic composition is dominated by nitrate
371 (NO₃⁻/2SO₄²⁻>1), whereas when NO₃⁻/2SO₄²⁻<1, about 86% of aerosol pH is lower than 4 (Figure
372 8). In recent years, the average annual concentration of SO₄²⁻ in Beijing decreased significantly due
373 to the strict emission control measures for industries and power plants, in most cases NO₃⁻
374 dominates inorganic ions (Zhao et al., 2017; Huang et al., 2017; Ma et al., 2017), which may be

375 another reason responsible for the moderately acidic aerosol.

376 Elevated NH_3 and NH_4^+ could reduce aerosol acidity by decreasing H_{air}^+ concentration
377 exponentially. In this work, NH_3 is rich in spring ($21.5 \pm 8.7 \mu\text{g m}^{-3}$), summer ($19.6 \pm 6.4 \mu\text{g m}^{-3}$) and
378 autumn ($16.8 \pm 8.0 \mu\text{g m}^{-3}$), and poor in winter ($4.9 \pm 2.8 \mu\text{g m}^{-3}$). The ratio of $[\text{TA}]/2[\text{TS}]$ provides
379 qualitative description for the ammonia abundance, where $[\text{TA}]$ and $[\text{TS}]$ are the total (gas + aqueous
380 + solid) molar concentrations of ammonia and sulfate. The rich-ammonia is defined as $[\text{TA}] > 2[\text{TS}]$,
381 while if the $[\text{TA}] < 2[\text{TS}]$, then it is defined as poor-ammonia (Seinfeld and Pandis, 2016). In this
382 work, the ratio of $[\text{TA}]/2[\text{TS}]$ is much higher than 1 and belongs to rich-ammonia (Fig. S8). In the
383 poor-ammonia case, there is insufficient NH_3 to neutralize the available sulfate, hence the aerosol
384 will be acidic. Whereas in the rich-ammonia case there is excess ammonia, the remaining ammonia
385 after reaction with sulfuric acid will be available to react with nitric acid to produce NH_4NO_3 , so
386 that the aerosol phase will be neutralized to a large extent. However, the moderate aerosol acidity
387 suggests that though there is excess ammonia in the atmosphere, due to the limited ALWC compared
388 with the cloud liquid water content and precipitation, in most cases the aerosol will not be alkaline.

389 Furthermore, elevated Ca^{2+} concentration could increase the aerosol pH and the change of HNO_3
390 concentration has little effect on pH. Elevated temperature in favor of enhancement the aerosol
391 acidity by reducing ALWC and increasing H_{air}^+ .

392 **Figure 8**

393 **3.4 Size distribution of aerosol components and pH**

394 According to the average $\text{PM}_{2.5}$ concentration during every sampling period, all the samples are
395 also classified into three groups (clean, polluted, heavily polluted) with the same rule described in
396 Section 3.2. A severe haze episode occurred during the autumn sampling, hence there were more
397 heavily polluted samples for autumn than that in other seasons. Figure 9 shows the averaged size
398 distributions of PM components and pH on clean, polluted and heavily polluted days in summer,
399 autumn and winter, respectively. The NO_3^- , SO_4^{2-} , NH_4^+ , Cl^- , K^+ , OC, and EC were mainly
400 concentrated in the size range with aerodynamic diameters between $0.32 \sim 3.1 \mu\text{m}$, while Mg^{2+} and
401 Ca^{2+} were predominantly distributed in the coarse mode. As shown in Figure 9, the concentration
402 levels for all chemical components increased with the increasing pollution. During the haze episodes,

403 the sulfate and nitrate in the accumulated mode increased significantly. However, the increase of
404 Mg^{2+} and Ca^{2+} in the coarse mode were not as obvious as secondary ions, mainly due to the low
405 wind speed and calm atmosphere which make it more difficult to raise dust during the heavy
406 pollution. More detailed information about size distributions of mass concentration for all analyzed
407 species during three seasons is shown in Zhao et al. (2017) and Su et al. (2018).

408 **Figure 9**

409 The aerosol pH for both accumulation mode and coarse mode in summer were lowest among
410 three seasons, then followed by autumn and winter. In summer, the predominance of sulfate in the
411 fine mode resulted in a low pH, ranging between 1.8 and 3.9. The sensitivity analysis of this work
412 shows sulfate plays a key role in predicting pH, its high hygroscopicity leads to the formation of the
413 aqueous drops and provides H_{air}^+ (Fang et al., 2017). Aerosol pH for fine particles in autumn and
414 winter are in the range of 2.4 ~ 6.3 and 3.5 ~ 6.5, respectively. As for coarse particles, the predicted
415 pH is approximately near or even higher than 7 for all of the three seasons in this work. It should be
416 noted that assuming coarse mode particles in equilibrium with the gas phase generally overestimates
417 acidity ($pH < 4$) (Fang et al., 2017).

418 On heavily polluted days, the aerosol pH in coarse mode showed a marked fall in autumn and
419 winter. For example, the pH in stage 3 (3.1-6.2 μm) declined from 7.8 on clean days to 4.5 on heavily
420 polluted days in winter, implying that the aerosols in coarse mode during severe hazy days would
421 become weak acid from neutral. The obvious increase of nitrate in coarse mode may responsible for
422 this. Moreover, the significant decrease of mass ratios of Ca^{2+} and Mg^{2+} also weakened the alkaline.

423 The size distribution of aerosol pH and all analyzed chemical components in the daytime and
424 nighttime are illustrated in Figure 10. For summer and autumn, the pH in the nighttime is higher
425 than that in the daytime. Whereas, in winter, the pH is higher in the daytime. The diurnal variation
426 for aerosol pH based on MOUDI data is consistent with the online data. In the daytime of summer
427 and autumn, the solar radiation is strong and photochemical reaction is active as well as the RH is
428 lower, leading to a lower aerosol pH than nighttime. In winter, the averaged RH during the sampling
429 period is 43%, leading to a low ALWC, but the SO_4^{2-} and NO_3^- in the nighttime are obviously higher
430 due to the lower boundary layer. Therefore, H_{air}^+ is more abundant in nighttime while the low ALWC

431 had little effect on pH.

432 **Figure 10**

433 5. Summary and conclusions

434 Aerosol acidity is important for the formation of secondary aerosol and is of many challenges to
435 be measured directly. In this work, ISORROPIA-II with forward mode is applied to calculate the
436 H_{air}^+ and ALWC based on the 1-h $PM_{2.5}$ inorganic ions, precursor gases (HCl, HNO_3 , NH_3) and RH,
437 T. Moreover, the size distribution of pH is predicted based on the MOUDI samples with the same
438 way, the gas-phase NH_3 , HNO_3 and HCl are determined through an iteration procedure. In Beijing,
439 the mean aerosol pH over four seasons is 4.3 ± 1.6 (spring), 4.5 ± 1.1 (winter), 3.9 ± 1.3 (summer),
440 4.1 ± 1.0 (autumn), respectively, showing the moderate aerosol acidity. The seasonal variation of
441 aerosol pH is closely related to the SO_4^{2-} . Overall, the aerosol is more acidic on hazy days than clean
442 days. The aerosol pH in fine mode is in the range of 1.8 ~ 3.9, 2.4 ~ 6.3 and 3.5 ~ 6.5 for summer,
443 autumn and winter, respectively. As for coarse particles, the predicted pH is approximately near or
444 even higher than 7.

445 Due to the significantly high level of hygroscopic components in particulate matter in Beijing,
446 pH has a diurnal trend that follows both aerosol components (especially the sulfate) and ALWC. For
447 spring, summer and autumn, the averaged nighttime pH is 0.3~0.4 unit higher than that on daytime.
448 However, in winter, H_{air}^+ in nighttime is slightly higher than that in daytime and the aerosol pH is
449 relatively low at night and higher at sunset. This result is very different from that found in
450 southeastern United States: the pH diurnal variation is largely driven by meteorological conditions.

451 A sensitivity analysis is performed in this work to investigate how aerosol components, precursor
452 gases and meteorological conditions affect aerosol acidity. The RH affects ALWC most, then
453 followed by SO_4^{2-} and NO_3^- . For H_{air}^+ , SO_4^{2-} is the most influential factor, and RH, NO_3^- , NH_3 are
454 also important factors affecting H_{air}^+ . Synthetically, SO_4^{2-} and RH are two crucial factors affecting
455 aerosol pH. For spring, winter and autumn, the effect of SO_4^{2-} on aerosol pH is greater than RH, and
456 it is comparable with RH in summer. The aerosol pH decreases with elevated SO_4^{2-} concentration,
457 the variation of SO_4^{2-} concentration could generate dramatic changes in aerosol pH in spring and
458 winter. As the NO_3^- concentration increases, the aerosol pH firstly increases and then decrease at a

459 inflection point with $30 \mu\text{g m}^{-3}$. In this work, sulfate-dominant aerosols are more acidic with pH
460 lower than 4, whereas nitrate-dominated aerosols are weak in acidity with pH ranges 3~5. In recent
461 years, the SO_4^{2-} concentration of $\text{PM}_{2.5}$ in Beijing decreased significantly due to the strict emission
462 control measures, in most cases NO_3^- dominates inorganic ions, which may be another reason
463 responsible for the moderately acidic aerosol.

464 ALWC has a different effect on aerosol pH in different seasons. In winter, the increasing RH
465 could reduce the aerosol pH whereas it shows a totally reverse tendency in summer, and the elevated
466 RH has little effect on aerosol pH in spring and autumn when the RH is between 30% and 80%. The
467 sensitivity analysis of this work highlights the diverse influence of ALWC on aerosol pH, the
468 dilution effect of ALWC on H_{air}^+ is only obvious in summer. The elevated NH_3 and NH_4^+ could
469 reduce aerosol acidity by decreasing H_{air}^+ concentration exponentially. In the North China Plain, the
470 ammonia is rich, the remaining ammonia after reaction with sulfuric acid will be available to react
471 with nitric acid to produce NH_4NO_3 , so that the aerosol phase will be neutralized to a large extent.
472 However, the moderate aerosol acidity suggests that though there are excess ammonia in the
473 atmosphere, in most cases the aerosol will not be alkaline due to the limited ALWC.

Table captions

648 **Table 1.** The averaged $PM_{2.5}$ and NO_3^- , SO_4^{2-} , NH_4^+ mass concentration as well as RH, ALWC,

649 H_{air}^+ , pH on clean, polluted and heavily polluted days over four seasons.

650 **Table 2.** Sensitivity of aerosol chemical components (NO_3^- , SO_4^{2-} , NH_4^+ , Ca^{2+}), precursor gases

651 (NH_3 , HNO_3) and meteorological parameters (RH, T) to aerosol acidity, ALWC and H_{air}^+ . The larger

652 magnitude of the deviation represents the larger impact.

Figure captions

667 **Figure 1.** Time series of relative humidity (RH), temperature (T) (a, e, i, m); PM_{2.5}, PM₁₀, and NH₃
668 (b, f, g, n); dominant water-soluble ion species: NO₃⁻, SO₄²⁻, NH₄⁺ (c, g, k, o); aerosol pH colored
669 by PM_{2.5} concentration (d, h, l, p) over four seasons.

670 **Figure 2.** Comparisons of predicted NO₃⁻, NH₄⁺ to measured values based on (a, b) online ion
671 chromatography data and (c, d) MOUDI data.

672 **Figure 3.** Wind dependence map of aerosol pH over four seasons. In each picture, the shaded
673 contour indicates the average of variables for varying wind speeds (radial direction) and wind
674 directions (transverse direction).

675 **Figure 4.** Diurnal patterns of predicted aerosol liquid water content (ALWC) (a-d); H_{air}⁺ predicted
676 by ISORROPIAII (i-l); predicted aerosol pH (m-p) over four seasons. Mean and median values are
677 shown, together with 25% and 75 % quantiles.

678 **Figure 5.** Sensitivities of chemical components (NO₃⁻, SO₄²⁻, NH₄⁺, Ca²⁺), precursor gases (NH₃,
679 HNO₃) as well as meteorological parameters (RH, T) to ALWC in summer and winter.

680 **Figure 6.** Sensitivities of chemical components (NO₃⁻, SO₄²⁻, NH₄⁺, Ca²⁺), precursor gases (NH₃,
681 HNO₃) as well as meteorological parameters (RH, T) to H_{air}⁺ in summer and winter.

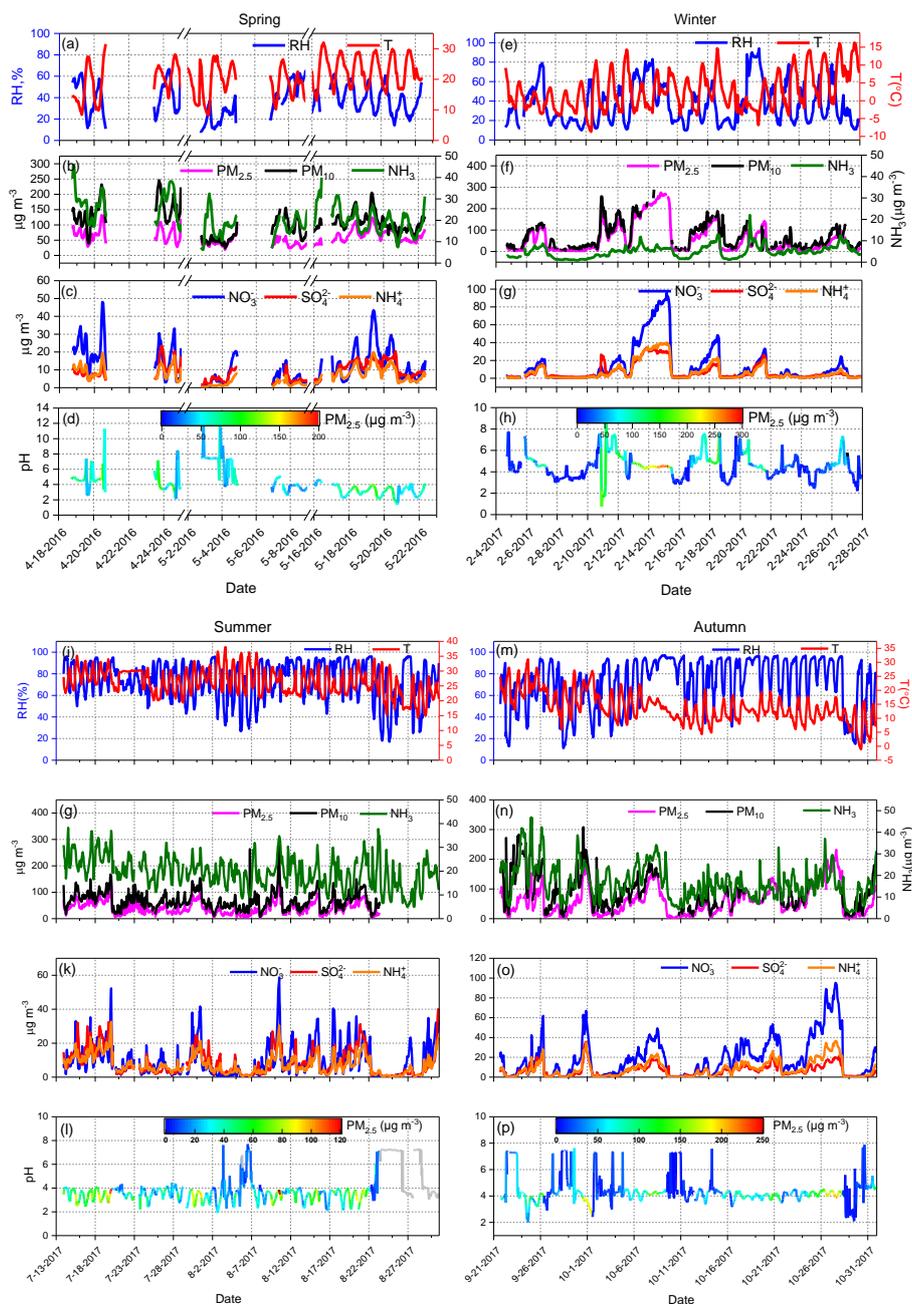

682 **Figure 7.** Sensitivities of chemical components (NO₃⁻, SO₄²⁻, NH₄⁺, Ca²⁺), precursor gases (NH₃,
683 HNO₃) as well as meteorological parameters (RH, T) to pH in summer and winter.

684 **Figure 8.** Measured NO₃⁻/2SO₄²⁻ ratio (mole mole⁻¹) versus predicted pH colored by ambient RH.
685 NO₃⁻, SO₄²⁻ dominant zone denotes NO₃⁻/2SO₄²⁻ > 1 or < 1.

686 **Figure 9.** The size distribution of aerosol pH and all analyzed chemical components on clean (a, d,
687 g), polluted (b, e, h) and heavily polluted days (c, f, i) in summer, autumn and winter.

688 **Figure 10.** The size distribution of pH and all analyzed chemical components in the daytime (a, c,
689 e) and (b, d, f) nighttime in summer, autumn and winter.
