

Analyzing the turbulent Planetary Boundary Layer by remote sensing systems: Doppler wind lidar, aerosol elastic lidar and microwave radiometer *by Gregori de Arruda Moreira et al.*

Author's response.

We thank the anonymous reviewers for their comments, corrections and suggestions, which have helped to improve the quality of the manuscript. According to the referees' reports, the following changes have been done in the original manuscript and a point-by-point response is included below.

In order to show that this paper is a nice contribution to demonstrate the broad spectrum of the EARLINET special issue the following phrases have been added:

(Lines 96 – 101)

“One of the goals is to show the feasibility of using EL at 532 nm, considering the widespread use of lidar systems based on laser emission at this wavelength in different coordinated networks, like as EARLINET (Pappalardo et al., 2014) and LALINET – Latin American Lidar Network (Guerrero-Rascado et al., 2016). In addition, this study shows the variety of application that can be done with EARLINET data applying some simple changes in the data acquisition procedures.”

Reviewer 1

General comments

This manuscript presents results from the SLOPE campaign in Granada, Spain, in which the objective was to obtain closure between remote sensing and in-situ measurements. For this manuscript, the focus is on characterizing the planetary boundary layer using a Doppler lidar, multi-wavelength lidar (MULHACEN), and a profiling microwave radiometer, all operating at high temporal resolution (2 seconds). The authors investigate the use of fluctuations in aerosol number density from the elastic system (EL), vertical velocity fluctuations obtained from the Doppler lidar (DL), and potential temperature profiles retrieved from the microwave radiometer (MWR), to identify the boundary layer height (PBLH). As stated in the first and second review, the methodology

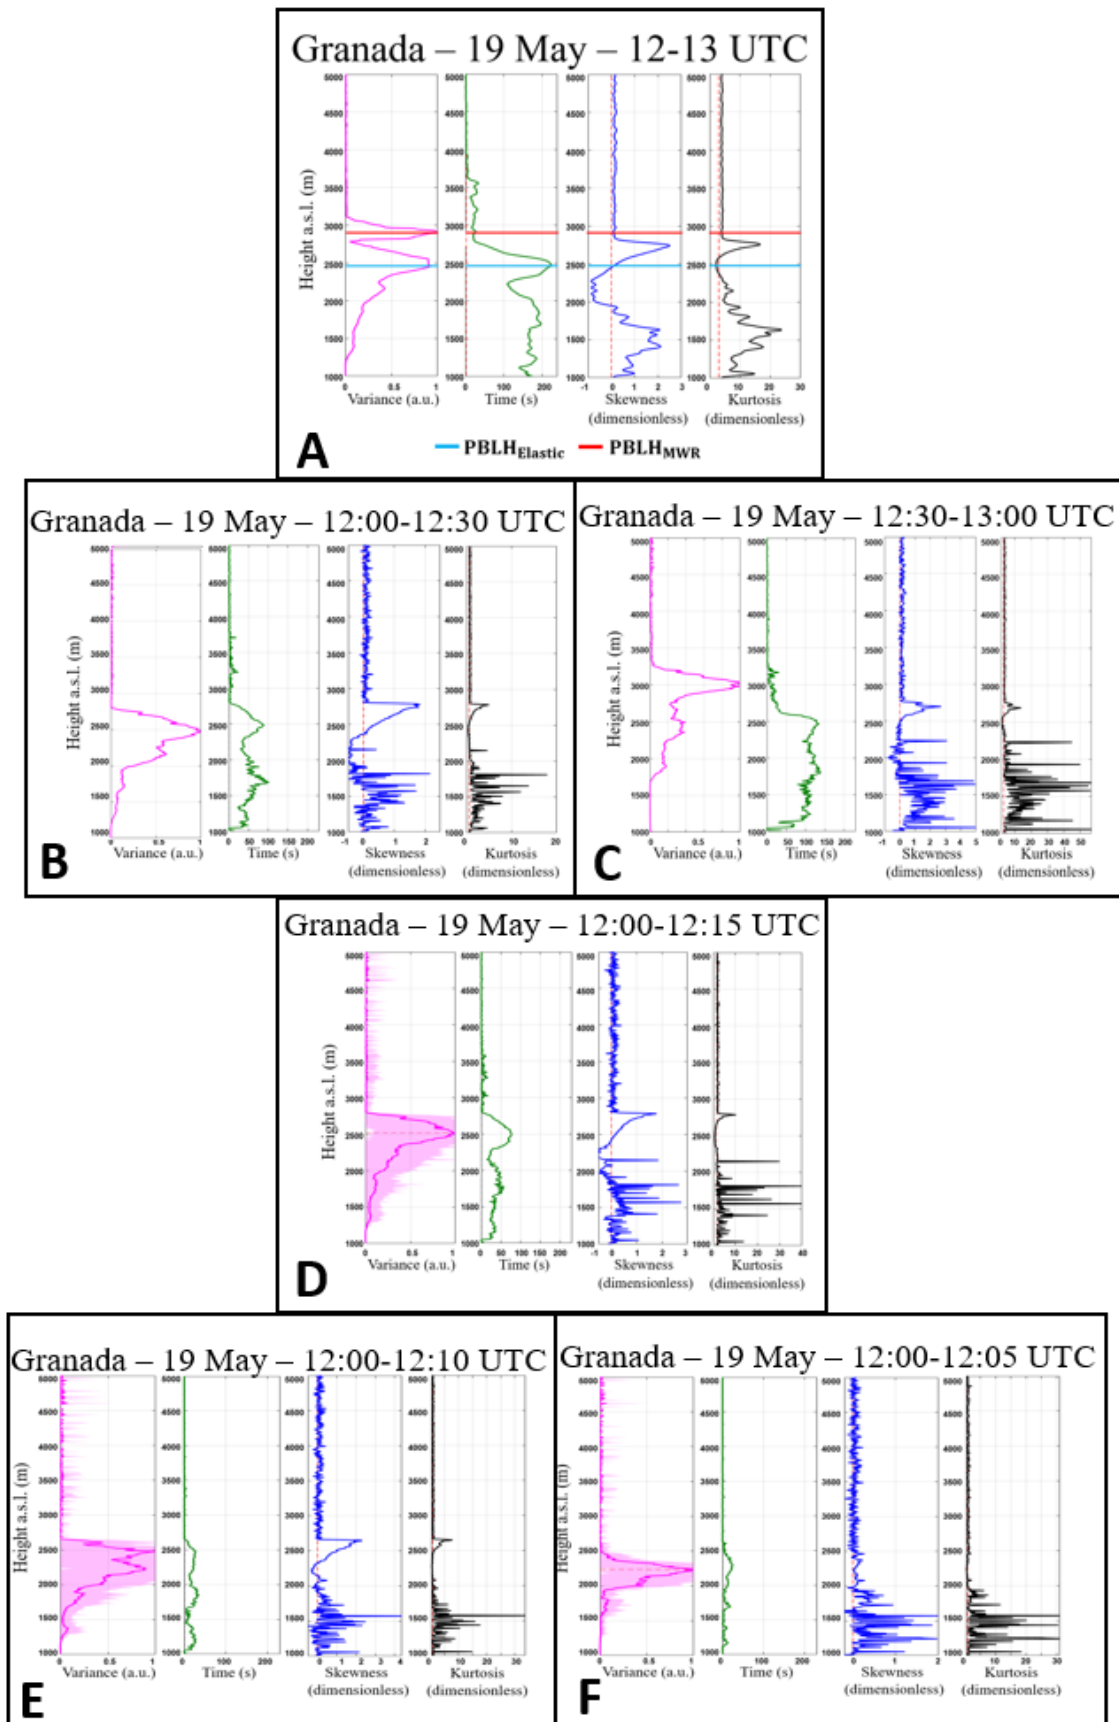

is relevant, and the influence of random error introducing extra noise in higher-order moments has merit and is explored using suitable techniques.

The manuscript has now been improved significantly, with a clearer focus, and explores the impact of applying the elastic lidar methodology at different wavelengths. New Figures 9 and 10 now show that, although backscattering coefficients are wavelength-dependent (molecular and aerosol), the methodology and correction procedure can account for these differences. It is now clear that the higher moments exhibit more correction at 532 nm but the methodology used to derive PBLH from elastic lidar is not unduly sensitive to the wavelength used, at least.

The new supplementary figures are much better, and clearly display where reliable data may be obtained. However, there are still a few issues for the authors to address before the manuscript is suitable for publication.

This question was asked previously: "The EL and DL parameters are calculated over 1-hour periods. Is this 1-hour timescale suitable during rapidly varying conditions such as during the morning growth of the boundary layer?" This question is asking whether a 1 hour timescale is suitable when, during the morning growth, a particular region may have been calm for 30 minutes, and then strongly turbulent for 30 minutes. What happens to the integral timescale for both EL and DL properties when you include atmospheric regions with very different turbulent attributes (e.g calm and convective) within the same averaging period? With one hour averaging, you will always miss the rapid growth of the CBL. I understand you want to capture the integral time scale, but how can you do this when the turbulence characteristics themselves are changing?

We thank the Reviewer for this comment. Answer Figure 1-A (case study I of the main document) shows a situation with a fast growth of the PBL during 30 min followed by 30 min interval with a PBLH almost constant. In figures 1-B and 1-C we show the analyses of this case split in two 30 min intervals corresponding to the two different situations, fast growth and almost constant PBLH. In both cases the integral time scale is lower than that computed for the whole 1 hour interval and the profiles of Skewness and Kurtosis are rather noisy, thus complicating the observation of determined phenomena, although the profiles are very similar. So it is evident that the analyses of intervals below 1 hour are not good enough, the degradation of the analyses increases with the reduction of the considered interval as can be seen in the figures (15 min [Fig. 1-D], 10 min [Fig. 1-E] and 5 min [Fig. 1-F]). In this sense, it is evident that the features of our equipment does not allow the detection, with appropriate quality, of turbulent events with a temporal resolution lower than 1 hour. So when the PBL present faster changes we can only observe the average behavior of the turbulence with this time window.

Answer Figure 1 – Statistical moments obtained from 532 nm wavelength data of elastic lidar (Mulhacen) in Granada - 19 May 2016.

Minor comments

Lines 42-47. Please check and reformulate these sentences.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 42 - 48)

“In an ideal situation, some instants after sunrise, the ground surface temperature increases due to the positive net radiative flux (R_n). This process intensifies the convection, where there is an ascension of warm air masses, causing the downward displacement of colder air masses and consequently originating the Convective Boundary Layer (CBL) or Mixing Layer (ML). Such layer has this name due to the mixing process generated by the ascending air parcels. Slightly before sunset, the gradual reduction of incoming solar irradiance at the Earth’s surface causes the decrease of the positive R_n and, consequently, its sign change. In this situation, there is a reduction of the convective processes and a weakening of the turbulence.”

Line 78: Replace 'turbulenc' with 'turbulence'.

Done

Line 86: The convective PBL is the CBL.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Line 87)

“... PBL height (PBLH) during the convective period ...”

Line 96: Replace 'realibility' with 'reliability'. Explain why measurements at 532 nm should be more reliable, or suggest removing this sentence.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 97 - 99)

“... considering the widespread use of lidar systems based on laser emission at this wavelength in different coordinated networks, like as EARLINET (Pappalardo et al., 2014) and LALINET – Latin American Lidar Network (Guerrero-Rascado et al., 2016).”

Lines 129-130: Suggest replacing 'This system record the backscattered signal with 300 gates, being the range gate length 30 m, with the first gate at 60 m' with 'This system records the backscattered signal with a range resolution of 30 m in 300 range gates with the first range gate starting at 60 m from the instrument.'

Done

Line 131: Suggest stating 'The instrument was operated in vertical stare mode with a temporal resolution of 2 s'. Using the phrase 'with respect to the ground surface' could mean that, on a sloping surface, you imply you are pointing normal (90 degrees) to the surface. Pointing vertically is unambiguous and doesn't require the qualifier.

We thank the Reviewer for this comment. In order to clarify this point the suggested change has been applied.

Line 168: Replace 'performed campaign of comparison' with 'intercomparison campaign'.

Done

Line 173: Replace 'allow to estimate the CBL height' with 'allows the estimation of the CBL height'.

Done

Lines 179, 182, 186: σ_w^2 , σ_{RCS} , q , are used before being defined.

We thanks the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Line 184)

"... the variance of vertical wind speed (σ_w^2) ..."

(Lines 187-188)

"...the variance of Range Corrected Signal (σ_{RCS}^2) ..."

(Lines 191)

"...gathered data [$q(z, t)$] with a temporal resolution ..."

Line 179: Do you mean the PBLH_Doppler is attributed to the height where σ_w^2 drops below a pre-determined threshold?

Yes, exactly. In order to clarify this point the text has been changed as follow:

(line 184)

"... (σ_w^2) is lower than a determinate threshold ..."

Line 191: Replace 'isthe' with 'is the'.

Done

Line 222: Replace 'depends' with 'depend'.

Done

Lines 242-244: Suggest rewriting this phrase as it is unclear. You could use ' in this study we evaluate using RCS532 fluctuations to determine turbulence following the procedure described in Figure 3. This EL methodology is very similar to that described earlier for DL.'

Done

Line 257 and elsewhere: Suggest using 'below the PBLH' rather than 'under the PBLH'.

Done in line 264 and line 270

Line 259: Replace 'relation the other' with 'relation to the other'.

Done

Lines 263-265. This statement is only true in high SNR conditions - figure 5 only shows data within 1200 m of the instrument.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 270-271)

"...Therefore, considering high Signal-to-Noise Ratio (SNR) conditions, although the presence of ϵ ..."

Lines 272-273: Suggest replacing 'its spread use in observation network with higher reliability than 1064 nm' with 'its widespread use in observation networks'.

We thank the Reviewer for this comment. In order to clarify this point the suggested change has been applied.

Lines 274-275: Suggest replacing 'As expected, in both cases the increase of height produces the increase of ϵ ,' with 'As expected, ϵ increases with range'.

Done

Lines 278-283: The difference in noise levels between the two wavelengths depends on the SNR at each wavelength, which is more likely to be determined by the laser output power, filters, and detectors used, at the two wavelengths. Higher molecular extinction at 532 nm can then reduce SNR relative to the 1064 nm wavelength, as does separation of the molecular and aerosol backscattering. Figure 8 is not necessary for the manuscript.

We thank the Reviewer for this comment. In order to clarify this point the figure 8 has been removed and the text has been changed as follow:

(Lines 286-292)

“Although the level of influence of ϵ in each wavelength depends on the SNR of them (which is associated to technical factors such as laser output power, filters, type of detectors), considering the proposed methodology, to evaluate the composition of each wavelength is also important. The large contribution of $\beta_{Molecular}^{532}$ to the total β at 532 nm in comparison with the behavior at 1064 nm, can influence the results obtained from such wavelength, because our methodology is based on the use of $\beta'_{Aerosol}$. In addition, the larger extinction (due to both aerosol particles and molecules) at 532 nm produces a lower two-way transmittance, resulting in the reduction of the SNR values at this wavelength.”

Line 299: SNR is reduced, the noise doesn't increase.

We thank the Reviewer for this comment. In order to clarify this point the figure 8 has been removed and the text has been changed as follow:

(Lines 308-310)

“...which reduces the SNR of the profiles in comparison with 1064 nm, the application of the proposed corrections, mainly the first lag, reduces significantly such influence and...”

Lines 303-304: Suggest rewriting this phrase as it is unclear.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 312-313)

“The first lag correction was adopted as default because it provides better results than the -2/3 law correction.”

Lines 315-318: It is not clear that the integral time scale can be retrieved throughout the whole PBL, especially if PBLH_MWR is taken as a reference. It is not necessarily true that the grey areas are where T_w' is lower than the DL acquisition time, just that the DL sensitivity is not high enough to measure T_w' . This can be seen in the supplementary material, where SNR is low above 1500 m and the upper portion of the CBL may not be captured during daytime. I would expect T_w' to be just as large here.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 322-325)

“Figure 10 (A) shows the integral time scale obtained from DL data (τ_w). The gray area represents the region where it is not possible to analyze the turbulent process using our DL data, either because of the low SNR values, which results in null values of the τ_w , or because the no null τ_w is smaller than the acquisition time of the DL. However, the gray area is located almost entirely above the PBLH_{MWR} (white stars).”

Lines 319-320: This sentence can be removed.

Done

Lines 327-328: I suggest removing this sentence.

Done

Lines 329-320: Not correct, skewness describes the distribution of the turbulent velocities - positive skewness implies strong but narrow updrafts surrounded by weaker but more widespread downdrafts, and vice versa for negative skewness.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

Lines (333-335)

“The skewness of w' (S_w) is shown in Figure 11-C. The S_w describes the distribution of the turbulent velocities. Thus positive S_w implies strong but narrow updrafts surrounded by weaker but more widespread downdrafts, and vice versa for negative S_w .”

Line 336: Do you mean that that the MWR method is now selecting for SBLH?

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 341-342)

“... Thus, the reduction observed in the $PBLH_{MWR}$ is due to the detection of SBL height.”

Lines 344-353: Suggest removing these paragraphs. Some of these statements could replace phrases in lines 329-337.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 349-351)

“Figure 10-E presents the values of surface air temperature and surface relative humidity (RH). Air surface temperature has a daily pattern similar to that of R_n and S_{wr} . On the other hand, RH is inversely correlated with the temperature.”

Lines 365-367: The $PBLH$ values in Figure 13 don't agree with Figure 12, where there is a large difference between $PBLH_{MWR}$ and $PBLH_{Elastic}$.

We thank the Reviewer for this comment. In order to clarify this point the figures 12 and 13 have been remade as shwon below:

Granada – 19 May – 13-14 UTC

Figure 12 – Statistical moments obtained from 532 nm wavelength data of elastic lidar (Mulhacen) in Granada at 13 to 14 UTC - 19 May 2016. From left to right: variance [$\sigma_{RCS'}^2$], integral time scale [$\tau_{RCS'}$], skewness [$S_{RCS'}$] and kurtosis [$K_{RCS'}$].

Granada – 19 May – 13-14 UTC

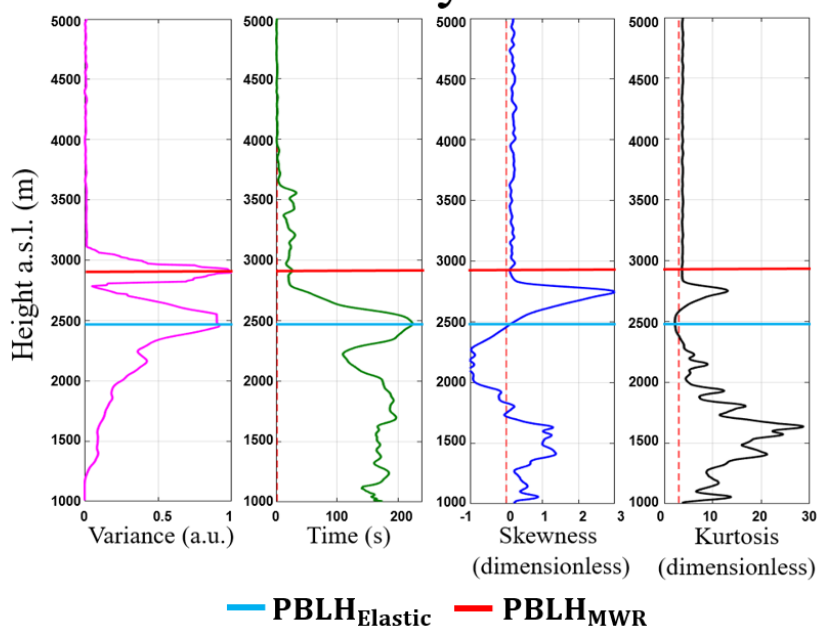

Figure 13 – Statistical moments obtained from 1064 nm wavelength data of elastic lidar (Mulhacen) in Granada at 13 to 14 UTC - 19 May 2016. From left to right: variance [$\sigma_{RCS'}^2$], integral time scale [$\tau_{RCS'}$], skewness [$S_{RCS'}$] and kurtosis [$K_{RCS'}$].

The text has been changed as follow:

(Lines 366-374)

“Due to presence of a decoupled aerosol layer at 13:30, the average values of $PBLH_{Elastic}$ and $PBLH_{MWR}$ have a difference of around 500 m. The $\sigma_{RCS'}^2$ has small and practically constant values between 1000 and 1400m, evidencing the homogeneity of the aerosol distribution in this region. Starting at 1400 m the value of $\sigma_{RCS'}^2$ begins to increase, reaching a positive peak at $PBLH_{MWR}$, which represents the Entrainment Zone (region characterized by an intense mixing between air parcels coming from CBL and Free Troposphere (FT), causing a high variation in aerosol concentration). The $PBLH_{Elastic}$ observed at approximately 2900 m demonstrate an inherent difficulty of the variance method to detect the PBLH in the presence of several aerosol layers (Kovalev and Eichinger, 2004). Above $PBLH_{Elastic}$ the values of $\sigma_{RCS'}^2$ decrease slowly due to location of the lofted aerosol around 2500 m.”

Line 372: Define FT here.

Done

Line 392: Do you refer to the correct figure here?

We thank the Reviewer for this comment. In order to clarify this mistake the text has been changed as follow:

(Lines 392 -393)

“The results provided by DL, pyranometer and MWR data agree with the results observed in figures 12 and 13.”

Line 399. Suggest removing the second phrase of this sentence.

Done

Line 400: Not true according to the figure.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 399-400)

“...the greatest part of grey area is situated above the $PBLH_{MWR}$...”

Lines 411-414: No clouds are observed in the DL data until 1400 UTC, and it is difficult to prove that the negative skewness extends to 3 km in altitude. Are you sure that all of the white regions are cloud before 1400? One at 1230 and one at 1330 maybe.

We thank the Reviewer for this comment. During this period there is the presence of both middle altitude clouds and very intense dust layers. In order to clarify this point the text has been changed as follow:

(Lines 411 - 415)

“From Figure 16 we can observe the presence of both middle altitude clouds and very intense dust layers from 12:00 to 15:00 UTC. Such combination contributes to the intense negative values of S_w , observed in this period until around 2 km, because, as mentioned previously, S_w is directly associated with the direction of the turbulent movements. The present situation can be considered representative of cloud-top long-wave radiative cooling in the CBL (Ansmann et al., 2010).”

Lines 415-420. As above, it is clear that the Saharan dust layer is having an impact, but R_n alone is probably not sufficient to attribute negative skewness directly to clouds.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 417-420)

“The observation of S_w , and R_n between 12:00 and 14:00, as well as, the presence of clouds and geometrically thick dust layers during this same period, reinforces the hypothesis that we have a situation of cloud-top long-wave radiative cooling in the CBL.”

Line 423: See above comment. Not all of the high RCS values (white regions) before 1300 can be attributed to clouds, and there is very little attenuation seen in the profile before 1230.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Line 425 - 426)

“...the presence of both middle altitude clouds and very intense dust layers ...”

Line 463: This is only true at high SNR.

We thank the Reviewer for this comment. In order to clarify this point the text has been changed as follow:

(Lines 467-468)

“...low influence of the noise in high SNR conditions.”

Line 467: Replace 'lower two ways' with 'reduced two-way'.

Done

Figure 12: Replace 'blues stars' with 'blue stars'.

Done

Analyzing the turbulent Planetary Boundary Layer by remote sensing systems: Doppler wind lidar, aerosol elastic lidar and microwave radiometer

Abstract

The Planetary Boundary Layer (*PBL*) is the lowermost region of troposphere and endowed with turbulent characteristics, which can have mechanical and/or thermodynamic origins. Such behavior gives to this layer great importance, mainly in studies about pollutant dispersion and weather forecasting. However, the instruments usually applied in studies about turbulence in the *PBL* have limitations in spatial resolution (anemometer towers) or temporal resolution (instrumentation onboard aircraft). Ground-based remote sensing, both active and passive, offers an alternative for studying the *PBL*. In this study we show the capabilities of combining different remote sensing systems (microwave radiometer [*MWR*], Doppler lidar [*DL*] and elastic lidar [*EL*]) for retrieving a detailed picture on the *PBL* turbulent features. The statistical moments of the high frequency distributions of the vertical wind velocity, derived from *DL* and of the backscattered coefficient derived from *EL*, are corrected by two methodologies, namely first lag and $-2/3$ correction. The corrected profiles, obtained from *DL* data, present small differences when compared against the uncorrected profiles, showing the low influence of noise and the viability of the proposed methodology. Concerning *EL*, in addition to analyze the influence of noise, we explore the use of different wavelengths that usually include *EL* systems operated in extended networks, like EARLINET, LALINET, MPLNET or SKYNET. In this way we want to show the feasibility of extending the capability of existing monitoring networks without strong investments or changes in their measurements protocols. Two case studies were analyzed in detail, one corresponding to a well-defined *PBL* and another one corresponding to a situation with presence of a Saharan dust lofted aerosol layer and clouds. In both cases we discuss results provided by the different instruments showing their complementarity and the cautions to be applied in the data interpretation. Our study shows that the use of *EL* at 532nm requires a careful correction of the signal using the first lag time correction in order to get reliable turbulence information on the *PBL*.

Keywords: Turbulence, Planetary Boundary Layer, Doppler lidar, elastic lidar, microwave radiometer, Earlinet.

38 1 Introduction

39 The Planetary Boundary Layer (*PBL*) is the atmospheric layer directly influenced by the Earth's surface
40 that responds to its changes within time scales around an hour (Stull, 1988). Such layer is located at the
41 lowermost region of troposphere, and is mainly characterized by turbulent processes and a daily evolution
42 cycle. In an ideal situation, some instants after sunrise, the ground surface temperature increases due to the
43 positive net radiative flux (R_n). This process intensifies the convection, where there is an ascension of warm
44 air masses, causing the downward displacement of colder air masses and consequently originating the
45 Convective Boundary Layer (*CBL*) or Mixing Layer (*ML*). Such layer has this name due to the mixing
46 process generated by the ascending air parcels. Slightly before sunset, the gradual reduction of incoming
47 solar irradiance at the Earth's surface causes the decrease of the positive R_n and, consequently, its sign
48 change. In this situation, there is a reduction of the convective processes and a weakening of the turbulence.
49 In this process the *CBL* leads to the development of two layers, namely a stably stratified boundary layer
50 called Stable Boundary Layer (*SBL*) close to the surface, and the Residual Layer (*RL*) that contains features
51 from the previous day's *ML* and is just above the *SBL*.

52 Knowledge of the turbulent processes in the *CBL* is important in diverse studies, mainly for atmospheric
53 modeling and pollutant dispersion, since turbulent mixing can be considered as the primary process by
54 which aerosol particles and other scalars are transported vertically in atmosphere. Because turbulent
55 processes are treated as nondeterministic, they are characterized and described by their statistical properties
56 (high order statistical moments). When applied to atmospheric studies such analysis provide information
57 about the field of turbulent fluctuation, as well as, a description of the mixing process in the *PBL* (Pal et
58 al., 2010).

59 Anemometer towers have been widely applied in studies about turbulence (e.g., Kaimal and Gaynor, 1983;
60 van Ulden and Wieringa, 1996), however the limited vertical range of these equipment restrict the analysis
61 to regions close to surface. Aircraft have also been used in atmospheric turbulence studies (e.g., Lenschow
62 et al., 1980; Williams and Hacker, 1992; Lenschow et al., 1994; Albrecht et al., 1995; Stull et al., 1997;
63 Andrews et al., 2004; Vogelmann et al., 2012), nevertheless their short time window limits the analysis. In
64 this scenario, systems with high spatial and temporal resolution and enough range are necessary in order to
65 provide more detailed results along the day throughout the whole thickness of the *PBL*.

66 In the last decades, lidar systems have been increasingly applied in this kind of study due to their large
67 vertical range, high data acquisition rate and capability to detect several observed quantities such as vertical
68 wind velocity [Doppler lidar] (e.g. Lenschow et al., 2000; Lothon et al., 2006; O'Connor et al., 2010), water
69 vapor [Raman lidar and DIAL] (e.g. Wulfmeyer, 1999; Kiemle et al., 2007; Wulfmeyer et al., 2010; Turner
70 et al., 2014; Muppa et al., 2015), temperature [rotational Raman lidar] (e.g. Behrendt et al., 2015) and
71 aerosol [elastic lidar] (e.g. Pal et al., 2010; McNicholas et al., 2015). This allows the observation of a wide
72 range of atmospheric processes. For example, Pal et al. (2010) demonstrated how the statistical analyses
73 obtained from high-order moments of elastic lidar can provide information about aerosol plume dynamics
74 in the *PBL* region. In addition, when different lidar systems operate synergistically, as for example in

75 Engelmann et al. (2008), who combined elastic and Doppler lidar data, it is possible to identify very
76 complex variables such as vertical particle flux.

77 Different works (Ansmann et al., 2010; O'Connor et al., 2010) have evidenced the feasibility for
78 characterizing the *PBL* turbulence by *DL*. Pal et al. (2010) have shown the feasibility for retrieving
79 information on the *PBL* turbulence from high high-order moments of elastic lidar operating at 1064. Such
80 approaches are even more attractive when considering facilities of networks, e. g. European Aerosol
81 Research Lidar NETwork (EARLINET) (Pappalardo et al., 2014), Microwave Radiometer Network
82 (MWRNET) (Rose et al., 2005; Caumont et al., 2016) and ACTRIS CLOUDNET (Illingworth et al., 2007).
83 For these reasons, and having in mind the wide spread of elastic lidar systems operated at other wavelengths,
84 like 532 nm or 355 nm, it would be worthy test the feasibility of these other wavelengths in the
85 characterization of the *PBL* turbulent behavior.

86 The use of simple techniques, applied to the aforementioned remote systems provide robust and similar
87 information on the *PBL* height (*PBLH*) during the convective period (see for example Moreira et al, 2018),
88 or a complementary information when the *CBL* is substituted by the presence of the *SBL* and the *RL*
89 (Moreira et al., in preparation). Thus, the combination of information obtained from the active remote
90 sensing systems, *DL* and *EL*, acquired with a temporal resolution close to 1 s, and that provided by *MWR*
91 can provide a detailed understanding about different features of the *PBL*, like structure (*CBL* versus *SBL*
92 and *RL*), height of the layers, rate of growth of the *PBLH* and turbulence.

93 In this study we show the feasibility of obtaining a clear insight on the *PBL* behavior using a combination
94 of active and passive remote sensing systems (Elastic Lidar [*EL*], Doppler Lidar [*DL*] and Microwave
95 Radiometer [*MWR*]) acquired during the SLOPE-I campaign, held at IISTA-CEAMA (Andalusian Institute
96 for Earth System Research, Granada, Spain) from May to August 2016. One of the goals is to show the
97 feasibility of using *EL* at 532 nm, considering the widespread use of lidar systems based on laser emission
98 at this wavelength in different coordinated networks, like as EARLINET (Pappalardo et al., 2014) and
99 LALINET – Latin American Lidar Network (Guerrero-Rascado et al., 2016). In addition, this study shows
100 the variety of application that can be done with EARLINET data applying some simple changes in the data
101 acquisition procedures.

102 This paper is organized as follows. Description of the experimental site and the equipment setup are
103 presented in Section 2. The methodologies applied are introduced in Section 3. Section 4 presents the results
104 of the analyses using the different methodologies. Finally, conclusions are summarized in Section 5.

105

106 2 Experimental site and instrumentation

107 The SLOPE-I (Sierra nevada Lidar aerOsol Profiling Experiment) campaign was performed from May to
108 September 2016 in South-Eastern Spain in the framework of the European Research Infrastructure for the
109 observation of Aerosol, Clouds, and Trace gases (ACTRIS). The main objective of this campaign was to
110 perform a closure study by comparing remote sensing system retrievals of atmospheric aerosol properties,

111 using remote systems operating at the Andalusian Institute of Earth System Research (IISTA-CEAMA)
112 and in-situ measurements operating at different altitudes in the Northern slope of Sierra Nevada, around 20
113 km away from IISTA-CEAMA (Bedoya-Velásquez et al., 2018; Román et al., 2018). The IISTA-CEAMA
114 station is part of EARLINET (Pappalardo et al., 2014) since 2005 and at present is an ACTRIS station
115 (<http://actris2.nilu.no/>). The research facilities are located at Granada, a medium size city in Southeastern
116 Spain (Granada, 37.16°N, 3.61°W, 680 m a.s.l.), surrounded by mountains and with Mediterranean-
117 continental climate conditions that are responsible for cool winters and hot summers. Rain is scarce,
118 especially from late spring to early autumn. Granada is affected by different kind of aerosol particles locally
119 originated and medium-long range transported from Europe, Africa and North America (Lyamani et al.,
120 2006; Guerrero-Rascado et al., 2008, 2009; Titos et al., 2012; Navas-Guzmán et al., 2013; Valenzuela et
121 al., 2014, Ortiz-Amezcuca et al., 2014, 2017).

122 MULHACÉN is a biaxial ground-based Raman lidar system operated at IISTA-CEAMA in the frame of
123 EARLINET research network. This system operates with a pulsed Nd:YAG laser, frequency doubled and
124 tripled by Potassium Dideuterium Phosphate crystals, emitting at wavelengths of 355, 532 and 1064 nm
125 with output energies per pulse of 60, 65 and 110 mJ, respectively. MULHACÉN operates with three elastic
126 channels: 355, 532 (parallel and perpendicular polarization) and 1064 nm and three Raman-shifted
127 channels: 387 (from N₂), 408 (from H₂O) and 607 nm (from N₂). MULHACÉN's overlap is complete at
128 90% between 520 and 820 m a.g.l. for all the wavelengths, reaching full overlap around 1220 m a.g.l.
129 (Navas-Guzmán et al., 2011; Guerrero-Rascado et al. 2010). Calibration of the depolarization capabilities
130 is done following Bravo-Aranda et al. (2013). This system was operated with a temporal and spatial
131 resolution of 2 s and 7.5 m, respectively. More details can be found at Guerrero-Rascado et al. (2008, 2009).

132 The Doppler lidar (Halo Photonics, model Stream Line XR) is also operated at IISTA-CEAMA. This
133 system works in continuous and automatic mode from May 2016. It operates at 1.5 μm with pulse energy
134 and repetition rate of 100 μJ and 15 KHz, respectively. This system records the backscattered signal with a
135 range resolution of 30 m in 300 range gates with the first range gate starting at 60 m from the instrument.
136 The telescope focus is set to approximately 800 m. The instrument was operated in vertical stare mode with
137 a temporal resolution of 2 s.

138 Furthermore, we operated the ground-based passive microwave radiometer (RPG-HATPRO G2,
139 Radiometer Physics GmbH), which is member of the MWRnet [<http://cetemps.aquila.infn.it/mwrnet/>]. This
140 system operates in automatic and continuous mode at IISTA-CEAMA since November 2011. The
141 microwave radiometer (MWR) measures the sky brightness temperature with a radiometric resolution
142 between 0.3 and 0.4 K root mean square error at 1 s integration time, using direct detection receivers within
143 two bands: K-band (water vapor – frequencies: 22.24 GHz, 23.04 GHz, 23.84 GHz, 25.44 GHz, 26.24 GHz,
144 27.84 GHz, 31.4 GHz) and V-band (oxygen – frequencies: 51.26 GHz, 52.28 GHz, 53.86 GHz, 54.94 GHz,
145 56.66 GHz, 57.3 GHz, 58.0 GHz). From these bands is possible to obtain profiles of water vapor and
146 temperature, respectively, by inversion algorithms described in Rose et al. (2005). The range resolution of
147 these profiles vary between 10 and 200 m in the first 2 km and between 200 and 1000 m in the layer between
148 2 and 10 km (Navas-Guzmán et al., 2014).

149 The meteorological sensor (HMP60, Vaisala) is used to register the air surface temperature and surface
150 relative humidity, with a temporal resolution of 1 minute. Relative humidity is monitored with an accuracy
151 of $\pm 3\%$, and air surface temperature is acquired with an accuracy and precision of 0.6°C and 0.01°C ,
152 respectively.

153 A CM-11 pyranometer manufactured by Kipp&Zonen (Delft, The Netherlands) is also installed in the
154 ground-based station. This equipment measures the shortwave (SW) solar global horizontal irradiance data
155 (305–2800 nm). The CM-11 pyranometer complies with the specifications for the first-class WMO (World
156 Meteorological Organization) classification of this instrument (resolution better than $\pm 5\text{ Wm}^{-2}$), and the
157 calibration factor stability has been periodically checked against a reference CM-11 pyranometer (Antón
158 et. al, 2012).

159 **3 Methodology**

160 **3.1 MWR data analysis**

161 The MWR data are analyzed combining two algorithms, Parcel Method [*PM*] (Holzworth, 1964) and
162 Temperature Gradient Method [*TGM*] (Coen, 2014), in order to estimate the *PBL* Height ($PBLH_{MWR}$) in
163 convective and stable situations, respectively. The different situations are discriminated by comparing the
164 surface potential temperature ($\theta(z_0)$) with the corresponding vertical profile of $\theta(z)$ up to 5 km. Those
165 cases where all the points in the vertical profile have values larger than $\theta(z_0)$ are labeled as stable, and
166 *TGM* is applied. Otherwise the situation is labeled as unstable and the *PM* is applied. The vertical profile
167 of $\theta(z)$ is obtained from the vertical profile of $T(z)$ using the following equation (Stull, 2011):

$$168 \quad \theta(z) = T(z) + 0.0098 * z \quad (1)$$

169 where $T(z)$ is the temperature profile provided by *MWR*, z is the height above the sea level, and 0.0098
170 K/m is the dry adiabatic temperature gradient. A meteorological station co-located with the *MWR* is used
171 to detect the surface temperature [$T(z_0)$]. In order to reduce the noise, $\theta(z)$ profiles were averaged
172 providing a $PBLH_{MWR}$ value at 30 minutes intervals. This methodology of *PBLH* detection was selected as
173 the reference due to the results obtained during a performed **intercomparison campaign** between *MWR* and
174 radiosonde data, where twenty-three radiosondes were launched. High correlations were found between
175 *PBLH* retrievals provided by both instruments in stable and unstable cases. Further details are given by
176 Moreira et al. (2018a).

177 **3.2 Lidar retrieval of the PBLH.**

178 The simple processing of *DL* and *EL* data **allows the estimation of the CBL height**. Moreira et al. (2018),
179 have discussed this issue in depth, while Moreira et al. (in preparation) have exploited the complementarity
180 of the data obtained from distinct remote sensing systems in order to distinguish the sublayers during the

181 period when the *SBL* and *RL* substitute the *CBL*, as well as, in complex situations, like as, presence of dust
 182 layers.

183 The *PBLH* obtained from *DL* data ($PBLH_{Doppler}$) is estimated from variance threshold method. In this
 184 method the $PBLH_{Doppler}$ is attributed to height where the variance of vertical wind speed (σ_w^2) is lower than
 185 a determinate threshold, which was adopted as 0.16 m²/s² (Moreira et al., 2018). For the $PBLH_{Doppler}$
 186 calculations was selected a time interval of 30 minutes. In concerning the *PBLH* obtained from *EL*
 187 ($PBLH_{Elastic}$), the variance method is applied. Such method assumes the maximum of the variance of
 188 Range Corrected Signal (σ_{RCS}^2) as $PBLH_{Elastic}$ (Moreira et al., 2015). The σ_{RCS}^2 is obtained from a time
 189 interval of 30 minutes.

190 3.3 Lidar turbulence analysis

191 Both lidar systems, *DL* and *EL*, gathered data $[q(z, t)]$ with a temporal resolution of 2 seconds. Then, the
 192 data are averaged in 1-hour packages, from which the mean value is extracted $[\bar{q}(z)]$. Such mean value is
 193 subtracted from each $q(z, t)$ profile in order to estimate the vertical profile of the fluctuation for the
 194 measured variable $[q'(z, t)]$ (i.e. vertical velocity for the *DL*):

$$195 \quad q'(z, t) = q(z, t) - \bar{q}(z) \quad (2)$$

196 Then, from $q'(z, t)$ is possible to obtain the high-order moments (variance (σ^2), skewness (*S*) and kurtosis
 197 (*K*)), as well as, the integral time scale (τ - which is the time over which the turbulent process are highly
 198 correlated to itself) as shown in Table 1. These variables can also be obtained from the following
 199 autocovariance function, M_{ij} :

$$200 \quad M_{ij} = \int_0^{t_f} [q'(z, t)]^i [q'(z, t + t_f)]^j dt \quad (3)$$

201 where t_f is the final time, *i* and *j* indicate the order of autocovariance function.

202 However, it is necessary to considerer that the acquired real data contain instrumental noise, $\varepsilon(z)$.
 203 Therefore, the equation 3 can be rewritten as:

$$204 \quad M_{ij} = \int_0^{\tau} [q(z, t) + \varepsilon(z, t)]^i [q(z, t + \tau) + \varepsilon(z, t + \tau)]^j dt \quad (4)$$

205 The autocovariance function of a time series with zero lag results in the sum of the variances of the
 206 atmospheric variable and its $\varepsilon(z)$. Nevertheless, atmospheric fluctuations are correlated in time, but the
 207 $\varepsilon(z)$ is random and uncorrelated with the atmospheric signal. Consequently, the noise is only associated
 208 with lag 0 (Fig. 1). Based on this concept Lenschow et al. (2000) suggested to obtain the corrected
 209 autocovariance function, $M_{11}(\rightarrow 0)$, from two methods, namely first lag correction or -2/3 law correction.
 210 In the first method, $M_{11}(\rightarrow 0)$ is obtained directly by the subtraction of lag 0, $\Delta M_{11}(0)$, from the
 211 autocovariance function, $M_{11}(0)$. In the second method $M_{11}(\rightarrow 0)$ is generated by the extrapolation of

212 $M_{11}(0)$ at firsts nonzero lags back to lag zero (-2/3 law correction). The extrapolation can be performed
 213 using the inertial subrange hypothesis, which is described by the following equation (Monin and Yaglom,
 214 1979):

$$215 \quad M_{11}(\rightarrow 0) = \overline{q'^2(z, t)} + Ct^{2/3} \quad (5)$$

216 where C represents a parameter of turbulent eddy dissipation rate. The high-order moments and τ
 217 corrections and errors are shown in Table 1 (columns 2 and 3, respectively).

218 The same procedure of analysis is applied in studies with DL and EL , being the main difference the tracer
 219 used by each system, which are the fluctuation of vertical wind speed (w') for DL and aerosol number
 220 density (N') for EL . DL provides $w(z, t)$ directly, and therefore the procedure described in Figure 2 can be
 221 directly applied. Thus, the two corrections described above are applied separately and finally τ and high-
 222 order moments with and without corrections can be estimated.

223 On the other hand, the EL does not provide $N(z, t)$ directly. Under some restrictions, it is possible to ignore
 224 the particle hygroscopic growth and to assume that the vertical distribution of aerosol type does not changes
 225 with time, and to adopt the following relation (Pal et al., 2010):

$$226 \quad \beta_{par}(z, t) \approx N(z, t)Y(z) \Rightarrow \beta'_{par}(z, t) = N'(z, t) \quad (6)$$

227 where β_{par} and β'_{par} represent the particle backscatter coefficient and its fluctuation, respectively, and
 228 $Y(z)$ does not depend on time.

229 Considering the lidar equation:

$$230 \quad P_{\lambda}(z) = P_0 \frac{ct_d}{2} AO(z) \frac{\beta_{\lambda}(z)}{z^2} e^{-2 \int_0^z \alpha_{\lambda}(z' dz')} \quad (7)$$

231 where $P_{\lambda}(z)$ is the signal returned from distance z at time t , z is the distance [m] from the lidar of the
 232 volume investigated in the atmosphere, P_0 is the power of the emitted laser pulse, c is the light speed [m/s],
 233 t_d is the duration of laser pulse [ns], A is the area [m²] of telescope cross section, $O(z)$ is the overlap
 234 function, $\alpha_{\lambda}(z)$ is the total extinction coefficient (due to atmospheric particles and molecules) [(km)⁻¹] at
 235 distance z , $\beta_{\lambda}(z)$ is the total backscatter coefficient (due to atmospheric particles and molecules) [(km·sr)⁻¹]
 236 at distance z and the subscript λ represents the wavelength. The two path transmittance term related to
 237 $\alpha(z)$ is considered as nearly negligible at 1064 nm (Pal et al., 2010). Thus, it is possible to affirm that:

$$238 \quad RCS_{1064}(z) = P(z)_{1064} \cdot z^2 \cong G \cdot \beta_{1064}(z) \quad (8)$$

239 and consequently:

$$240 \quad RCS'_{1064}(z, t) \cong \beta'_{1064}(z, t) = \beta'_{par}(z, t) = N'(z, t) \quad (9)$$

241 where RCS_{1064} and RCS'_{1064} are the range corrected signal and its fluctuation, respectively, G is a constant
 242 and the subscripts represent the wavelength.

243 In this way, Pal et al. (2010) have shown the feasibility of using *EL* operating at 1064 nm for describing
244 the atmospheric turbulence. However, having in mind the more extended use of lidar systems based on
245 laser emission at 532 nm in different coordinated networks, e.g., in EARLINET and LALINET around 76%
246 and 45% of the systems include the wavelength of 1064 nm, while 95% of the EARLINET systems and
247 73% of the LALINET systems operate systems that include the wavelength 532 nm (Guerrero-Rascado et
248 al., 2016), in this study we evaluate using RCS_{532} fluctuations to determine turbulence following the
249 procedure described in Figure 3. This *EL* methodology is very similar to that described earlier for *DL*.

250 we perform the validation of the RCS_{532} in analyses about turbulence using *EL*, following the procedure
251 described in Figure 3, which is basically the same methodology described earlier for *DL*.

252 4 Results

253 4.1 Error Analysis

254 The influence of random error in noisy observations rapidly grows for higher-order moments (i.e., the
255 influence of random noise is much larger for the fourth-order moment than for the third-order moment).
256 Therefore, the first step, in order to ascertain the applied methodology and our data quality, we performed
257 the error treatment of *DL* data as described in Figure 2. For the *DL* analysis we selected the period 08-09
258 UTC of 19th May, the same day that will be presented in Case Study 1. This day is characterized by a well-
259 defined PBL.

260 Figure 4 illustrates the autocovariance function, generated from w' , at three different heights. As mentioned
261 before, the lag 0 is contaminated by noise (ϵ), and thus the impact of the ϵ increases together with height,
262 mainly above $PBLH_{MWR}$ (1100 m a.g.l. in our example).

263 Figure 5-A illustrates the comparison between integral time scale ($\tau_{w'}$) without correction and the two
264 corrections cited in section 3.2. Except for the first height-bins, below the $PBLH_{MWR}$ the profiles have little
265 differences, as well as small errors bars. Above the $PBLH_{MWR}$ the first lag correction presents higher
266 differences in relation to the other profiles at around 1350 m.

267 Figures 5-B and 5-C show the comparison of variance ($\sigma_{w'}^2$) and skewness ($S_{w'}$), respectively, with and
268 without corrections. The profiles corrected by -2/3 law do not present significant differences in comparison
269 to uncorrected profiles. On the other hand, the profiles corrected by the first lag correction have slight
270 differences below the $PBLH_{MWR}$, mainly the $\sigma_{w'}^2$ ($S_{w'}$ only in the first 50 m). Therefore, considering high
271 Signal-to-Noise Ratio (SNR) conditions, although the presence of ϵ can change slightly the value of high
272 order moments, it is not enough to distort the observed phenomena as shown by the impact of the corrections
273 applied.

274 For *EL* we use the same procedure for the correction and error analysis that we apply to the *DL* data. The
275 same day was chosen (19th May), however the period selected is between 12 and 13 UTC, due to the
276 incomplete overlap of MULHACÉN.

277 In this sense, we studied the influence of noise at two wavelengths: 1064 nm, that has been previously
278 analyzed by Pal et al. (2010) as presented in the section 2 and adopted as reference (considering the rather
279 low impact of molecular signal and the two ways transmittance shown in 9) and 532 nm, just in order to
280 check the feasibility of this wavelength for turbulence studies considering its widespread use in observation
281 networks (Pappalardo et al., 2014; Guerrero-Rascado et al., 2016). Figures 6 and 7 shows the
282 autocovariance function, obtained from RCS'_{1064} and RCS'_{532} , respectively, at three distinct heights. As
283 expected, ε increases with range, principally above the $PBLH_{MWR}$. However, the wavelength 532 nm is
284 more influenced by the noise, what can be verified by the higher peak at lag 0 in figure 7, in comparison
285 with peaks at same lag in figure 6.

286 Although the level of influence of ε in each wavelength depends on the SNR of them (which is associated
287 to technical factors such as laser output power, filters, type of detectors), considering the proposed
288 methodology, to evaluate the composition of each wavelength is also important. The large contribution of
289 $\beta_{Molecular}^{532}$ to the total β at 532 nm in comparison with the behavior at 1064 nm, can influence the results
290 obtained from such wavelength, because our methodology is based on the use of $\beta'_{Aerosol}$. In addition, the
291 larger extinction (due to both aerosol particles and molecules) at 532 nm produces a lower two-way
292 transmittance, resulting in the reduction of the SNR values at this wavelength. As we used Elastic lidar
293 technique, we could not calculate aerosol extinction profiles, but an estimation of these transmittances was
294 done on the basis of Klett method (Klett, 1985). With this method, a constant lidar ratio value was
295 constrained for each profile using the AOD derived from a collocated AERONET Sun-photometer
296 (Guerrero-Rascado et al., 2008). Using these constrained lidar ratios, the transmittances were calculated
297 together with aerosol backscatter profiles, integrated up to 2.5 km. The estimated two-way transmittance
298 was 0.85 for the case analyzed in this subsection (19th May).

299 Figures 8-A, 8-B, 8-C and 8-D show the vertical profiles of $\tau_{RCS'}$, $\sigma_{RCS'}^2$, $S_{RCS'}$ and kurtosis ($K_{RCS'}$),
300 respectively, obtained at 1064 nm, with and without the corrections described in section 3.2. In general, the
301 corrections do not affect the profiles generated from 1064 nm data in a significant way, so that, the higher
302 influence of corrections is observed in the $K_{RCS'}$ profile, which is underestimated in some regions. In the
303 figures 9-A, 9-B, 9-C and 9-D we show same high order moments calculated from 532 nm data. As the
304 complexity of moments increases, it is possible to observe the larger influence of the corrections, due to
305 propagation of noise. Nonetheless, the application of the corrections, mainly first lag correction, make these
306 profiles very similar to those generated from the wavelength 1064 nm, so that the same phenomena can be
307 observed in both.

308 Therefore, in spite of the larger attenuation expected at 532 nm wavelength, which reduces the SNR of the
309 profiles in comparison with 1064 nm, the application of the proposed corrections, mainly the first lag,
310 reduces significantly such influence and enable the observation of the same phenomena detected in the
311 high-order moments obtained from 1064 nm. Consequently, the wavelength 532 nm will be applied in the
312 analysis presented in section 4.2. The first lag correction was adopted as default because it provides better
313 results than the -2/3 law correction.

314 4.2 Case studies

315 In this section we present two study cases, in order to show how the products indicated in table 2 can
316 provide a detailed description about the turbulence in the *PBL*. The first case represents a typical day with
317 a clear sky situation. The second case corresponds to a more complex situation, where there is presence of
318 clouds and Saharan mineral dust layers.

319 4.2.1 Case study I: clear sky situation

320 In this case study we use measurements gathered with *DL*, *MWR* and pyranometer during 24 hours. The
321 *EL* was operated under operator-supervised mode between 08:20 to 18:00 UTC.

322 Figure 10 (A) shows the integral time scale obtained from *DL* data ($\tau_{w'}$). The gray area represents the region
323 where it is not possible to analyze the turbulent process using our *DL* data, either because of the low *SNR*
324 values, which results in null values of the $\tau_{w'}$, or because the no null $\tau_{w'}$ is smaller than the acquisition time
325 of the *DL*. However, the gray area is located almost entirely above the $PBLH_{MWR}$ (white stars).

326 The $\sigma_{w'}^2$ has low values during the entire period when the *SBL* is present (Figure 10-B). Nevertheless, as air
327 temperature begins to increase (around 07:00 UTC), the $\sigma_{w'}^2$ increases together, as well as, the $PBLH_{MWR}$.
328 The $\sigma_{w'}^2$ reaches its maximum values in the middle of the day, when we also observe the maximum values
329 of air temperature and $PBLH_{MWR}$. The combination of $\sigma_{w'}^2$ and $PBLH_{MWR}$ provides us a better
330 comprehension about the *PBLH* growth speed, so that, in the moments where high values of $\sigma_{w'}^2$ are
331 observed, it means higher values of Turbulent Kinetic Energy (*TKE*), which favor the fast ascension of
332 *PBLH*.

333 The skewness of w' ($S_{w'}$) is shown in Figure 11-C. The $S_{w'}$ describes the distribution of the turbulent
334 velocities. Thus positive $S_{w'}$ implies strong but narrow updrafts surrounded by weaker but more widespread
335 downdrafts, and vice versa for negative $S_{w'}$. Consequently, positive values (red regions) correspond with a
336 surface-heating-driven boundary layer, while negative (blue regions) ones are associated to cloud-top long-
337 wave radiative cooling. During the stable period, there is predominance of low absolute values of $S_{w'}$.
338 Nevertheless, as air temperature increases (transition from stable to unstable period), $S_{w'}$ values begin to
339 become larger. Air temperature begins to decrease around 18:00 UTC, and there is a reduction of $S_{w'}$, so
340 that, the generation rate of convective turbulence decreases. Therefore, the turbulence cannot be maintained
341 against dissipation, then the *CBL* becomes a *SBL* covered by the *RL*. Thus, the reduction observed in the
342 $PBLH_{MWR}$ is due to the detection of *SBL* height.

343 Figure 10-D shows the values of net surface radiation (R_n) that are estimated from solar global irradiance
344 values using the seasonal model described in Alados et al. (2003). The negative values of R_n are
345 concentrated in the stable region. The R_n begins to increase around 06:00 UTC and reaches its maximum
346 in the middle of the day. Comparing figures 8-C and 8-D, we can observe similarity among the behavior of
347 $S_{w'}$ and R_n , so that, the joint analysis of these variables reinforce the characterization of this *PBL* as surface-
348 heating-driven *CBL*.

349 Figure 10-E presents the values of surface air temperature and surface relative humidity (RH). Air surface
350 temperature has a daily pattern similar to that of R_n and S_{wv} . On the other hand, RH is inversely correlated
351 with the temperature.

352 Figure 11 shows the RCS_{532} profile obtained from 08:00 to 18:00 UTC. At the beginning of the
353 measurement period (08:20 to 10:00 UTC) it is possible to observe the presence of a thin residual layer
354 (around 2000 m a.s.l.), and later from 13:00 to 18:00 UTC it is evident a lofted aerosol layer. In this picture
355 there are the $PBLH_{MWR}$ (pink stars), the $PBLH_{Doppler}$ (blue stars), obtained from the maximum of σ_{wv}^2 ,
356 (Moreira et al., 2018a), and the $PBLH_{Elastic}$ (black stars), obtained from the maximum of σ_{RCS}^2 , (Moreira
357 et al., 2015). In the initial part of measurement, all profiles have similar behavior. However due to distinct
358 $PBLH$ definition and tracer applied by each one, the differences increase as CBL becomes more complex,
359 e.g. the presence of lofted aerosol layer at 14 UTC. The joint observation of the results provided by these
360 three methods can provide us information about the sublayers in the PBL , both in convective and stable
361 situations. Due to low variability of $PBLH$, the period between 13:00 and 14:00 UTC has been selected to
362 be analyzed from the high order moments.

363 Figure 12 presents the statistical moments generated from RCS' of wavelength 532 nm, which were obtained
364 from 13:00 and 14:00 UTC. The red line in all graphics represent the $PBLH_{Elastic}$ (2200 m a.s.l.) and the
365 blue one the average value of $PBLH_{MWR}$ (2250 m a.s.l.), both obtained between 13 and 14 UTC.

366 Due to presence of a decoupled aerosol layer at 13:30, the average values of $PBLH_{Elastic}$ and $PBLH_{MWR}$
367 have a difference of around 500 m. The σ_{RCS}^2 has small and practically constant values between 1000 and
368 1400m, evidencing the homogeneity of the aerosol distribution in this region. Starting at 1400 m the value
369 of σ_{RCS}^2 begins to increase, reaching a positive peak at $PBLH_{MWR}$, which represents the Entrainment Zone
370 (region characterized by an intense mixing between air parcels coming from CBL and Free Troposphere
371 (FT), causing a high variation in aerosol concentration). The $PBLH_{Elastic}$ observed at approximately 2900
372 m demonstrate an inherent difficulty of the variance method to detect the $PBLH$ in the presence of several
373 aerosol layers (Kovalev and Eichinger, 2004). Above $PBLH_{Elastic}$ the values of σ_{RCS}^2 decrease slowly due
374 to location of the lofted aerosol around 2500 m. However, above this aerosol layer the value of σ_{RCS}^2 is
375 reduced to zero, indicating a large homogeneity in aerosol distribution at this region, what is expected,
376 because the aerosol concentration at the FT is negligible in this case. The integral time scale obtained from
377 RCS' ($\tau_{RCS'}$) has values higher than EL time acquisition throughout the CBL , evidencing the feasibility for
378 studying turbulence using this elastic lidar configuration. The skewness values obtained from RCS' ($S_{RCS'}$)
379 give us information about aerosol motion. The positive values of $S_{RCS'}$, observed in the lowest part of profile
380 and above the $PBLH_{Elastic}$ represents the updrafts aerosol layers. The negative values of $S_{RCS'}$, indicates the
381 region with low aerosol concentration due to clean air coming from FT . This movement of ascension of
382 aerosol layers and descent of clean air with zero value of $S_{RCS'}$, at $PBLH$ (characteristic of the CBL growing)
383 was also detected by Pal et al. (2010) and McNicholas et al. (2014). The kurtosis of RCS' ($K_{RCS'}$) determines
384 the level of mixing at different heights. There are values of $K_{RCS'}$, larger than 3 in the lowest part of profile
385 and around 2500 m, showing a peaked distribution in this region. On other hand, values of $K_{RCS'}$, lower than
386 3 are observed close to the $PBLH_{Elastic}$, therefore this region has a well-mixed CBL regime. Pal et al. (2010)

387 and McNicholas et al. (2014) also detected this feature in the region nearby the *PBLH*. In figure 13 are
388 shown the high-order moments obtained at the same period described above, however from the 1064 nm
389 data (our reference wavelength). It is possible to observe a similarity between the profiles obtained from
390 each wavelength, so that, the same phenomena observed in the profiles generated from 532 nm and
391 described above, also are detected in the profiles obtained from the reference wavelength.

392 The results provided by *DL*, pyranometer and *MWR* data agree with the results observed in figures 12 and
393 13. In the same way, the analysis of high order moments of *RCS'* fully agree with the information in Figure
394 10. Thus, the large values of $S_{RCS'}$ and $K_{RCS'}$ detected around 2500 m a.s.l., where we can see a lofted aerosol
395 layer, suggest the ascent of an aerosol layer and presence of a peaked distribution, respectively.

396 4.2.2 Case study: dusty and cloudy scenario

397 In this case study measurements with *DL*, *MWR* and pyranometer expand during 24 hours, while *EL* data
398 are collected from 09:00 to 16:00 UTC.

399 Figure 14-A shows τ_{wv} . Outside the period 13:00 to 17:00 UTC, the greatest part of grey area is situated
400 above the $PBLH_{MWR}$ (white stars), thus *DL* time acquisition is enough to perform studies about turbulence
401 in this case.

402 σ_{wv}^2 has values close to zero during all the stable period (Figure 14-B). However, when air temperature
403 begins to increase (around 06:00 UTC), the σ_{wv}^2 also increases and reaches its maximum in the middle of
404 the day. The higher values of *PBL* growth speed are observed in the moments where σ_{wv}^2 reaches its
405 maximum values. In the late afternoon, as air temperature decrease, the values of σ_{wv}^2 (and consequently
406 the *TKE*) decrease gradually, until reach the minimum value associated to the *SBL*. Figure 14-C shows the
407 profiles of S_{wv} . The main features of this case are: the low values of S_{wv} , the slow increase and ascension
408 of positive S_{wv} values and the predominance of negative S_{wv} values from 12:00 to 13:00 UTC. The first two
409 features are likely due to the presence of the intense Saharan dust layer (Figure 15), which reduces the
410 transmission of solar irradiance, and consequently the absorption of solar irradiance at the surface,
411 generating weak convective process. From figure 16 we can observe the presence of both middle altitude
412 clouds and very intense dust layers from 12:00 to 15:00 UTC. Such combination contributes to the intense
413 negative values of S_{wv} observed in this period until around 2 km, because, as mentioned previously, S_{wv} is
414 directly associated with the direction of turbulent movements. The present situation can be considered
415 representative of cloud-top long-wave radiative cooling in the *CBL* (Ansmann et al., 2010).

416 The influence of Saharan dust layer can also be evidenced on the R_n pattern (Figure 14-D), which maintains
417 negative values until 12:00 UTC and reaches a low maximum value (around 200 W/m²). The observation
418 of S_{wv} and R_n between 12:00 and 14:00, as well as, the presence of clouds and geometrically thick dust
419 layers during this same period, reinforces the hypothesis that we have a situation of the cloud-top long-
420 wave radiative cooling in the *CBL*. Air surface temperature and *RH* (Figure 14-E) present the same
421 correlation and anti-correlation (respectively) observed in the earlier case study, where the maximum of air

422 surface temperature and the minimum of RH are detected in coincidence with the maximum daily value of
423 $PBLH_{MWR}$.

424 As mentioned before, Figure 15 shows the RCS profile obtained from 09:00 to 16:00 UTC in a complex
425 situation, with presence of decoupled dust layer (around 3800 m a.s.l.) from 09:00 to 12:00 UTC and **the**
426 **presence of both middle altitude clouds and very intense dust layers** (around 3500 m a.s.l.) from 11:30 to
427 16:00 UTC. The pink, black and blue stars represent the $PBLH_{MWR}$, $PBLH_{Doppler}$ and $PBLH_{Elastic}$
428 respectively. Due to the presence of dusty layers and clouds, the difference between the methods is more
429 evident, mainly of the $PBLH_{Elastic}$, which uses the aerosol as tracers. This method only produces results
430 close to the others at 15 UTC, when dust layer is mixed with the CBL .

431 Figure 16 illustrates the statistical moments of RCS' of 532 nm wavelength obtained from 11:00 to 12:00
432 UTC. The $\sigma_{RCS'}^2$ profile presents several peaks due to the presence of distinct aerosol sublayers. The first
433 peak is coincident with the value of $PBLH_{MWR}$. The value of $PBLH_{elastic}$, is coincident with the base of
434 the dust layer. This difficulty to detect the $PBLH$ in presence of several aerosol layers is inherent to the
435 variance method (Kovalev and Eichinger, 2004). However, the joint observation of $PBLH_{MWR}$ and
436 $PBLH_{elastic}$, enable us to characterize and distinguish the several sublayers. The values of $\tau_{RCS'}$ are higher
437 than EL acquisition time all along the PBL , evidencing the feasibility of EL time acquisition for studying
438 the turbulence of PBL in this case. The $S_{RCS'}$ profile has several positive values, due to the large number of
439 aerosol sublayers that are present. The characteristic inflection point of $S_{RCS'}$ is observed in coincidence
440 with the $PBLH_{MWR}$, that confirming the agreement between this point and the $PBLH$. From the analysis of
441 $S_{RCS'}$ and S_w is possible to justify this phenomena from the mixing process demonstrated in the earlier case
442 study. The $K_{RCS'}$ has predominantly values lower than 3 below 2500 m, thus shown how this region is well
443 mixed as can see in Figure 16. Values of $K_{RCS'}$ larger than 3 are observed in the highest part of profile, where
444 the dust layer is located.

445 In order to show the feasibility of 532 nm wavelength, in the figure 17 are presented the high-order moments
446 obtained between 11-12 UTC from 1064 nm wavelength data. Although the error of $\sigma_{RCS'}^2$ obtained from
447 532 nm (pink shadow) is considerably higher than the error of same variable obtained from 1064 nm, all
448 profiles are very similar, so that, the same phenomena can be observed in both graphics (figure 16 and 17).

449 Figure 18 shows the RCS' 532 nm wavelength high-order moments obtained from 12:00 and 13:00 in
450 presence of cloud cover. The method based on maximum of $\sigma_{RCS'}^2$ locates the $PBLH_{Elastic}$ at the cloud base,
451 due to the high variance of RCS' generated by the clouds. $\tau_{RCS'}$ presents values larger than EL time
452 acquisition, therefore this configuration enable us to study turbulence by EL analyses. $S_{RCS'}$ has few peaks,
453 due to the mixing between CBL and dust layer, generating a more homogenous layer. The highest values
454 of $S_{RCS'}$ are observed in regions where there are clouds, and the negative ones (between 3500 and 4000 m)
455 occur due to presence of air from FT between the two aerosol layers (Figure 15). The inflection point of
456 $S_{RCS'}$ profile is observed in $PBLH_{MWR}$ region. $K_{RCS'}$ profile has low values in most of the PBL , demonstrating
457 the high level of mixing during this period, where dust layer and PBL are combined. The higher values of
458 $K_{RCS'}$ are observed in the region of clouds. In the same way of the previous analysis, the high-order moments
459 of the period mentioned above were calculated for the wavelength of 1064 nm (figure 19). Although there

460 are some differences in the absolute values of some profiles, the high-order moments generated using 1064
461 and 532 nm have similar profiles, so that, the same phenomena can be observed, demonstrating the viability
462 of 532 nm wavelength in the proposed methodology.

463 **5 Conclusions**

464 In this paper we perform an analysis about the *PBL* turbulent features from three different types of remote
465 sensing systems (*DL*, *EL* and *MWR*) and surface sensors during SLOPE-I campaign. We applied two kind
466 of corrections to the lidar data: first lag and $-2/3$ corrections. The corrected *DL* statistical moments showed
467 little variation with respect to the uncorrected profiles, denoting a rather **low influence of the noise in high**
468 **SNR conditions**. The *EL* high-order moments were obtained from two wavelengths: 1064 nm, adopted as
469 reference, and 532 nm, in order to verify the viability to use the last one in turbulence analysis. From this
470 comparison, was possible to observe that the wavelength 532 nm is more affected by noise, in comparison
471 with 1064 nm, due to the large contribution of the molecular component and the **reduced two-way**
472 transmittance at that wavelength. However, the application of proposed corrections, mainly the first lag,
473 can reduce such influence, so that, the same phenomena can be observed in the high-order moments
474 provided from both wavelengths

475 The case studies present two kind of situations: well-defined *PBL* and a more complex situation with the
476 presence of Saharan dust layer and some clouds. In both cases was possible to identify the events describe
477 in table 2. The-combined use of remote sensing systems shows how the results provided by the different
478 instruments can complement one each other, providing a detailed observation of some phenomena, mainly
479 in complex situations.

480 Therefore, this study shows the feasibility of the described methodology based on the combination of
481 remote sensing systems for retrieving a detailed picture on the *PBL* turbulent features. In addition, the
482 feasibility of using the analyses of high order moments of the *RCS* collected at 532 nm at a temporal
483 resolution of 2 s offers the possibility for using the proposed methodology in networks such as EARLINET
484 or LALINET with a reasonable additional effort.

Table 1 – Variables applied to statistical analysis (Lenschow et al., 2000)

	Without Correction	Correction	Error
Integral Time Scale (τ)	$\int_0^{\infty} q'(t) dt$	$\frac{1}{\overline{q'^2}} \int_{t \rightarrow 0}^{\infty} M_{11}(t) dt$	$\tau \cdot \sqrt{\frac{4\Delta M_{11}}{M_{11}(\rightarrow 0)}}$
Variance (σ_q^2)	$\frac{1}{T} \sum_{t=1}^T (q(t) - \bar{q})^2$	$M_{11}(\rightarrow 0)$	$q^2 \cdot \sqrt{\frac{4\Delta M_{11}}{M_{11}(\rightarrow 0)}}$
Skewness (S)	$\frac{\overline{q^3}}{\sigma_q^3}$	$\frac{M_{21}(\rightarrow 0)}{M_{11}^{3/2}(\rightarrow 0)}$	$\frac{\Delta M_{21}}{\Delta M_{11}^{3/2}}$
Kurtosis (K)	$\frac{\overline{q^4}}{\sigma_q^4}$	$\frac{3M_{22}(\rightarrow 0) - 2M_{31}(\rightarrow 0) - 3\Delta M_{11}^2}{M_{11}^2(\rightarrow 0)}$	$\frac{4\Delta M_{31} - 3\Delta M_{22} - \Delta M_{11}^2}{\Delta M_{11}^2}$

Table 2 – Products and their respective meaning, provided by each system

Product	System	Meaning
$\tau_{w'}(z)$	Doppler lidar	Measurement in time of length of turbulent eddies
$\sigma_{w'}^2(z)$	Doppler lidar	Turbulent Kinetic Energy
$S_{w'}(z)$	Doppler lidar	Direction of turbulent movements
$PBLH_{Doppler}$	Doppler lidar	Top of CBL obtained from variance threshold method
$\tau_{RCS'}(z)$	Elastic lidar	Measurement in time of length of turbulent eddies
$\sigma_{RCS'}^2(z)$	Elastic lidar	Homogeneity of aerosol distribution
$S_{RCS'}(z)$	Elastic lidar	Aerosol motion ($S < 0 \rightarrow$ Downdrafts, $S > 0 \rightarrow$ Updrafts)
$K_{RCS'}(z)$	Elastic lidar	Level of aerosol mixing ($K < 3 \rightarrow$ Well-Mixed, $K > 3 \rightarrow$ Low Mixing)
$PBLH_{Elastic}$	Elastic lidar	Top of aerosol layer obtained from variance method
$PBLH_{MWR}$	MWR	Top of CBL/SBL layer obtained from Potential Temperature
