32 **Abstract**

33       Secondary organic aerosols (SOA) contribute substantially to PM<sub>2.5</sub> during  
34 severe wintertime haze events in northern China, yet ambient volatile organic  
35 compounds (VOCs) as SOA precursors are not well characterized in winter, especially  
36 in rural areas. In this study, ambient air samples were collected in 2014 from 25  
37 October to 31 December at a rural site on the campus of the University of Chinese  
38 Academy of Sciences (UCAS) in northeastern Beijing for the analysis of VOCs. Since  
39 temporary intervention measures were implemented on 3-12 November to improve  
40 the air quality for the Asian-Pacific Economic Cooperation (APEC) summit held on  
41 5-11 November in Beijing, and wintertime central heating started on 15 November in  
42 Beijing after the APEC summit, this sample collection period provided a good  
43 opportunity to study the influence of temporary control measures and wintertime  
44 heating on ambient VOCs. As a result of the temporary intervention measures  
45 implemented during 3-12 November (period II), the total mixing ratios of  
46 non-methane hydrocarbons averaged 11.25 ppb, approximately 50% lower than that  
47 the values of 23.41 ppb in period I (25 October-2 November) and 21.71 ppb in period  
48 III (13 November-31 December). The ozone and SOA formation potentials decreased  
49 by ~50% and ~70%, respectively, with the larger decrease in SOA formation  
50 potentials attributed to more effective control over aromatic hydrocarbons mainly  
51 from solvent use. Back trajectory analysis revealed that the average mixing ratios of  
52 VOCs in southerly air masses were 2.3, 2.3 and 2.9 times those in northerly air masses  
53 during periods I, II and III, respectively; all VOC episodes occurred under the  
54 influence of southerly winds, suggesting much stronger emissions in the southern

55 urbanized regions than in the northern rural areas. Based on a positive matrix  
56 factorization (PMF) receptor model, the altered contributions from traffic emissions  
57 and solvent use could explain 47.9% and 37.6% of the reduction in ambient VOCs,  
58 respectively, during Period II relative to the Period I, indicating that the temporary  
59 control measures on vehicle emissions and solvent use were effective at lowering the  
60 ambient levels of VOCs. Coal/biomass burning, gasoline exhaust, and industrial  
61 emissions were among the vital sources, and altogether contributed 60.3%, 78.6% and  
62 78.7% of the VOCs during the periods I, II and III, respectively. Coal/biomass  
63 burning, mostly residential coal burning, became the dominant source, accounting for  
64 45.1% of the VOCs during the wintertime heating period, with a specifically lower  
65 average contribution percentage in southerly air masses (38.2%) than in northerly air  
66 masses (48.8%). The results suggests that emission control in the industry and traffic  
67 sectors is more effective in lowering ambient reactive VOCs in non-heating time;  
68 however, reducing emissions from residential burning of solid fuels for heating would  
69 be of greater importance and would have health co-benefits from lowing both indoor  
70 and outdoor air pollution.

71

72 **1. Introduction**

73 Volatile organic compounds (VOCs) are precursors of tropospheric ozone and  
74 secondary organic aerosols (SOA) (Forstner et al., 1997; Odum et al., 1997; Atkinson,  
75 2000; O'Dowd et al., 2002; Sato et al., 2010). As ozone formation in urban areas is  
76 largely VOC-limited (Shao et al., 2009; Tang et al., 2010) and SOA are important  
77 components of fine particles or PM<sub>2.5</sub> (particulate matter with an aerodynamic  
78 diameter less than 2.5 μm) (Cabada et al., 2004; Lonati et al., 2005; Huang et al.,  
79 2014), reducing emissions of VOCs would be very important for improving the air  
80 quality in megacities, such as China's capital city Beijing, where air pollution has  
81 become an widespread concern, with increasing surface ozone levels during summer  
82 and severe PM<sub>2.5</sub> pollution during winter (Streets et al., 2007; Ji et al., 2012; Wang et  
83 al., 2014).

84 While exposure to indoor air pollution from burning solid fuels affects nearly  
85 half of the world's population and household air pollution has long been a major  
86 environmental cause of death (Martin et al., 2011; Lim et al., 2012; Subramanian,  
87 2014), emissions from residential energy use such as heating and cooking, prevalent  
88 in India and China, also have the largest impact on global premature mortality from  
89 outdoor air pollution (Lelieveld et al., 2015). In fact, Juda-Rezler et al. (2011) showed  
90 that coal combustion in residential boiler during winter was a major source of PM<sub>10</sub> in  
91 four cities of central eastern European. A recent study revealed that even in Beijing  
92 and its surrounding regions, residential use of solid fuels might be a major and  
93 underappreciated ambient pollution source for PM<sub>2.5</sub> (particularly BC and OC) during

94 winter heating period (Liu et al., 2016). Since substantial amounts of VOCs are  
95 released from poor-technology burning of coal and biomass/biofuels (Yokelson et al.,  
96 2008; Shrivastava et al., 2015; Fang et al., 2017; Liu et al., 2017; Cheng et al., 2018),  
97 it is of wide concern how residential use of solid fuels, particularly for wintertime  
98 household heating, would influence ambient levels and compositions of VOCs. In  
99 residential areas of Izmir, Turkey, for example, household burning of coal on  
100 uncontrolled burners for domestic heating during winter was found to be a larger  
101 source of VOCs than the local traffic (Sari and Bayram, 2014).

102       Due to a wide variety of emission sources of VOCs and large uncertainties of the  
103 emission inventories of VOCs, to formulate emission control measures on reducing  
104 ambient VOCs is a highly challengeable task. More field measurements are therefore  
105 needed to characterize VOCs in ambient air and in emission sources for better source  
106 attribution. In Beijing, for example, since higher levels of ozone mostly occur during  
107 hot seasons, many field measurements of VOCs were conducted in summer with a  
108 focus on their sources (Song et al., 2007; Lu et al., 2007; Yuan et al., 2009; Wang et  
109 al., 2010a) and their mixing ratios (Liu et al., 2009; An et al., 2012; Zhang et al.,  
110 2012a; Liu et al., 2013), particularly during ozone episodes. On the other hand, during  
111 extremely severe and persistent haze events in Beijing, organic matter (OM) could  
112 contribute 30-70% of the total PM<sub>2.5</sub> with higher fractions of SOA in OM (Guo et al.,  
113 2014; Huang et al., 2014; Zhang et al., 2014a). However, the effect of VOCs on  
114 wintertime PM<sub>2.5</sub> pollution is much less understood, although the control of VOCs, as  
115 SOA precursors, is also of great importance in the control of PM<sub>2.5</sub> air pollution. A

116 previous study already demonstrated that levels of aromatic hydrocarbons and  
117 carbonyls increased significantly on haze days in urban Beijing from 2008 to 2010  
118 (Zhang et al., 2014b), yet few reports are available about wintertime precursor VOCs,  
119 especially about the potential contribution by burning solid fuels for household  
120 heating.

121       Apart from health benefits from lowering indoor air pollution, controlling  
122 emissions in the residential sector would be of greater importance to further improve  
123 outdoor air quality worldwide in the future (Liu et al., 2016), although previously  
124 efforts have been overwhelmingly targeted on reducing emissions from industrial and  
125 traffic sectors in many regions. In northern China, for example, air quality has been  
126 greatly improved in recent years due to the implementation of long-term pollution  
127 control actions (Hao and Wang, 2005; Wang et al., 2009; Zhang et al., 2012b; Liu et  
128 al., 2015a; Kelly and Zhu, 2016). However, the air quality there is not satisfactory  
129 compared to that in cities in the United States and Europe, especially in winter, with  
130 frequent haze events and high PM<sub>2.5</sub> levels. Consequently, during critical international  
131 events such as the 2008 Olympic Games (Wang et al., 2010b; Huang et al., 2010) and  
132 the 2014 Asia-Pacific Economic Cooperation (APEC) summit, temporary intervention  
133 measures were adopted to guarantee better air quality. This type of temporary  
134 intervention provided a good opportunity to assess the relative importance of  
135 different sources and to study the effectiveness of various control measures on the  
136 reduction of ambient air pollutants including VOCs (Yao et al., 2013; Huang et al.,  
137 2017). For the 21<sup>th</sup> Asia-Pacific Economic Cooperation (APEC) summit held in

138 Beijing on 5-11 November 2014, temporary control measures in Beijing and its  
139 surrounding regions resulted in significant decreased in air pollutants, including PM<sub>2.5</sub>  
140 and NO<sub>x</sub> (Huang et al., 2015; Liu et al., 2015b; Wang et al., 2015; Xu et al., 2015;  
141 Zhang et al., 2016a). For the VOCs in ambient air, as observed by Li et al. (2015) at  
142 an urban site on the campus of Peking University, the total mixing ratios of VOCs  
143 were reduced by 44% during the APEC summit control period compared to those in  
144 the period before. As the 2008 Olympic Games or the 2014 APEC were all held in the  
145 non-heating periods, it is not certain in what extent the temporary intervention  
146 measures mostly targeted on industrial and traffic emissions would take effect in the  
147 winter heating period.

148 While vehicle exhaust is an important source of VOCs in urban areas (McDonald  
149 et al., 2015; Liu et al., 2015c; Ortega et al., 2016; Deng et al., 2017; Gentner et al.,  
150 2017), coal burning and biomass/biofuel burning may also contribute substantially to  
151 VOCs particularly in winter when raw coal and biofuels are widely used for  
152 household heating in regions like the northern China (Liu et al., 2016; Zhang et al.,  
153 2016b; Liu et al., 2017). In fact, a study by Wang et al. (2013) in 2011-2012 revealed  
154 that even at an urban site in Beijing, coal combustion could account for 28-39% of the  
155 VOCs observed in ambient air. As raw coal and/or biofuel burning widely occur in  
156 rural areas in winter (Liu et al., 2016), it is necessary to investigate extensively on  
157 how enhanced emissions due to wintertime household heating would influence  
158 ambient VOCs particularly in rural areas, as forming SOA or ozone is an issue of  
159 regional scale.

160 In this study, ambient air samples were collected at a rural site in the north of  
161 Beijing from 25 October to 31 December 2014, covering the period with enhanced  
162 temporary emission control (3-12 November) for the APEC summit and the  
163 wintertime heating period starting from 15 November. The objectives of the present  
164 study are as follow: (1) to study changes in the mixing ratios and composition of  
165 VOCs at a rural site in Beijing in response to the emission control during the APEC  
166 summit and wintertime heating; (2) to identify the crucial sources of VOCs in Beijing  
167 and their changes during the PM-polluted winter; (3) to evaluate the impact of control  
168 measures implemented during the APEC summit on the reduction of VOCs in ambient  
169 air in rural areas; and (4) to assess the contribution of residential use of solid fuels for  
170 household heating to the ambient VOCs during winter.

## 171 **2. Methodology**

### 172 *2.1 Sampling Site and Field Sampling*

173 The ambient air samples were collected at a site (40.41° N, 116.68° E; Fig. 1) on  
174 the campus of the University of Chinese Academy of Science (UCAS) in the Huairou  
175 district of Beijing. UCAS is located approximately 60 km northeast of the central of  
176 Beijing and approximately 150 km northwest of the city of Tianjin. It is surrounded  
177 by several small villages and farmlands. The samples were collected 16 meters above  
178 the ground on the top of a four-story building, approximately 100 m west of a national  
179 road and only 1.5 km away from the main APEC conference hall.

180 Ambient air samples were collected from 25 October-31 December 2014 using  
181 cleaned and evacuated 2 L silica-lined stainless steel canisters. During field sampling,

182 a model 910 canister sampler (Xonteck Inc., California, USA) with a constant flow  
183 rate of  $66.7 \text{ ml min}^{-1}$  was adopted to allow each canister to be filled in 60 min.  
184 Samples were collected at approximately 10:00 and 15:00 local time (LT) on sunny  
185 days, and one or two more samples were collected at 12:00 and/or 18:00 LT on haze  
186 days when the visibility was less than 10 km at a relative humidity of less than 90%  
187 (Fu et al., 2016). A total of 153 samples were collected during sampling. According to  
188 the air pollution control measures, the field campaign was divided into periods I (25  
189 October-2 November), II (3-12 November) and III (13 November-31 December).  
190 Period II was when temporary control measures (Table 1;  
191 [http://www.zhb.gov.cn/gkml/hbb/qt/201411/t20141115\\_291482.htm](http://www.zhb.gov.cn/gkml/hbb/qt/201411/t20141115_291482.htm)) implemented for  
192 better air quality. Wintertime heating started on 15 November just after the cease of  
193 temporary control measures on 13 November. During the sampling periods, the  
194 prevailing winds were mostly from north to northwest ( $315\text{-}360^\circ$ ); the average wind  
195 speeds were 3.5, 3.9, and  $4.1 \text{ m s}^{-1}$ ; and the average temperature was 11.4, 7.0, and  
196  $0.6^\circ\text{C}$  during periods I, II and III, respectively.

## 197 *2.2 Laboratory Analysis of VOCs and Carbon Monoxide*

198 All ambient air samples were analyzed with a Model 7100 pre-concentrator  
199 (Entech Instruments Inc., California, USA) coupled with an Agilent 5973N gas  
200 chromatography-mass selective detector/flame ionization detector (GC-MSD/FID,  
201 Agilent Technologies, USA). Detailed cryogenically concentration steps are described  
202 elsewhere (Zhang et al., 2012c). Briefly, 500 ml ambient air samples in the canister  
203 were first pumped into the primarily trap with glass beads and then concentrated with

204 liquid-nitrogen cryogenic trap at  $-180^{\circ}\text{C}$ . Following the primary trap was heated to  
205  $10^{\circ}\text{C}$ , and all target compounds were transferred by pure helium to a secondary trap at  
206  $-50^{\circ}\text{C}$  with Tenax-TA as adsorbents. Majority of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  were removed through  
207 these two traps. The secondary trap then was heated to get VOCs transferred by  
208 helium to a third cryo-focus trap at  $-170^{\circ}\text{C}$ . After the focusing step, the third trap was  
209 rapidly heated and the VOCs were transferred to the GC-MSD/FID system. The  
210 mixture were first separated by a DB-1 capillary column ( $60\text{ m}\times 0.32\text{ mm}\times 1.0\text{ }\mu\text{m}$ ,  
211 Agilent Technologies, USA) with helium as carrier gas, and then split into two ways,  
212 one is a PLOT-Q column ( $30\text{ m}\times 0.32\text{ mm}\times 20.0\text{ }\mu\text{m}$ , Agilent Technologies, USA)  
213 followed by FID detector, another is to a  $0.35\text{ m}\times 0.10\text{ mm}$  I.D. stainless steel line  
214 followed by MSD detection. The GC oven temperature was programmed to be  
215 initially at  $10^{\circ}\text{C}$ , holding for 3 min; next increased to  $120^{\circ}\text{C}$  at  $5^{\circ}\text{C min}^{-1}$ , and then  
216  $10^{\circ}\text{C min}^{-1}$  to  $250^{\circ}\text{C}$  with a final holding time of 7 min. The MSD was selected ion  
217 monitoring (SIM) mode and the ionization method was electron impacting. Carbon  
218 monoxide (CO) in the ambient air samples were also analyzed with an Agilent model  
219 6890 gas chromatography equipped with a FID and a packed column ( $5\text{ \AA}$  Molecular  
220 Sieve 60/80 mesh,  $3\text{ m}\times 1/8\text{ inch}$ ). CO was first separated by packed column, then  
221 converted to  $\text{CH}_4$  by Ni-based catalyst and finally detected by FID (Zhang et al.,  
222 2016b).

### 223 *2.3 Quality Control and Quality Assurance*

224 Before sampling, all canisters were flushed at least five times by repeatedly  
225 filling and evacuating humidified zero air. In order to check if there was any

226 contamination in the canisters, all canisters were evacuated after the cleaning  
227 procedures, re-filled with pure nitrogen, stored in the laboratory for at least 24 h, and  
228 then analyzed the same way as field samples to make sure that all the target VOC  
229 compounds were not present.

230 Target compounds were identified based on their retention times and mass  
231 spectra, and quantified by external calibration methods. The calibration standards  
232 were prepared by dynamically diluting the Photochemical Assessment Monitoring  
233 Stations (PAMS) standard mixture and TO-14 standard mixture (100 ppbv, Spectra  
234 Gases Inc., New Jersey, USA) to 0.5, 1, 5, 15 and 30 ppb. The calibration curves were  
235 obtained by running the five diluted standards plus humidified zero air the same way  
236 as the field samples. The humidified zero air was initially analyzed every day to  
237 ensure the cleanness of system and then the analytical system was challenged daily  
238 with a one-point (typically 1 ppb) calibration before running air samples. If the  
239 response was beyond +/-10% of the initial calibration curve, recalibration was  
240 performed. The method detection limits (MDL) for each VOCs species were  
241 presented in Table 2.

#### 242 *2.4 Positive Matrix Factorization (PMF)*

243 PMF is a multivariate factor analysis tool that decomposes a matrix of sample  
244 data into two matrices: factor contributions (G) and factor profiles (F). The method is  
245 reviewed briefly here and described in greater detail elsewhere (Paatero and Tapper,  
246 1994; Paatero, 1997). PMF uses both concentration and user-provided uncertainty  
247 associated with the data to weight individual points. Data values below the MDL were

248 substituted with MDL/2; missing data values were substituted with median  
249 concentrations. If the concentration is less than or equal to the MDL provided, the  
250 uncertainty is calculated using the equation of  $Unc = 5/6 \times MDL$ ; if the concentration  
251 is greater than the MDL provided, the uncertainty is calculated as  $Unc = [(\text{Error}$   
252  $\text{fraction} \times \text{mixing ratio})^2 + (\text{MDL})^2]^{1/2}$ . The number of factors in PMF was initially  
253 chosen based on the result of PCA/APCS model (Zhang et al., 2012c).

### 254 **3. Results and discussion**

#### 255 *3.1 Changing mixing ratios and compositions*

256 As mentioned above, during period II (3-12 November), temporary emission  
257 control measures were implemented to improve air quality during the 2014 APEC  
258 summit. The total mixing ratio of VOCs observed at the rural site at UCAS during the  
259 period II was  $11.25 \pm 3.22$  ppb on average, significantly lower than the value of  
260  $23.41 \pm 5.76$  ppb during period I and  $21.71 \pm 2.97$  ppb during period III (Fig. 2). These  
261 levels were less than half the values (57.45, 36.17, and 56.56 ppb) observed by Li et al.  
262 (2015) at an urban site in Beijing before, during and after the APEC summit,  
263 respectively. However, our measurements at a rural site in this study and the  
264 measurements at an urban site by Li et al. (2015) consistently demonstrated that the  
265 temporary emission control resulted in a large decrease in ambient VOCs during the  
266 APEC summit, with a more than 30% reduction in urban areas (Li et al., 2015) and an  
267 approximately 50% reduction in rural areas, as observed in this study. This reduced  
268 ambient mixing ratios of VOCs during the period II was also in line with the  
269 decreased  $PM_{2.5}$  concentrations observed in Beijing during the APEC summit (Liu et

270 al., 2015b), and the reduced NO<sub>2</sub> vertical column density (VCD) and aerosol optical  
271 depth (AOD) in Beijing during the APEC summit based on remote sensing (Huang et  
272 al., 2015).

273 The percentages of alkanes, alkenes, and ethyne in total VOCs were similar:  
274 alkanes accounted for 54, 57 and 54% of VOCs; alkenes accounted for 12, 16 and  
275 17%; and ethyne accounted for 13, 14 and 14% of VOCs during periods I, II and III,  
276 respectively. Instead, the percentages of aromatics was lower during period II (12%)  
277 than during period I (21%) and period III (15%).

278 The mean mixing ratios of alkanes, alkenes, aromatics and ethyne during period  
279 II were 6.47, 1.83, 1.33, and 1.62 ppb (Fig. 2), and they were 49.0, 32.5, 72.8, and  
280 48.1% lower than those during period I, respectively. Aromatics evidently underwent  
281 a more substantial decrease. Benzene, toluene, ethylbenzene, and m,p-xylene, which  
282 are the most abundant aromatics and usually collectively termed BTEX, were 52.8,  
283 73.1, 78.8, and 80.5% lower during period II than during period I, respectively.

284 Table S1 shows a comparison of VOCs from our study with those observed at  
285 other metropolitan areas in the world. Mixing ratios of VOCs from this study at a  
286 rural site in Beijing during period I (23.41 ppb) and period III (21.71 ppbv) were  
287 comparable to that in urban Shanghai from January 2007 to March 2010 (Cai et al.,  
288 2010), but lower than those in Beijing during June 2008 (Wang et al., 2010a),  
289 Guangzhou from June 2011 to May 2012 (Zou et al., 2015), Lille, French from May  
290 1997 to April 1999 (Borbon et al., 2002) and Houston in August-September 2006  
291 (Leuchner and Rappengluck, 2010). Average mixing ratios of VOCs during period II

292 (11.25 ppbv) with enhanced emission control in the present study were significantly  
293 lower than those reported in other metropolitan areas. As for the most abundant VOC  
294 species including ethane, propane, ethylene, benzene, toluene and ethyne, the mixing  
295 ratios of ethane and ethylene at UCAS were similar to that at Beijing during June  
296 2008 (Wang et al., 2010a) and urban Guangzhou from June 2011 to May 2012 (Zou et  
297 al., 2015), but significantly lower than that in urban Beijing during 2014 APEC (Li et  
298 al., 2015). Propane in present study are comparable to that in Hong Kong from  
299 September 2002 to August 2003 (Guo et al., 2007) and Lille, French from May 1997  
300 to April 1999 (Borbon et al., 2002), but factors of 2-3 lower than that reported in  
301 urban Shanghai from January 2007 to March 2010 (Cai et al., 2010) and Guangzhou  
302 from June 2011 to May 2012 (Zou et al., 2015). Mixing ratios of benzene and toluene  
303 in Lille, French from May 1997 to April 1999 (Borbon et al., 2002) were over 2 times  
304 higher than that in present study. Mixing ratios of ethylene, benzene and toluene in  
305 present study were comparable to those observed in Houston during  
306 August-September 2006 (Leuchner and Rappengluck, 2010), meanwhile ethyne, a  
307 tracer of incomplete combustion, had mixing ratios 3-4 times higher than that in  
308 Houston.

309 The total ozone formation potential (OFP), based on the simplified approach of  
310 MIR (maximum incremental reactivity) scale (Carter, 2009), on average was 60.64,  
311 28.51, and 61.47 ppb (Table S2) during periods I, II and III, respectively, with a 53.0%  
312 reduction during period II relative to the period I (Fig. 2). The secondary organic  
313 aerosol formation potential (SOAFP) under high-NO<sub>x</sub> and low-NO<sub>x</sub> conditions (Ng et

314 al., 2007; Lim and Ziemann, 2009) were also calculated (Table S3). As shown in Fig.  
315 2, the total SOAFP under low-NO<sub>x</sub> conditions decreased by 71.0% from 8.77  $\mu\text{g m}^{-3}$   
316 during the period I to 2.54  $\mu\text{g m}^{-3}$  during period II, and the total SOAFP under  
317 high-NO<sub>x</sub> conditions decreased by 64.4% from 4.02  $\mu\text{g m}^{-3}$  during period I to 1.43  $\mu\text{g}$   
318  $\text{m}^{-3}$  during period II. This significant decrease in OFP and SOAFP during period II is  
319 related to lowered VOC mixing ratios, especially larger decreases in reactive alkenes  
320 and aromatics: alkenes and aromatics explain 26% and 52% of the reduction in total  
321 OFP, respectively, while the decrease in total SOAFP is mostly due to the altered  
322 contribution of aromatics (Table S3), whose SOAFP decreased from 7.30  $\mu\text{g m}^{-3}$   
323 during period I to 1.93  $\mu\text{g m}^{-3}$  during period II under low-NO<sub>x</sub> conditions and from  
324 2.39  $\mu\text{g m}^{-3}$  during period I to 0.75  $\mu\text{g m}^{-3}$  during period II under high-NO<sub>x</sub> conditions.  
325 The results suggest that enhancing the emission control of reactive alkenes and  
326 aromatics would be more effective for reducing OFPs and SOAFPs of ambient VOCs.

### 327 *3.2 Pollution episodes and influence of source regions*

328 As shown in Fig. 3d and 3e, a number of episodes with mixing ratios of VOCs  
329 over 30 ppb were recorded along with an increase in the CO and SO<sub>2</sub> concentrations  
330 (Fig. 3d) during the campaign, such as those on 4-5 November, 15-16 November,  
331 18-21 November, 28-30 November, 17 December, and 26-28 December. During the  
332 episode on 3-5 November, for example, the total mixing ratio of VOCs was 14.30 ppb  
333 on 3 November, reached 31.96 ppb on 4 November, and then decreased again to 13.83  
334 ppb on 5 November. As shown in Fig. 3a, the wind speeds were all below 2  $\text{m s}^{-1}$   
335 during 3-5 November, and the planetary boundary layer (PBL) height on 4 November

336 (477 m) was approximately 83% of that on 3 November (578 m) (Fig. 3c). This lower  
337 PBL height on 4 November could only partly explain the higher levels of VOCs.  
338 Figure S2a shows the 72-h back trajectories (HYSPLIT, ver. 4.0; <http://www.arl.noaa.gov/ready/hysplit4.html>) of air masses from 3-5 November at a height of 100 m in  
339 12-h intervals and the corresponding mixing ratios of VOCs. It demonstrated that the  
340 mixing ratios of VOCs increased rapidly while air masses changed from northerly to  
341 southerly, and then declined sharply while the air masses turned back from southerly  
342 to the northerly. The southern areas of UCAS are in central Beijing where emissions  
343 are stronger; consequently, air masses that passed through these areas would carry  
344 higher levels of pollutants to the sampling site, leading to the quick increase in the  
345 mixing ratios of VOCs. This rapid change in the source region could reasonably  
346 explain more than the PBL height during the pollution episode of VOCs. As shown in  
347 Fig. S2b, 2c, and 2d, back trajectories also suggested that the episodes on 18-21  
348 November, 28-30 November and 26-28 December are related to the altered source  
349 regions.

351 According to the 72-h back trajectories, air masses arriving at the sampling site  
352 could be categorized into two types (Fig. 4): 1) southerly (S) air masses, which passed  
353 through Hebei, Shandong, Tianjin, and central Beijing with high-density emissions  
354 before reaching UCAS, and 2) northerly (N) air masses, which originated from  
355 Mongolia and quickly passed through areas with less anthropogenic activity and  
356 low-density emissions before reaching UCAS. The pollution episodes with higher  
357 mixing ratios of VOCs and CO, including the cases on 26-30 October, 4-5 November,

358 15-16 November, 18-20 November, 25-26 November and 26-28 December (Fig. 3d  
359 and 3e), all occurred under the influence of southerly air masses, also suggesting the  
360 impacts of emissions in the south.

361 During periods I, II and III, the average mixing ratios of VOCs for southerly air  
362 masses were 2.3, 2.3 and 2.9 times those for northerly air masses (Fig. 4), respectively;  
363 the OFPs in southerly air masses was 2.0, 2.0 and 3.3 times that in northerly air  
364 masses, respectively; and the SOAFPs in air masses from the south was 1.7, 3.3, and  
365 3.7 times that in air masses from the north under low-NO<sub>x</sub> conditions and 1.9, 2.7,  
366 and 3.5 times that in air masses from the north under high-NO<sub>x</sub> conditions,  
367 respectively. These results indicate that the northern and southern regions are  
368 completely different in their source strengths. Stricter control measures in the  
369 southern region would be an effective way for abating VOCs pollution in Beijing.

370 As mentioned above, the mixing ratios of VOCs, as well as their OFP and  
371 SOAPF, decreased greatly during period II. The changes in the southerly and  
372 northerly air masses indicate the changes in different source regions. In the southerly  
373 air masses, compared to that during period I, the average mixing ratios of alkanes,  
374 alkenes, aromatics, and ethyne during period II were 8.32, 2.16, 1.93, and 2.23 ppb,  
375 with reduction rates of 46.0, 33.3, 64.3, and 44.7%, respectively; accordingly, the OFP  
376 decreased by 48.1% and the SOAFP decreased by 63.5 % (low-NO<sub>x</sub> conditions) and  
377 57.6% (high-NO<sub>x</sub> conditions) during period II compared to those during period I (Fig.  
378 4). In the northerly air masses, the average mixing ratios of alkanes, alkenes,  
379 aromatics, and ethyne decreased 37.7, 4.8, 87.0, and 18.4% during period II compared

380 to that during period I, respectively; the OFP decreased by 48.9% and SOAFP  
381 decreased by over 70% during period II relative to those in period I (Fig. 4). As  
382 discussed below, a more drastic decrease in aromatics in both the northerly and  
383 southerly air masses implied more effective control over emissions from industrial  
384 solvent use during the APEC summit, and the much less changes in the mixing ratios  
385 of alkenes in the northerly air masses were related to the less effective control over  
386 domestic coal/biomass burning in the northern regions. The mixing ratios of VOCs in  
387 the southerly and northerly air masses during period III were 36.1% and 7.2% higher  
388 than those during period I, respectively. Those different increases rates might be  
389 explained by the fact that the urban areas in the south were largely central heating  
390 areas where heat sources were only available after 15 November and the northern  
391 areas were largely rural areas where individual household heating might have started  
392 during period I.

### 393 *3.3 Source attribution and apportionment*

#### 394 *3.3.1 Indication from tracers*

395 The great changes in the mixing ratios of VOCs during the campaign might have  
396 resulted from the altered contributions from emission sources, such as enhanced  
397 emission control during the APEC summit or intensified emissions due to wintertime  
398 heating. These changes could be indicated by the characteristic fingerprints of  
399 different sources (Guo et al., 2007).

400 The toluene/benzene (T/B) ratio, a widely used indicator for sources of aromatics,  
401 was 1.09, 0.67 and 0.70 on average during periods I, II and III, respectively (Fig. S3a).

402 While the T/B ratios during periods II and III approached 0.6, which is characteristic  
403 of coal/biomass burning (Liu et al., 2008; Liu et al., 2015d), the ratios during period I  
404 fell between that of coal/biomass burning (0.6) and vehicle exhaust (1.6) (Wang et al.,  
405 2002; Liu et al., 2009; Zhang et al., 2013a). Carbon monoxide (CO), a typical tracer  
406 of the incomplete combustion of biomass or fossil fuels (Parrish et al., 2009; Zhang et  
407 al., 2015a), showed highly significant correlations with benzene during period II  
408 ( $r^2=0.96$ , Fig. S3b) and period III ( $r^2=0.88$ , Fig. S3b). SO<sub>2</sub>, a good indicator of coal  
409 burning (Li et al., 2017), had similar concentrations during period II and period I, but  
410 its concentration increased 56.5% on average during period III compared to that  
411 during period I (Fig. 3d), suggesting an increased contribution of coal burning after  
412 the start of central heating. Methyl tert-butyl ether (MTBE), a specific indicator of  
413 gasoline related traffic emissions (Song et al., 2007; Cai et al., 2010), showed better  
414 correlation with benzene during period I ( $r^2=0.88$ , Fig. S3c) than during periods II and  
415 III.

416 As toluene, ethylbenzene and xylene (TEX) mainly originate from solvent use in  
417 paint, decorations and coatings (Guo et al., 2007; Zhang et al., 2012c), the ratios of  
418 TEX to CO are widely used to examine the impact of solvent use relative to  
419 combustion emissions (Zhang et al., 2013a). The ratios of T/CO, E/CO and X/CO  
420 were  $0.61\pm 0.09$ ,  $0.23\pm 0.06$  and  $0.35\pm 0.07$  (ppb/ppm) during period II, obviously  
421 lower than the values of  $1.16\pm 0.49$ ,  $0.59\pm 0.24$  and  $0.99\pm 0.41$  during period I and of  
422  $1.34\pm 0.27$ ,  $0.40\pm 0.06$  and  $0.83\pm 0.09$  during period III (Fig. 5B), respectively. This  
423 decrease in the ratios of aromatics to CO during period II also reflected more effective

424 control over solvent use during the APEC summit.

425 If further categorized according to the air masses trajectories, the ratios of T/CO,  
426 E/CO and X/CO decreased 29.5, 45.7 and 45.7% in the southerly air masses during  
427 period II relative to those in period I, and decreased 68.0, 80.3 and 83.0% in the  
428 northerly air masses during period II relative to those in period I, respectively (Fig.  
429 5A). A larger decrease in the TEX/CO ratios in northerly air masses reflects the fact  
430 that the control of solvent use was more effective in northern regions.

### 431 3.3.2 Source Apportionment by PMF

432 The 35 most abundant VOCs, including alkanes, alkenes, aromatics, and ethyne,  
433 and source tracers, such as chloromethane, trichloroethylene, tetrachloroethylene and  
434 MTBE, plus SO<sub>2</sub> and CO, were selected for use with the PMF receptor model. Figure  
435 6 shows the 5 sources retrieved by the model.

436 Factor 1 has high values of MTBE and C<sub>5</sub>-C<sub>6</sub> alkanes. MTBE is a common  
437 gasoline additive in China, and 2,2-dimethylbutane is used to enhance the octane  
438 levels of gasoline (Chang et al., 2004; Song et al., 2007; Cai et al., 2010). Ethyne can  
439 be formed during fuel combustion (Blake and Rowland, 1995; Song et al., 2007;  
440 Suthawaree et al., 2010). C<sub>5</sub>-C<sub>6</sub> alkanes are associated with unburned vehicular  
441 emissions (Guo et al., 2004; Cai et al., 2010; Zhang et al., 2013b). Consequently factor  
442 1 is related to gasoline vehicle emissions.

443 Factor 2 is distinguished by a strong presence of trichloroethylene and  
444 tetrachloroethylene and moderate contributions by propene and butenes.  
445 Trichloroethylene and tetrachloroethylene are species from industrial manufacturing

446 (Yuan et al., 2013; Zhang et al., 2015b); propene and butenes are gases widely used in  
447 industry to prepare organic chemicals (Guo et al., 2007), such as during the  
448 production of synthetic rubber in the petrochemical industry (Lau et al., 2010). Thus,  
449 factor 2 was identified as industrial emissions.

450 Factor 3 accounts for larger percentages of toluene, ethylbenzene, m/p-xylene  
451 and o-xylene. TEX is known to be the primary constituent of solvent (Guo et al., 2004;  
452 Yuan et al., 2009; Zheng et al., 2013; Zhang et al., 2014c; Ou et al., 2015). These  
453 compounds are also the main components in emissions from automobile factories,  
454 paint and building coatings (Liu et al., 2008; Yuan et al., 2010). Therefore, this source  
455 is considered to be solvent use related to painting and architecture.

456 Factor 4 is diesel exhaust, which is characterized by a significant amount of  
457 n-undecane and n-dodecane (Song et al., 2007; Zhang et al., 2012c).

458 Factor 5 is characterized by the presence of ethane, ethylene, CO, SO<sub>2</sub> and  
459 chloromethane. Chloromethane is the typical tracer of biomass burning (Liu et al.,  
460 2008; Cai et al., 2010; Zhang et al., 2014c). Ethylene, ethane and propene are the top  
461 3 species emitted during rice straw burning (Zhang et al., 2013c; Fang et al., 2017).  
462 The VOC species from coal burning are mainly ethyne, C<sub>2</sub>-C<sub>3</sub> alkenes and alkanes,  
463 and as well as aromatics such as benzene (Liu et al., 2008). SO<sub>2</sub> is mainly from coal  
464 burning (Li et al., 2017). Thus, factor 5 is related to coal/biomass burning.

465 Figure 7 shows the source contributions during periods I, II and III. During  
466 period I, gasoline exhaust was the largest source and accounted for 24.0% of the  
467 VOCs, while during period II, coal/biomass burning became the largest source. The

468 most significant changes due to the temporary emission control during period II were  
469 in the contribution percentages of coal/biomass burning (22.3% in period I and 42.4%  
470 in period II) and solvent use (21.9% in period I and 5.8% in period II). The large  
471 decrease in the contribution from solvent use was consistent with the above discussion  
472 about the TEX/CO ratios.

473 In period III (13 November-31 December), with central heating starting on 15  
474 November, coal/biomass burning became the largest source (45.1%), and industrial  
475 emission, solvent use, diesel exhaust and gasoline exhaust accounted for 25.2, 12.8,  
476 8.7 and 8.2% of the VOCs, respectively. The time series of source contributions  
477 during the campaign are shown in Fig. S4; the contribution percentage of  
478 coal/biomass burning increased gradually with the increase in wintertime heating,  
479 while that of gasoline exhaust decreased.

480 Coal/biomass burning was an important source of VOCs during winter in Beijing,  
481 especially during period III with the start of central heating. In Beijing, coal  
482 consumption was greater than that of residential biomass (Liu et al., 2016). Coal is  
483 consumed in residential, industrial and power sectors in Beijing. As showed in Fig.  
484 S5a, while annual total coal consumptions dropped rapidly during 2006-2015, the  
485 annual residential coal consumptions remained almost unchanged with their  
486 percentages in total coal consumptions rising from 8.7% in 2006 to 23.4% in 2015  
487 (Beijing Municipal Bureau of Statistics, 2016; Yu et al., 2018). As a matter of fact,  
488 over 60% of the residential coal consumption occurred in rural areas of Beijing (Fig.  
489 S5b), and residential coal is mainly burned in the cool winter season for house heating

490 (Xue et al., 2016). While emission factors of VOCs from residential coal burning have  
491 been found to be a factor of 20 greater than those from coal-fired power plants (Liu et  
492 al., 2017), the differences in coal quality between the urban and rural areas augment  
493 emissions in rural areas: coal used in urban area was entirely anthracite with  
494 comparatively much lower emissions of volatiles than other types of coal (Xu et al.,  
495 2017); instead only 5-15% of coal used in rural area was anthracite (Xue et al., 2016).  
496 Consequently, residential coal combustion could have been a major contributor to the  
497 ambient VOCs in rural areas of Beijing during winter.

498       Compared with that in the period I (Fig. S6), the contribution from solvent use  
499 during period II was reduced to a greater extent than other sources; it became 4.29  
500 ppb lower and could explain 37.6% of the reduction in ambient VOCs (Table S4). The  
501 contribution from gasoline vehicles was 3.18 ppb lower and accounted for 27.9% of  
502 the total reductions. The contribution from diesel exhaust and industrial emissions  
503 decreased 2.28 ppb and 1.35 ppb and explained 20.0 and 11.8% of the total reduction,  
504 respectively. Coal/biomass burning made similar contributions during periods I and II,  
505 with an elevated contribution percentage in period II due to the reduction in other  
506 sources. This is consistent with the fact that during the APEC summit residential  
507 coal/biomass burning was not restricted in the rural areas. Traffic-related sources  
508 (gasoline and diesel vehicles) and solvent use accounted for 47.9 and 37.6% of the  
509 total reduction in ambient VOCs, indicating that control measures (Table 1) related to  
510 the control of traffic and solvent use were among the most effective ways to reduce  
511 the ambient VOCs.

512 Figure 8 shows the source contributions in the southerly and northerly air masses  
513 during periods I, II and III. In the southerly air masses, traffic related emission  
514 (gasoline and diesel vehicles) were the largest source, contributing 44.1 and 41.5% of  
515 the VOCs during periods I and II, respectively, while coal/biomass burning was the  
516 largest source during period III, contributing 38.2% of the VOCs. In the northerly air  
517 masses, coal/biomass burning contributed 28.8, 51.6 and 48.8% of the VOCs during  
518 periods I, II and III, respectively. Overall, gasoline vehicle exhaust contributed more  
519 VOCs in the southern regions (mostly densely populated urban areas) and  
520 coal/biomass burning and diesel exhaust accounted for more emissions of VOCs in  
521 northern regions (mostly rural areas). The contributions of different sources to most  
522 reactive alkenes and aromatics based on PMF was presented in Fig. 9. Alkenes mainly  
523 originated from coal/biomass burning, with shares of 31.2-68.0%, and gasoline  
524 exhaust ranked second, with contributions of 3.0-26.5%. Unlike alkenes, solvent use  
525 was the major contributor of aromatics, accounting for 77.5% during period I and 29.0%  
526 during period II in the northerly air masses; gasoline exhaust contributed 8.2-43.6% of  
527 the aromatics during the campaign. In the southerly air masses, the reductions in  
528 solvent use, gasoline exhaust, and diesel exhaust during period II relative to period I  
529 could explain 38.1, 31.1, and 15.8% of the total reduction in VOCs, respectively. In  
530 the northerly air masses, reductions in solvent use, diesel exhaust, and gasoline  
531 exhaust during period II relative to the period I could explain 46.5, 35.8 and 11.9% of  
532 the total reduction in VOCs, respectively. Consequently, control measures related to  
533 solvent use and gasoline exhaust were more effective in the southern regions, while

534 the control of solvent use and diesel exhaust emissions were more effective in the  
535 northern region.

### 536 3.3.3 Source contributions to the SOAFP

537 With the PMF source apportionment results, the contributions of the SOAFP of  
538 different sources were further estimated. As shown in Fig. 10, under low-NO<sub>x</sub>  
539 conditions, the SOAFP of solvent use was much higher than that of other sources,  
540 which was 4.88, 0.68 and 2.89  $\mu\text{g m}^{-3}$ , accounting for 56.9, 27.2 and 54.7% of the  
541 total SOAFP during periods I, II and III, respectively. Gasoline exhaust contributed  
542 19.2, 29.5 and 10.9%, and diesel exhaust contributed 16.5, 26.8 and 11.3% of the  
543 SOAFP during periods I, II and III, respectively. During period II, with temporary  
544 intervention measures, the reduction in SOAFP was mainly due to reduced  
545 contributions from solvent use, gasoline exhaust and diesel exhaust, which could  
546 explain 69.1, 14.9 and 12.2% of the reduction in SOAFP, respectively. Under  
547 high-NO<sub>x</sub> conditions, the calculated reduction in SOAFP during period II relative to  
548 period I could largely be explained by the reduced contributions from solvent use,  
549 diesel exhaust and gasoline exhaust, which accounted for 54.0, 25.8 and 16.8% of the  
550 reduction in SOAFP, respectively.

551 It is worth noting that recent chamber studies revealed that aromatic  
552 hydrocarbons and traditional VOCs could not fully explain the SOA formed during  
553 atmospheric aging of source emissions (Zhao et al., 2014; 2015; Liu et al., 2015c;  
554 Deng et al., 2017; Fang et al., 2017), particularly for emissions from diesel vehicles or  
555 biomass burning (Zhao et al., 2015; Deng et al., 2017; Fang et al., 2017). Therefore

556 the discussion on the SOAFP in this study is limited to traditional anthropogenic SOA  
557 precursor species (mainly aromatic hydrocarbons), and intermediate-volatility organic  
558 compounds (IVOCs), which are important SOA precursors (Zhao et al., 2014), should  
559 be further considered in order to fully understand the influence of control measures on  
560 ambient SOA.

#### 561 **4. Conclusions**

562 During severe wintertime haze events in recent years in Beijing, SOA often  
563 composed higher fractions of organic aerosols, yet their precursor VOCs in ambient  
564 air during winter are not well understood, especially in rural areas. In this study, we  
565 collected ambient air samples from 25 October to 31 December in 2014 at a rural site  
566 on the campus of UCAS in north Beijing. As the APEC summit was held in Beijing  
567 on 5-11 November 2014, temporary control measures were adopted to improve the air  
568 quality, and the so-called “APEC Blue” was achieved due to the enhanced emission  
569 control. Therefore, we took advantage of this opportunity to see how the control  
570 measures influenced the ambient VOCs in rural areas. On the other hand, wintertime  
571 heating from coal burning has been regarded as a major contributor to wintertime PM  
572 pollution and haze events; thus, we also compared the ambient VOC levels and  
573 composition before and after the start of central heating on 15 November, and  
574 investigated the influence of wintertime heating on ambient VOCs based on our  
575 observation at a rural site.

576 We observed that during the enhanced emission control period (period II; 3-12  
577 November), the average mixing ratios of VOCs decreased ~50% compared to those

578 before or after that period. In addition, the ozone and SOA formation potential  
579 accordingly decreased by ~50% and ~70%, respectively, as a result of the temporary  
580 intervention measures implemented during period II. The larger decrease in SOA  
581 formation potentials was attributable to more effective control over aromatic  
582 hydrocarbons mainly from solvent use. Based on PMF source apportionment, the  
583 control of traffic-related emissions (gasoline and diesel exhaust) and solvent use could  
584 explain 47.9 and 37.6% of the reduction in ambient VOCs. This result thus offered an  
585 observation-based evaluation of the temporary emission control measures.

586 Through back trajectory analysis, we could compare ambient VOCs with the  
587 change in wind direction and thus further investigate the source emission strength in  
588 different regions. The total mixing ratios of VOCs in southerly air masses were 2.3,  
589 2.3 and 2.9 times those in northerly air masses before, during and after the period with  
590 temporary emission control for the APEC summit. VOC episodes during the  
591 campaign all occurred under southerly winds. This confirms that emission control in  
592 the southern urbanized regions is crucial for reducing ambient VOCs.

593 As residential coal/biomass burning was not controlled during the APEC summit,  
594 its contribution to the ambient mixing ratios of VOCs was similar between period I  
595 and period II, although the contribution percentages of coal/biomass burning became  
596 the largest on average due to decreases in the percentages of other sources. During  
597 period III, with emissions from burning solid fuels for household heating,  
598 coal/biomass burning became the largest source, accounting for 45.1% of the VOCs.  
599 Specifically, during period III, coal/biomass combustion contributed 38.2% of the

600 VOCs in southerly air masses (or in the southern regions), and 48.8% of the VOCs in  
601 northerly air masses (or in the northern regions).

602 The finding of this study will provide useful information for the emission control  
603 strategy of VOCs. A comparison of VOCs between period I (without intervention  
604 measures) and period II (with intervention measures) revealed that the temporary  
605 intervention measures mostly targeted on the control in traffic and industry (industrial  
606 processes and solvent use) sectors are very effective to reduce reactive alkenes and  
607 aromatics and thereby to reduce the OFPs and SOAFPs of VOCs in ambient air.  
608 Therefore, enhancing emission control for solvent use (especially solvents with  
609 aromatic hydrocarbons) and vehicle exhaust would benefit the VOC-related air  
610 pollution. However, as observed in this study, even in megacities like Beijing, burning  
611 raw coal or biomass for household heating in winter could contribute near half of  
612 VOCs in ambient air. If the emission control over residential burning of solid fuels is  
613 underappreciated, the intervention measures targeted on traffic and industry sectors  
614 would be not so effective in the wintertime heating period as did in non-heating  
615 periods either to lower PM<sub>2.5</sub> as indicated by Liu et al. (2016) or to lower VOCs in  
616 ambient air as indicted by this study. In fact, a study by Yu et al. (2018) during the  
617 same field campaign of this study demonstrated that, without emission control over  
618 residential burning of solid fuels, ambient PM<sub>2.5</sub>-bound toxic polycyclic aromatic  
619 hydrocarbons in rural Beijing during the 2014 APEC summit remained unchanged  
620 despite of the temporary intervention control measures, and they were largely  
621 aggravated after the start of wintertime heating. Therefore, cleaner energy use instead

622 of poor-technology burning of solid fuels household heating would have tremendous  
623 health benefits in lowering both indoor and outdoor air pollution particularly in  
624 heavily polluted winter. It worth noting that this study was conducted in a rural area of  
625 the megacity Beijing. Emission from residential burning of solid fuels would be a  
626 source of greater importance and thus deserves more concern in less developed  
627 regions.

1038

1039 Table 1. Enhanced temporary air pollution control measures during the 2014  
 1040 Asian-Pacific Economic Cooperation (APEC) summit.

Control types	Details	Control areas
Traffic	1. Yellow label vehicles were banned to run inside the sixth ring of Beijing and the Huairou urban area; 2. The number of private vehicles in operation reduced by 50% through an odd/even-number-plate rule throughout Beijing; 3. Trucks were limited to drive inside the sixth ring of Beijing between 6 am and 24 pm; 4. 70% of government cars also ordered off the roads in Beijing.	Inside the sixth ring of Beijing and the Huairou urban area
Industrial	1. 9289 enterprises were suspended, 3900 enterprises were ordered to limit production; 2. More than 40000 construction sites were shut down.	Beijing, some areas of Tianjin, Hebei, Shanxi, Shandong and Inner Mongolia
Other fields	1. Open fire was completely controlled at North China Plain; 2. Increasing road cleaning and water spraying in Beijing; 3. Other relate control measures carried out in surrounding areas.	North China Plain Tianjin, Hebei, Shanxi, Shandong and Inner Mongolia

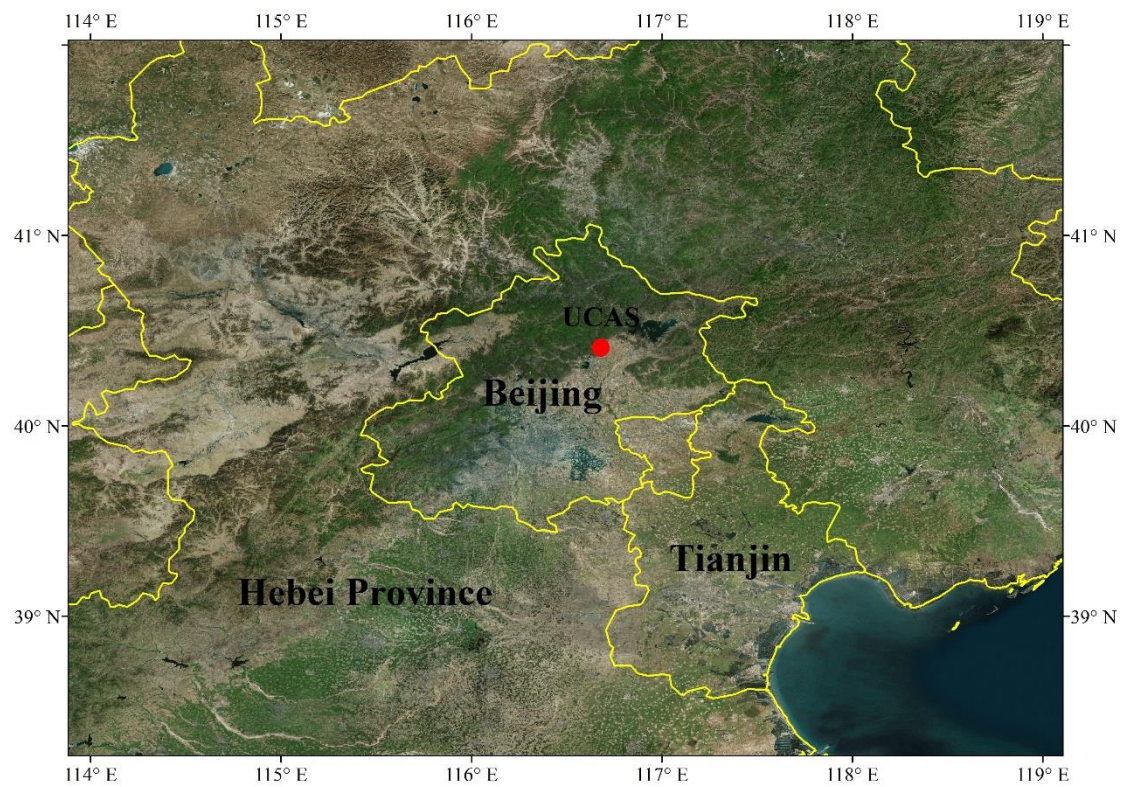

1041

1042 Table 2. The mixing ratios, ranges and 95% confidence intervals (95% C.I.) of VOCs  
 1043 during period I, II and III at the rural site inside UCAS (in parts per trillion by volume,  
 1044 pptv).

Species	MDL <sup>a</sup>	Period I		Period II		Period III	
		Range	Mean (95% C.I.)	Range	Mean (95% C.I.)	Range	Mean (95% C.I.)
