18 **Abstract:** Aerosol acidity affects the chemical transformation of aerosols and subsequent haze
19 formation. High resolution (1-h) observation of water-soluble inorganic ions in fine particles,
20 gaseous pollutants, and meteorological parameters was conducted from September 2015 to August
21 2016 at Wuhan, a megacity of Central China with high relative humidity and ambient temperature,
22 compared with north Chinese cities. By adopting thermodynamic model ISOROPPIA- II , the
23 aerosol acidity for different time scales, pollution episodes, and air mass directions was calculated.
24 Aerosols in Wuhan were moderate acidic, with pH averaged as 3.30 ± 0.49 . The aerosol acidity was
25 higher in July (pH as 2.64 ± 0.31), September (pH as 2.75 ± 0.30) and August (pH as 2.79 ± 0.29),
26 and lower in January (pH as 3.77 ± 0.28) and March (pH as 3.70 ± 0.16). It decreased with the air
27 pollution increasing, with the pH values of 3.07 ± 0.45 , 3.63 ± 0.27 and 3.84 ± 0.22 for clean,
28 transition and polluted episodes, respectively. The air masses in Wuhan transported from North
29 China exhibited higher aerosol acidity, with pH averaged as 3.17-3.22. The unique environmental
30 and meteorological conditions (high humidity, annual averaged RH as 0.74 ± 0.13) lead to excess
31 ammonium (on average of $6.06 \pm 4.51 \mu\text{g m}^{-3}$) and abundant aerosol water content (AWC, on
32 average of $71.0 \pm 82.8 \mu\text{g m}^{-3}$) in Wuhan, which can explain the lower $\text{PM}_{2.5}$ acidity in Wuhan than
33 other megacities of China. At lower AWC level (less than $\sim 15 \mu\text{g m}^{-3}$), the particle pH showed a
34 decreasing trend with AWC increased. When the AWC continuous increased from ~ 15 to $\sim 380 \mu\text{g}$
35 m^{-3} , there was an obvious increase of particle pH. Then no significant growth of pH was found when
36 AWC was higher than $\sim 380 \mu\text{g m}^{-3}$. With atmospheric RH increasing, the aerosol pH exhibited
37 decreasing trend firstly and then increased, with the turning point RH as about 0.48. There was a
38 logarithmic growth of aerosol pH with total NH_x ($\text{NH}_3 + \text{NH}_4^+$) increasing. From the fitted
39 logarithmic curve, the aerosol pH of Wuhan was at the range of pH rapid growth stage with NH_x
40 increasing, indicating that the control of ammonia emission in Wuhan could be an effective way to
41 reduce the aerosol pH and further mitigate air pollution. This paper firstly obtained the aerosol
42 acidity properties at a megacity under abundant ammonium and high humidity with high time-
43 resolution, which is an important supplementary for the current aerosol acidity research around the
44 world.

45 **Keywords:** water-soluble inorganic ions; aerosol acidity; high time-resolution; pollution episodes;
46 aerosol water content; excess ammonium

47 1 Introduction

48 Aerosol acidity is one of the key factors affecting the organic (Jang et al., 2002; Surratt et al.,
49 2007; Cao and Jang, 2010; Pathak et al., 2011) and inorganic secondary aerosol formation
50 (Underwood et al., 2001; Manktelow et al., 2010; Wang et al., 2016a), by gas-aerosol partitioning
51 (Grassian, 2001; Keene et al., 2004), acid-catalyzed heterogeneous reaction (Jang et al., 2002;
52 Nemitz et al., 2004; Xu et al., 2015a) and migration of redox minerals and metals (Meskhidze et al.,
53 2003), etc. Acidic aerosols have the capability to reduce atmospheric visibility (Watson, 2002),
54 disturb atmospheric radiative balance (Crumeyrole et al., 2008), threaten human health and
55 deteriorate ecosystems (Schindler, 1988; Larssen et al., 2006; Johnson et al., 2008). Recently,
56 aerosol acidity has raised wide attention and controversy in view of its vital role in haze formation
57 of China (Liu et al., 2017; Tian et al., 2018; Zhou et al., 2018).

58 The aerosol acidity exhibited spatiotemporal discrepancy, owing to the diversities of source
59 emission and meteorological conditions. Currently, the research of aerosol acidity in China is
60 becoming a hotspot, with studies mainly concentrated in northern cities like Beijing (He et al., 2012;
61 Yang et al., 2015; Cheng et al., 2016; Wang et al., 2016a), eastern coastal cities like Shanghai
62 (Pathak et al., 2009), southern coastal cities including Guangzhou (Huang et al., 2011) and
63 Hongkong (Pathak et al., 2003; Pathak et al., 2004a; Yao et al., 2006; Yao et al., 2007), and western
64 cities of Chongqing (He et al., 2012) and Lanzhou (Pathak et al., 2009). One study has been
65 conducted at a background mountainous site (Zhou et al., 2012). In general, aerosol acidity in China
66 was lower than those in Europe (Bougiatioti et al., 2016) and United States (Weber et al., 2016). He
67 et al. (2012) indicated that the aerosol acidity in North China was lower than that in the south. Even
68 in the same city, the aerosol acidity was different. He et al. (2012) observed that fine particles ($PM_{2.5}$)
69 in Beijing was strong acidic with pH ranging in 0-3; Liu et al. (2017) calculated the pH value of
70 $PM_{2.5}$ in Beijing as about 4.2; Wang et al. (2016a) indicated that $PM_{2.5}$ in Beijing was completely
71 neutralized with pH as about 7. One of the key factors for these diversities is that these studies were
72 done at a given period with different pollution levels. Liu et al. (2017) found that along with the
73 pollution levels increased, the aerosol pH values decreased for a typical haze formation processes
74 in Beijing. Former researchers highlighted the importance to obtain the aerosol acidity under
75 different time scales and different pollution episodes, which is important to better identify the
76 formation mechanism of air pollution at a certain region. Till now, few studies were reported to

77 analyze the aerosol acidity for a long-time period, owing to the absence of online high-resolution
78 dataset for gaseous pollutants and ionic components synchronously. It may limit the understanding
79 of how the aerosol acidity affects the atmospheric chemistry, in view of a pollution transition event,
80 monthly variation and diversities for different air mass trajectories.

81 The molar ratio of cations to anions is always used to estimate aerosol acid-alkaline property
82 qualitatively (Yao et al., 2006; Hennigan et al., 2015; Wang et al., 2016a), depending on the selected
83 ionic species (He et al., 2012). Thermodynamic models such as ISORROPIA (Nenes et al., 1998;
84 Fountoukis and Nenes, 2007), E-AIM (Carslaw et al., 1995; Clegg et al., 1998; Friese and Ebel,
85 2010) and SCAPE (Meng et al., 1995) were developed and widely adopted to calculate aerosols
86 acidity quantitatively, with outputs of pH, $[H^+]$ and aerosol water content (AWC), though inherent
87 imperfect existed for these models (Wang et al., 2018).

88 AWC exerts a driving role in the variation of aerosol acidity (Liu et al., 2017). Zhou et al.
89 (2012) indicated high water content can cause HSO_4^- dissociating to form free H^+ when $RH > 0.65$.
90 In addition, AWC serves as a medium for aqueous phase reaction of SO_2 oxidation (Pilinis et al.,
91 1989; Ervens et al., 2011; Cheng et al., 2016), which can also lead to the increase of aerosol acidity
92 (Seinfeld et al., 2006). However, high water content of aerosols in return may dilute the hydrogen
93 ion concentrations and increase pH value. Guo et al. (2015) showed that the diurnal variation of pH
94 was mainly driven by AWC dilution. It was observed that the temporal trends of particle pH were
95 in accordance with AWC rather than H^+ , and the aerosol acidity added with the decrease of AWC in
96 Beijing, despite the decreasing of H^+ (Liu et al., 2017). AWC was not only closely associated with
97 atmospheric relative humidity (RH) and temperature (Temp) (Guo et al., 2015), but also well
98 correlated with secondary inorganic salt (Cheng et al., 2016) which will again assimilate more water
99 because of hygroscopicity (Engelhart et al., 2011; Bian et al., 2014). So is there an inflection point
100 of AWC between the promoting role through the aqueous phase formation and the inhibition role
101 by the dilution effect on the acidic inorganic ions under a specific circumstance? Till now, as obvious
102 studies are always conducted in a limited season or pollution episodes (Zhou et al., 2012; Bian et
103 al., 2014; Guo et al., 2015; Cheng et al., 2016; Wang et al., 2016a; Liu et al., 2017; Wang et al.,
104 2018), no studies have listed observed evidence directly to answer this question.

105 Except for AWC, ammonia and ammonium were also regarded as determining factors on
106 aerosol acidity (Liu et al., 2017), which were the main species to neutralize acid (Sun and Wexler,

107 1998; Wang et al., 2015). The ammonium-to-sulfate ratio was used to describe the ammonium-rich
108 or ammonium-poor conditions (Pathak et al., 2004a; Huang et al., 2011; Kumar and Sunder Raman,
109 2016), with the ratio higher than 1.5 implying an ammonia rich atmosphere (Kumar and Sunder
110 Raman, 2016). Pathak (2004) indicated that pH increased with increasing ammonium-to-sulfate
111 ratio. The correlation of NH_4^+ with SO_4^{2-} and NO_3^- also can be used to judge the ammonia rich or
112 poor status (Kumar and Sunder Raman, 2016). Recently, Liu et al. (2017) concluded that the excess
113 ammonia resulted in the pH increasing by logarithm growth form in north China. Under ammonia-
114 rich air, positive correlation between excess NH_4^+ and NO_3^- was found (Pathak et al., 2009).
115 Therefore, for the regions with abundant agricultural activities which are the main emission sources
116 for ammonia, the relationship of ammonia, aerosol acidity and air pollution needs a clear illustration.

117 Wuhan and its surrounding cities (WSC) belong to the key regions in the State Council's Action
118 Plan on Prevention and Control of Atmospheric Pollution (Figure 1a). WSC has become the most
119 polluted region with high $\text{PM}_{2.5}$ concentrations except for the regions of Beijing-Tianjin-Hebei (Qi
120 et al., 2017; Gao et al., 2018), Yangtze River Delta (Shen et al., 2015; Chen et al., 2017) and Sichuan
121 Basin (Wang et al., 2017a; Ning et al., 2018) (Figure 1b). Meanwhile, as WSC is located in the
122 center of China, the air masses from other different polluted regions all can impact the aerosol
123 concentrations and compositions. At the west of WSC, there locates JiangHan Plain (JHP) which is
124 a key food-cotton base of China. The WSC and surrounding JHP hold high ammonium emission
125 intensity (Huang et al., 2012; Xu et al., 2015b; Wang et al., 2018). At the northeast and northwest
126 of WSC, there locates TongBai Mountain and DaBie Mountain (Figure 1c), which directly decided
127 the transportation routes of air masses in cold period from North China Plain when the north winds
128 dominated (Figure 1b). Wuhan belongs to subtropical monsoon climate, and owns hundreds of lakes
129 (Figure 1d), which lead to its higher ambient temperature and atmospheric relative humidity (RH).
130 The unique geographical, emission and meteorological conditions implied that the aerosol acidity
131 and its role in air pollution transition should be quite different from other regions, especially for the
132 recently studied cities in North China. Meanwhile, the high RH (annual mean 0.74, in this research,
133 all the $\text{PM}_{2.5}$ compositions and meteorological data for rainy day were excluded), temperature
134 (annual mean 292.2K) and serious air pollution in Wuhan provide an ideal site to identify how the
135 RH, AWC and precursor gases affect aerosol acidity.

136 Therefore, based on one-year continuous observation of hourly water-soluble inorganic ions in

137 PM_{2.5} and precursor gases from September 2015 to August 2016, PM_{2.5} acidity was calculated by
138 thermodynamic model ISOROPPIA- II . The variation of acidity in different months, pollution
139 episodes and for different air mass transportation directions were discussed and possible reasons
140 were investigated. The results are urgently and helpful to understand the relationship of chemical
141 composition-aerosol acidity-air pollution in different time scales and to enrich the formation
142 mechanism of serious air pollution out of North China Plain.

143 2 Method and modeling

144 2.1 Sampling and instrumentation

145 The observation site (30.53° E, 114.36° N) located in the city center (Figure 1d). It is about 20
146 m above ground and surrounded by commercial/residential mixed area with no obvious industrial
147 sources. Water-soluble ions (WSI) including SO₄²⁻, NO₃⁻, Cl⁻, NH₄⁺, Na⁺, K⁺, Ca²⁺ and Mg²⁺ in
148 PM_{2.5} and atmospheric NH₃, HCl, HNO₃, and HNO₂ were synchronously measured by an online ion
149 chromatography analyzer with one-hour resolution by Marga ADI 2080 (Monitor for Aerosols and
150 Gases in Ambient Air). The detailed description of the equipment can be found in previous studies
151 (Rumsey et al., 2014). One-year continuous monitoring was done from September 2015 to August
152 2016, except data missing due to equipment maintain in February. Concurrently, hourly PM_{2.5}, O₂,
153 SO₂, NO₂, and O₃ were observed by automatic on-line monitoring instrument, with the methods of
154 β-ray, ultraviolet fluorescence, chemiluminescence and ultraviolet absorption, respectively. The
155 synchronous meteorological data including relative humidity (RH) and temperature (Temp) were
156 obtained from local meteorological observatory. Ionic equivalent ratio was employed to a
157 preliminary qualitative estimation of the particle neutralization and acidity. The ratio of total cations
158 and anions were calculated as following (Zhang et al., 2007; Tanner et al., 2009; Hennigan et al.,
159 2015):

$$160 \quad \text{Cation} / \text{Anion} = \left(\text{NH}_4^+ + 2 * \text{Ca}^{2+} + \text{Na}^+ + 2 * \text{Mg}^{2+} + \text{K}^+ \right) / \left(2 * \text{SO}_4^{2-} + \text{NO}_3^- + \text{Cl}^- \right) \quad (1)$$

161 2.2 Fine particle acidity calculation

162 Thermodynamic model ISOROPPIA- II (<http://nenes.eas.gatech.edu/ISORROPIA>) was
163 employed to calculate in-situ aerosol acidity. It can predict which species exist in the gas or aerosol
164 phase and can calculate their concentrations at chemical equilibrium status, including H⁺, water
165 content and aerosol pH, with the inputs of SO₄²⁻, NO₃⁻, NH₄⁺, Cl⁻, K⁺, Ca²⁺, Na⁺, and Mg²⁺, as well

166 as temperature and relative humidity. In this study, the forward mode with metastable state was
167 adopted as its better performance (Fountoukis and Nenes, 2007; Guo et al., 2015; Hennigan et al.,
168 2015; Guo et al., 2016; Weber et al., 2016). Well correlations between the predicted and observation
169 data were found in Figure 2.

170 2.3 Trajectory clustering

171 Backward trajectory analysis by HYSPLIT model (Version 4) was used to explore the influence
172 of air masses originated from different directions on the aerosol acidity of Wuhan. 72 h backward
173 trajectories were calculated for 4 times each day (00:00, 06:00, 12:00 and 18:00), with the starting
174 height at 200 m above ground. The input meteorological data was in 6-h hourly resolution acquired
175 from NOAA/ARL. The trajectories were clustered by the clustering analysis procedure provided in
176 the HYSPLIT user's guide.

177 3 Results and discussions

178 3.1 General characteristic of WSI in Wuhan

179 As listed in Table 1, the annual average mass concentration of $PM_{2.5}$ in Wuhan was 63.4 ± 35.2
180 $\mu\text{g m}^{-3}$, exceeding the annual average secondary standard of China Ambient Air Quality ($35 \mu\text{g m}^{-3}$)
181 3). $PM_{2.5}$ showed the maximum concentration in winter ($92.6 \pm 45.6 \mu\text{g m}^{-3}$) and the minimum value
182 in summer ($37.3 \pm 12.0 \mu\text{g m}^{-3}$), which was consistent with former researches. Total WSI
183 concentrations accounted for 70% of $PM_{2.5}$ mass concentration on average, also higher in winter
184 and lower in summer.

185 The dominated ions were SO_4^{2-} , NO_3^- and NH_4^+ (SNA), with a proportion up to 91-93% and
186 55-73% in total ions and $PM_{2.5}$, respectively. The ratios of SNA to $PM_{2.5}$ in Wuhan were higher than
187 those in urban sites of Beijing (28%) (Zheng et al., 2005), Chongqing (30%) (He et al., 2012),
188 Shanghai (36%) and Guangzhou (27%) (Yang et al., 2011). The high relative humidity in Wuhan
189 (annual average as 0.74) may be one of the key factors. SO_4^{2-} production can increase along with
190 RH increasing due to the aerosol hygroscopicity and aqueous phase oxidation (Wang et al., 2016a).
191 The SNA concentrations were highest in winter ($61.1 \pm 35.1 \mu\text{g m}^{-3}$) and lowest in summer ($24.6 \pm$
192 $12.7 \mu\text{g m}^{-3}$), then followed by spring ($43.4 \pm 21.0 \mu\text{g m}^{-3}$) and fall ($32.4 \pm 14.2 \mu\text{g m}^{-3}$). It was
193 different from the results in North China Plain (NCP), Sichuan Basin (SB), Yangtze River Delta and
194 Pearl River Delta (Fu et al., 2016), where the lowest SNA proportions were found in spring or fall.
195 The meteorological condition and precursor emissions, can explain the seasonal variation pattern

196 (Fu et al., 2016). Although there was higher sulfate formation rate in summer in Wuhan, the SO₂ in
197 summer was low to 4.7 μg m⁻³ (Table 2). The low SNA concentrations in summer were mainly
198 related to the lower nitrate and ammonium formation rate (Table 2) and high atmospheric boundary
199 layer height (Figure 4a).

200 NO₃⁻ concentrations exhibited the highest concentration in winter (25.3 μg m⁻³) and the lowest
201 in summer (5.6 μg m⁻³), with winter/summer ratio of 4.5. SO₄²⁻ concentrations also exhibited the
202 same seasonal variation. Lower sulfate concentration in summer was contrary to previous studies
203 (Tai et al., 2010; Yang et al., 2011; Hand et al., 2012), which indicated that strong atmospheric
204 oxidation (higher O₃ concentration in summer), higher temperature and relative humidity were
205 beneficial to sulfate formation from SO₂. While in this study with lower precursor concentration
206 and higher boundary layer height, relatively low concentrations of sulfate and nitrate in summer
207 were found in Wuhan.

208 The averaged NH₄⁺ mass concentration was 10.4 μg m⁻³, higher than those in Beijing (7.4 μg
209 m⁻³) (He et al., 2012), Chongqing (7.9 μg m⁻³) (He et al., 2012), Guangzhou (5.2 μg m⁻³) (Lai et al.,
210 2016), Shanghai (6.0 μg m⁻³) (Wang et al., 2016b), Tianjin (6.9 μg m⁻³) (Shi et al., 2017) and Xi'an
211 (7.6 μg m⁻³) (Wang et al., 2014). NH₄⁺ exhibited higher concentrations in winter (15.4 ± 8.9 μg m⁻³)
212 and lower concentrations in summer (6.81 ± 3.42 μg m⁻³) in Wuhan. The reason may be that under
213 high temperature and strong solar insolation in summer, ammonium preferred to exist in the form
214 of gas phase due to the thermal equilibrium. Strong correlation was found between NO₃⁻ and NH₄⁺
215 (R² = 0.94, p < 0.05), as well as SO₄²⁻ and NH₄⁺ (R² = 0.92, p < 0.05), implying that (NH₄)₂SO₄ and
216 NH₄NO₃ could be the main existing forms in PM_{2.5} of Wuhan, similar to former cities (Han et al.,
217 2016).

218 Other species including K⁺, Ca²⁺, Na⁺, Mg²⁺, and Cl⁻ constituted a minor fraction, totally
219 accounting for 7-9% of total ions. The Cl⁻ concentration was higher, and subsequently followed by
220 K⁺, Ca²⁺, Na⁺, and Mg²⁺. Higher Cl⁻ concentrations were measured in winter (2.87 ± 1.25 μg m⁻³),
221 approximately two or three times than those in other seasons. The Na⁺/Cl⁻ ratio in winter (0.09) was
222 obviously lower than that of seawater (0.557) (Hegde et al., 2016), reflecting the dominance of other
223 sources for Cl⁻ instead of sea salt. The weak correlation (R² = 0.20, p < 0.05) between Cl⁻ and Na⁺
224 verified this. Furthermore, Cl⁻ was positively (p < 0.05) correlated with NO₃⁻ (R² = 0.78), SO₄²⁻ (R²
225 = 0.55), NH₄⁺ (R² = 0.71) and K⁺ (R² = 0.59), which were mainly derived from anthropogenic

226 emissions. Therefore, Cl^- was inferred to be associated with regional transport of domestic coal and
227 biofuel combustion emission for heating from North China (Yin et al., 2014). The dominated north
228 wind in Wuhan at winter favored it (Figure 4).

229 K^+ in Wuhan was not abundant compared with those in Shanghai (Wang et al., 2016b), Beijing
230 (Han et al., 2016) and coastal areas (Yin et al., 2014). It was moderately correlated with NO_3^- ($R^2 =$
231 0.64 , $p < 0.05$), SO_4^{2-} ($R^2 = 0.62$, $p < 0.05$), NH_4^+ ($R^2 = 0.63$, $p < 0.05$) and Cl^- ($R^2 = 0.59$, $p < 0.05$),
232 indicating homology source of them. The highest K^+ in winter of Wuhan can be related to the wood
233 burning (Fourtziou et al., 2017) for domestic heating in NCP (Zhang et al., 2017; Zhu et al., 2017).
234 High intensity discharge of K^+ from fireworks and crackers in Spring Festival periods could not be
235 ignored, which usually occurred in January or February (Kong et al., 2015).

236 Ca^{2+} was commonly derived from soil or crustal dust and construction activities (Hegde et al.,
237 2016). Ca^{2+} in Wuhan showed slightly higher value in winter and spring than those in summer and
238 fall, similar to previous studies (Zhao et al., 2010; He et al., 2012). Ca^{2+} was only significantly
239 correlated with Mg^{2+} ($R^2 = 0.80$, $p < 0.05$). Different from Beijing (Han et al., 2016) and Xi'an
240 (Wang et al., 2014), no correlations for Ca^{2+} - NO_3^- , Ca^{2+} - SO_4^{2-} , Mg^{2+} - NO_3^- and Mg^{2+} - SO_4^{2-} were
241 found in Wuhan, indicating different atmospheric chemical processes between northern and central
242 Chinese cities. In north China, the mineral dust fraction of $\text{PM}_{2.5}$ was higher (Tao et al., 2017), and
243 was involved in atmospheric processes by internally mixing with secondary aerosols (Cheng et al.,
244 2016; Wang et al., 2017b).

245 3.2 Aerosol acidity in Wuhan

246 Figure 3a shows the daily variation of $\text{PM}_{2.5}$ aerosol acidity in Wuhan. The daily pH values
247 ranged between 2.21 – 4.19, with an average of 3.30, indicating moderate acidic in Wuhan. The
248 lowest pH value occurred in summer, averaged as about 2.84. The pH values in winter were higher
249 as about 3.71. The AWC in autumn, winter, spring, and summer were 66.9, 118.5, 66.5 and 36.2 μg
250 m^{-3} , respectively, which can explain the seasonal variation of pH values primarily. There is a double
251 effect of AWC on aerosol pH, including the enhancement of bisulfate dissociation to form free H^+
252 through the hydrolysis process and dilution effects of proton concentrations in droplets (Pathak et
253 al., 2004a; Zhou et al., 2012). At higher RH, the dilution effect on the molarity of acidic species was
254 more important than H^+ releasing from bisulfate (Pathak et al., 2004a). Previous studies showed that
255 aerosol pH varied in consistency with AWC (Liu et al., 2017). From September to January, the

256 aerosol pH gradually increased from 2.75 to 3.77 (Figure 5) along with the increasing of AWC,
257 which buffered the aerosol acidity. From May to August, when AWC decreased from 80.8 to 32.4
258 $\mu\text{g m}^{-3}$, the pH decreased 0.65 units from 3.44 to 2.79. The H^+ concentrations generally exhibited
259 an opposite variation of pH value except for November when more H^+ did not result in lower pH
260 value (3.53) because of higher AWC ($151.7 \mu\text{g m}^{-3}$).

261 The ratios of cations to anions were also listed in Figure 3(c). It could be found that there was
262 no obvious relationship between pH and cations/anions ratios. The annual mean cations/anions ratio
263 was near unity (1.10), reflecting completely neutralized, which was not in accordance with the
264 prediction by thermodynamic models. It might be resulted from the negligence in considering the
265 particle liquid water and dissociation state of individual ion (Guo et al., 2015). Thus, ionic molar
266 ratios could not be the proxy for discussing aerosol acidity.

267 Table 3 compared the aerosol acidity of Wuhan with other cities. Aerosols mostly exhibited
268 acidic around the world. Particle pH in Wuhan was higher than most of the other cities. As discussed
269 above, the specific climate, geography, and emissions may explain it. Besides, aerosol acidity was
270 dynamically changing. The particle pH increased in last decade of Beijing as Table 3 shown, which
271 might be due to the increase of atmospheric NH_3 and decreasing of SO_2 (Meng et al., 2011; Liu et
272 al., 2013). Detailed discussion about the key impacting factors on aerosol acidity is listed below.

273 3.3 Key driving factors for aerosol acidity variation

274 As mentioned above, AWC exerted an important role in aerosol acidity variation. Figure 6a
275 exhibited the relationship between pH with AWC. From the fitting curve, the particle pH firstly
276 showed a decreasing trend with AWC increased under much lower AWC level (less than about 15
277 $\mu\text{g m}^{-3}$). Then, with the AWC increasing from ~ 15 to $\sim 380 \mu\text{g m}^{-3}$, the dilution effect on aerosol
278 acidity gradually dominated, which offset or even surpass the liquid-phase reaction and formation
279 of secondary inorganic ions, causing the obvious and quick increase of particle pH. The SNA
280 contents exhibited its peak value when the AWC increased to about $380 \mu\text{g m}^{-3}$, then with the AWC
281 increasing, SNA contents decreased (Figure 6d). When $\text{AWC} > 380 \mu\text{g m}^{-3}$, along with the
282 increasing of AWC, a slowly increasing and gradually no significant growth of pH was found.

283 It was favored by the SNA-RH correlation coefficient variations with RH increasing (Figure 7b)
284 and relationship of AWC-RH (Figure 7c), SNA-AWC (Figure 7d) and pH-RH (Figure 7e). Lower
285 RH corresponded to lower AWC (Figure 7c). Under lower RH ($< \sim 0.48$) and AWC ($< \sim 15 \mu\text{g m}^{-3}$)

286 values, the AWC dilution effect on aerosol acidity was negligible, and the dry particle quickly
287 deliquesced and release H^+ , resulting in the decrease of pH. The weaker or even negative correlation
288 coefficient of SNA with RH was found when RH varied in 0.48- 0.75, accompanied with AWC and
289 pH quick increasing, which reflected that the dominated role of dilution effects of AWC. As
290 discussed above, SNA content reached its peak values when the AWC increased to about $380 \mu g m^{-3}$,
291 3 , with corresponding RH as about 0.75-0.90, reflecting active liquid phase reaction, and resulting
292 in buffering effect on pH increase. That might be the reason for the pH slowly growth when AWC
293 was at $\sim 380 \mu g m^{-3}$. Then when RH was higher than 0.95, with the corresponding AWC was greater
294 than $380 \mu g m^{-3}$, obviously negative correlation between RH and SNA was obtained ($R^2=0.59$, $p <$
295 0.05), and it implied the dominated role of buffering effect of AWC, which lead to the continuously
296 increasing of pH and gradually slowdown.

297 AWC is closely related to atmosphere temperature and relative humidity (RH) (Bian et al.,
298 2014). High RH can facilitate the production of secondary inorganic salt, which will again assimilate
299 more water because of hygroscopicity (Engelhart et al., 2011; Bian et al., 2014). However, in this
300 study the RH was higher in July, August and September, while corresponding AWC were nearly
301 the lowest (Figure 5), which may be resulted from the higher water evaporation from aerosol
302 (Bougiatioti et al., 2016) due to the high temperature in summer period. It could be seen there was
303 an exponential relationship between AWC and RH ($R^2 = 0.71$, $p < 0.05$) (Figure 6c). The correlation
304 coefficient of atmospheric RH and fine particle pH in Wuhan was 0.39 ($p < 0.05$) by polynomial
305 fitting (Figure 6e), showing that pH decreased with RH when RH was less than about ~ 0.48 , and
306 then pH increased with RH increasing when RH was higher than about 0.48. Atmospheric
307 temperature can also pose impacts on AWC and pH (Figure 6f). Generally, lower temperature was
308 corresponded to the higher AWC and pH values. When the temperature was higher than about 303
309 K (about $30^\circ C$), the AWC was all less than $\sim 380 \mu g m^{-3}$, and particles were more acidic. Figure 6e
310 also showed that there were no obvious relations between SNA/ $PM_{2.5}$ ratio with pH. It illustrated
311 that the particle acidity or pH could be affected by other components except for inorganics, such as
312 organics whose role in aerosol acidity can not be ignored (Wang et al., 2018).

313 Except for the AWC, RH and temperature, the excess ammonia or ammonium was also proved
314 to affect aerosol acidity (Liu et al., 2017). Different from southeastern US (Weber et al., 2016)
315 where the aerosols usually presented strong acid, the higher pH in this study was also likely related

316 with abundant ammonia and ammonium. As discussed above, the ammonium in Wuhan was at a
317 higher level in China.

318 Ammonium was the primary basic species to neutralize acid (Seinfeld and Pandis, 2006) and it
319 preferred to neutralize sulfate first, then reacted with nitrate when redundant, owing to the higher
320 salting out efficiency of SO_4^{2-} than NO_3^- (Pathak et al., 2004a). A critical molar ratio of NH_4^+ to
321 SO_4^{2-} was suggested as 1.5, implying SO_4^{2-} was completely neutralized and NO_3^- was stabilized by
322 NH_4^+ (Pathak et al., 2004b; Huang et al., 2011). When the $\text{NH}_4^+/\text{SO}_4^{2-}$ ratio was higher than 1.5, it
323 indicated an ammonia rich atmosphere, and the excess NH_4^+ could be calculated as:

$$324 \quad \text{excess } \text{NH}_4^+ = \left(\frac{[\text{NH}_4^+]}{[\text{SO}_4^{2-}]} - 1.5 \right) * [\text{SO}_4^{2-}] \quad (2)$$

325 In Figure 7a, the molar ratio of NH_4^+ to SO_4^{2-} in Wuhan mainly varied from 2:1 to 6:1, indicating
326 that SO_4^{2-} was completely neutralized and mainly presented in the form of $(\text{NH}_4)_2\text{SO}_4$. Along with
327 the increase of $\text{NH}_4^+/\text{SO}_4^{2-}$ ratio, NO_3^- production increased, and it preponderated SO_4^{2-} formation
328 The correlation coefficient between $\text{NH}_4^+/\text{SO}_4^{2-}$ and $\text{NO}_3^-/\text{SO}_4^{2-}$ in Wuhan was 0.85. In adequate
329 ammonium condition, excess NH_4^+ was well correlated with NO_3^- ($R^2 = 0.95$) (Figure 7b), which
330 was in consistency with previous studies (Pathak et al., 2009). The correlation of NH_4^+ with SO_4^{2-}
331 and NO_3^- can also be used to judge the rich or poor status of NH_4^+ , which was not obvious in poor
332 NH_4^+ condition (Kumar and Sunder Raman, 2016). In Wuhan, the positive significant correlation
333 between NH_4^+ vs SO_4^{2-} and NH_4^+ vs NO_3^- verified the NH_4^+ rich conditions. The excess ammonium
334 may be in the form of NH_4Cl , with the high correlation between NH_4^+ and Cl^- ($R^2 = 0.71$).

335 Figure 8a showed the relationship between ammonium neutralized pH (with no excess NH_4^+
336 case) and pH variation (ΔpH , difference between the presence and absence of excess NH_4^+). The
337 distinct negative correlation implied that higher aerosol acidity would be more susceptible by excess
338 NH_4^+ . Based on current excess NH_4^+ concentrations, simulating NH_4^+ decreased by 0.5, 1, 1.5, 2,
339 2.5 times of excess NH_4^+ , and increased by 1, 2, 3, 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30,
340 35, 40, 45 and 50 times of excess NH_4^+ . The predicted corresponding pH showed logarithmic growth
341 with total NH_x ($\text{NH}_3 + \text{NH}_4^+$), implying that the pH increase insensitive gradually with NH_x
342 increasing.

343 The NH_x concentrations of Wuhan were in the range of 2.27 - 48.3 $\mu\text{g m}^{-3}$, averaged as 19.2 μg
344 m^{-3} , which still located in the range for the rapid growth stage of pH (Figure 8b). It was verified by

345 the positive relationship between ΔpH and the excess NH_4^+ ($R^2 = 0.45$, $p < 0.05$). However, it was
346 different from the curve in Beijing which performed a logarithmic relationship (Liu et al., 2017).
347 The same excess NH_4^+ concentrations in Beijing and Wuhan exhibited different stage of pH change,
348 and higher excess NH_4^+ was afforded in Wuhan than Beijing for reaching the inflection point when
349 the excess NH_4^+ increasing held little influence on pH change. Thus, it again confirmed that the
350 aerosol acidity in Wuhan of Central China was impacted more by excess NH_4^+ than that of Beijing
351 in North China. Wang et al. (2016a) indicated that the increase of pH value will promote precursor
352 solubility and increase aqueous reaction rates, which will accelerate the formation of secondary
353 inorganic salts and aggravate air pollution, resulting in more severe haze. Therefore, it should be
354 emphasized that if the excess NH_4^+ in Wuhan was not controlled, the aerosol pH value will increase,
355 which would worsen the air quality.

356 **3.4 Aerosol acidity transition from clean to polluted periods**

357 The visibility less than 5 km, 5-10 km and higher than 10 km were defined as polluted period,
358 transition and clean period, respectively. The averaged visibility in Wuhan for the three episodes
359 were 3.78 ± 0.96 km, 7.56 ± 1.59 km and 17.7 ± 5.71 km, with averaged $\text{PM}_{2.5}$ concentrations as
360 136.4 , 85.0 and $45.9 \mu\text{g m}^{-3}$, respectively. The average pH value at the clean stage was 3.07 ± 0.45 ,
361 accompanied with low AWC ($33.2 \pm 42.9 \mu\text{g m}^{-3}$), low excess NH_4^+ ($3.70 \pm 2.15 \mu\text{g m}^{-3}$), high
362 temperature (296.1 ± 8.02 K) and relative low RH (0.70 ± 0.12). The averaged pH value at transition
363 period was 3.63 ± 0.27 , and the AWC, excess NH_4^+ , temperature, and RH were $115.1 \pm 79.4 \mu\text{g m}^{-3}$,
364 $9.04 \pm 3.67 \mu\text{g m}^{-3}$, 286.2 ± 6.45 K and 0.80 ± 0.12 , respectively. From clean to transition and
365 polluted periods, the aerosol pH values gradually increased with the increasing of AWC, excess
366 NH_4^+ , RH and the decreasing of temperature (Figure 9). From transition to polluted periods, the
367 aerosol pH value increased by 0.21 units, which was less than that from the clean to transition
368 periods (by 0.56 units). However, the increasing amounts of AWC from the transition to polluted
369 periods were higher than those from the clean to transition periods. It further verified that the effect
370 of AWC on aerosol acidity was not linear as mentioned above.

371 The O_3 concentrations were the lowest in polluted periods, indicating weak photochemical
372 activity (Wang et al., 2016a). Moreover, accompanied with high RH, aqueous reaction was the
373 dominated atmospheric reaction in polluted periods, resulting in the increasing of SOR (sulfur
374 oxidation rate), NOR (nitrogen oxidation rate) and AOR (ammonia conversion rate). High pH can

375 further accelerate the SOR, NOR and AOR rate. During the transition processes, no significant
376 correlations were found between mineral components (Ca^{2+} , Mg^{2+} , K^+ , and Na^+) and pH, implying
377 the impact of mineral components on aerosol acidity was negligible in Wuhan.

378 A conceptual schematic was proposed as Figure 10 shown, along with the air quality worsened
379 from clean to transition and to polluted situation, the fraction of second inorganic salts in $\text{PM}_{2.5}$,
380 AWC, excess NH_4^+ and the pH of fine particles all added. Excess NH_4^+ and SNA formation showed
381 steady growth from clean-transition-polluted. However, the AWC increase was more significant at
382 higher polluted periods and the temperature decreasing was more obvious at lower polluted periods.
383 The aerosol pH increasing unit from clean to transition episodes were larger than that for the
384 pollution transformation from the transition to polluted episodes. The conceptual model
385 comprehensively explained the role of ambient RH and temperature on the formation of SNA and
386 AWC calculating, and furthermore the pH variation during different pollution periods.

387 3.5 Aerosol acidity for different origination of air masses

388 In the study period, there were four main directions for the air masses transported to Wuhan,
389 namely northeast (C1), northwest (C2), south (C3) and west (C4), with the proportion of 24%, 16%,
390 57% and 4%, respectively (Figure 11). The aerosol acidity for C1 and C2 air masses were higher
391 than those of C3 and C4, and associated with lower values of AWC and excess NH_4^+ . The RH in
392 southern China was always higher than those in northern China for each season (Figure 4b). Air
393 masses from northwest mainly in winter were usually dry and saturated with small amounts of water,
394 resulting in low pH of aerosols. More moisture air from south mainly in summer elevated aerosol
395 pH value. Although there were minor air masses from the west to Wuhan, the pH for C4 was higher,
396 which may be resulted from the higher AWC for C4 (Figure 11) with higher RH (Figure 4b). The
397 amounts of excess NH_4^+ was in the order as $\text{C4} > \text{C3} > \text{C2} \approx \text{C1}$, and interestingly, the pH value
398 exhibited the similar rule, which further reflected the effect of excess NH_4^+ on aerosol acidity in
399 Central China. Cluster analysis in this section highlighted that the current conclusions drawn from
400 the research on aerosol acidity and its role in a typical haze formation event in North China could
401 be not suitable for that in Wuhan, which needs a further detailed and comprehensive study, along
402 with more chemical components investigated.

403 4. Conclusion

404 This study observed the hourly water-soluble inorganic ions from September 2015 to August

405 2016 in Wuhan. Thermodynamic model ISOROPPIA-II was used to calculate the aerosol acidity.
406 The seasonal and monthly aerosol acidity variation and its role in air pollution transition were
407 discussed, and the possible impacting factors were identified.

408 The mass fraction of SNA in total water-soluble inorganic ions and $PM_{2.5}$ were 92% and 64%
409 on average, respectively. Moderate acidic of fine particles in Wuhan was found, with the average of
410 pH as 3.30. The aerosol acidity was higher in July, August and September and lower in January and
411 March. The higher RH (averaged as 0.74 ± 0.13), excess ammonium (averaged as $6.06 \pm 4.51 \mu\text{g}$
412 m^{-3}) and abundant aerosol water content (averaged as $71.0 \pm 82.8 \mu\text{g} \text{m}^{-3}$) were the key reasons for
413 the lower aerosol acidity in Wuhan compared with other cities. At much lower AWC level (about
414 lower than $15 \mu\text{g} \text{m}^{-3}$), the particle pH showed a decreasing trend with AWC increased. Along with
415 the AWC continuous increasing ($> \sim 15 \mu\text{g} \text{m}^{-3}$), a logarithmic correlation was found between AWC
416 and aerosol pH. When AWC was higher than about $380 \mu\text{g} \text{m}^{-3}$, along with the further increasing of
417 AWC, a slowly increasing and gradually no obvious growth of pH was found. pH firstly decreased
418 with atmospheric RH increasing at lower RH values and then increased with RH increasing, with
419 the turning point of RH as about 0.48. Lower temperature was corresponded with higher AWC and
420 pH, and when the temperature was higher than 303 K (about $30 \text{ }^\circ\text{C}$), more acidic aerosols were
421 found.

422 There also was a logarithmic growth of particle pH with total NH_x ($\text{NH}_3 + \text{NH}_4^+$) increasing.
423 Aerosol in Wuhan belonged to the stage of pH rapid growth with ammonia or ammonium increasing.
424 It can be predicted that fine particles pH in Wuhan will continuously increase if the ammonia or
425 ammonium was not controlled effectively, and the increasing extent will be more obvious than that
426 in northern China. Aerosol acidity gradually decreased from clean to transition and to polluted
427 periods. Air masses originated from northeast and northwest directions with lower AWC and excess
428 NH_4^+ contributed to the higher acidic aerosol of Wuhan, while air masses from south and west
429 regions exhibited lower aerosol acidity, with more AWC and excess NH_4^+ carried.

430 This paper firstly analyzed the aerosol pH values with a one-year high time resolution dataset
431 at a megacity with specific location, meteorological and environmental conditions of Central China,
432 which is meaningful for understanding the aerosol acidity and its dominated impacting factors. It
433 also highlights the importance of controlling ammonia in Wuhan in aggravating air pollution, which
434 is helpful for other megacities surrounded by abundant agricultural activities in the world.

*: SNA= SO₄²⁻+ NO₃⁻+ NH₄⁺

Table 2. Statistic of meteorological parameters and main gaseous pollutant concentrations (average \pm standard deviation, $\mu\text{g m}^{-3}$) in Wuhan during September 2015 to August 2016.

Season	Spring	Summer	Fall	Winter	Average
Temp. (K)	291.4 \pm 4.4	303.6 \pm 3.9	292.3 \pm 6.6	280.7 \pm 3.2	292.2 \pm 9.0
RH (%)	73.1 \pm 13.5	74.8 \pm 9.2	75.1 \pm 11.5	74.0 \pm 16.9	74.3 \pm 12.9
HCl	0.74 \pm 0.36	1.09 \pm 0.29	0.32 \pm 0.14	0.34 \pm 0.12	0.61 \pm 0.40
HNO ₂	5.11 \pm 4.05	4.24 \pm 1.77	3.48 \pm 2.26	3.44 \pm 2.56	4.07 \pm 2.83
HNO ₃	2.82 \pm 1.28	3.19 \pm 0.71	1.85 \pm 1.0	1.80 \pm 0.96	2.39 \pm 1.18
NH ₃	11.0 \pm 5.45	12.64 \pm 3.19	7.22 \pm 3.3	4.59 \pm 2.87	8.88 \pm 4.89
SO ₂	12.8 \pm 9.3	4.7 \pm 2.9	14.7 \pm 8.1	14.5 \pm 12.8	11.9 \pm 9.6
NO ₂	37.6 \pm 15.1	22.9 \pm 9.9	39.5 \pm 15.8	44.9 \pm 18.9	36.5 \pm 17.0
O ₃ *	104.9 \pm 35.5	146.6 \pm 36.3	107.3 \pm 67.9	35.6 \pm 29.3	100.5 \pm 59.7
SOR	0.48 \pm 0.15	0.63 \pm 0.14	0.42 \pm 0.17	0.53 \pm 0.20	0.51 \pm 0.18
NOR	0.24 \pm 0.11	0.16 \pm 0.10	0.16 \pm 0.09	0.30 \pm 0.14	0.21 \pm 0.12
AOR	0.49 \pm 0.15	0.32 \pm 0.10	0.52 \pm 0.15	0.74 \pm 0.14	0.52 \pm 0.20

*: hourly average value was adopted.

RH: relative humidity.

SOR: sulfur oxidation rate, $\text{SOR} = \text{SO}_4^{2-} / (\text{SO}_4^{2-} + \text{SO}_2)$ (equivalent molar concentration)NOR: nitrogen oxidation rate, $\text{NOR} = \text{NO}_3^- / (\text{NO}_3^- + \text{NO}_2)$ (equivalent molar concentration).AOR: ammonia conversion rate, $\text{AOR} = \text{NH}_4^+ / (\text{NH}_4^+ + \text{NH}_3)$ (equivalent molar concentration).

Table 3. Comparison of fine particle acidity around the world

^{a, b}: submicron particle

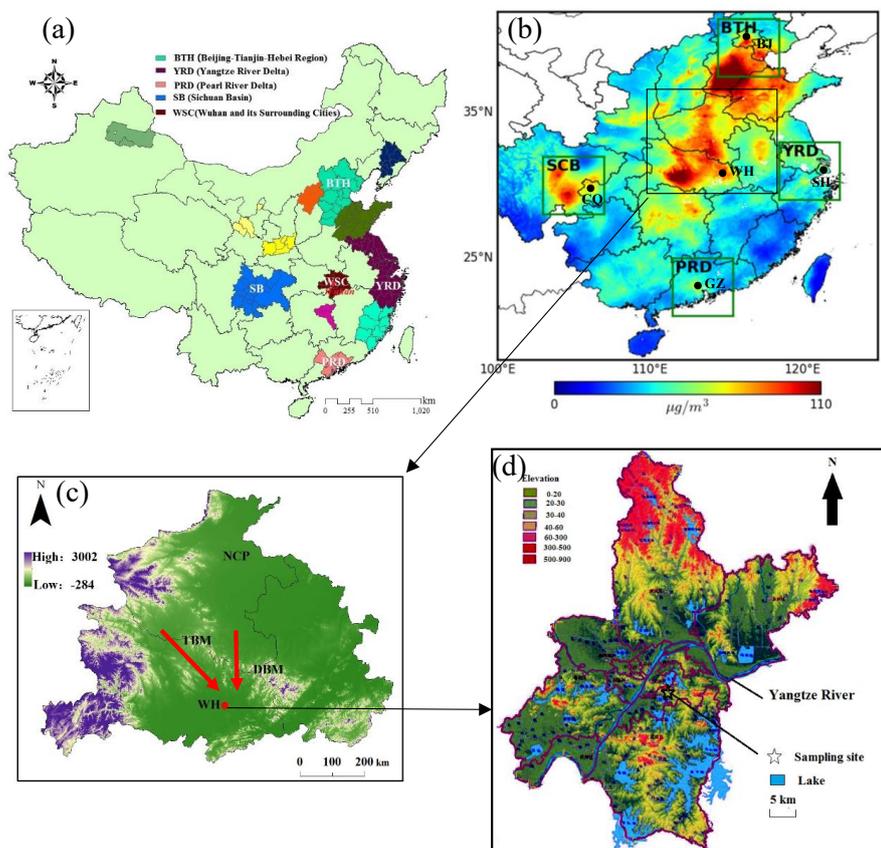

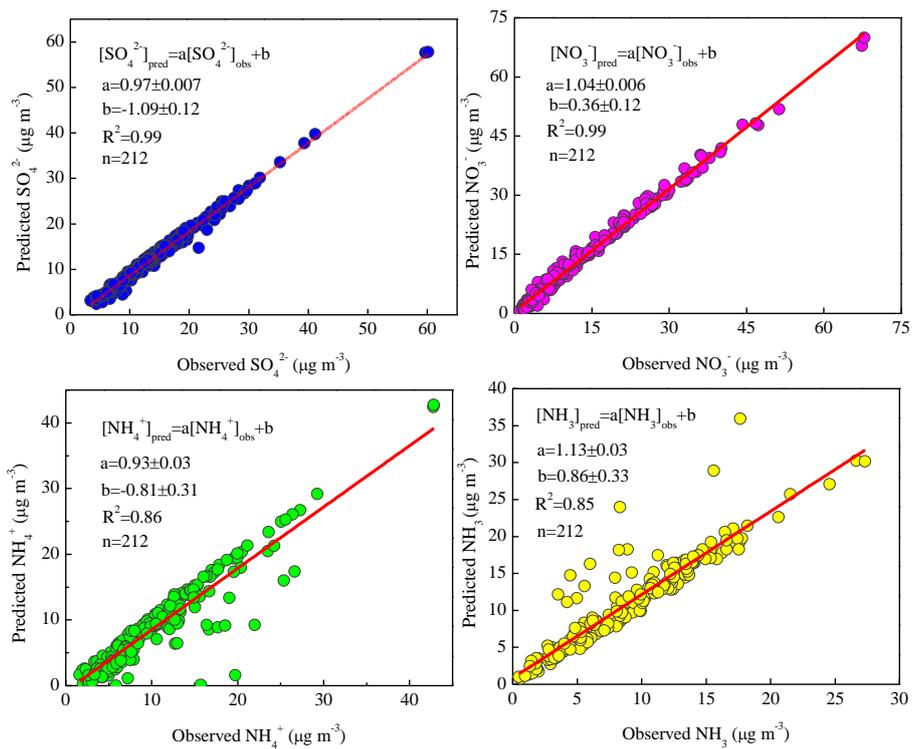

Figure 1 (a) Wuhan and its surrounding cities (WSC) belong to the key regions in the State Council's Action Plan on Prevention and Control of Atmospheric Pollution; (b) spatial distribution of the 15-year (2001-2015) mean $PM_{2.5}$ concentrations at a resolution of 1 km (Lin et al., 2018) (BTH-Beijing-Tianjin-Hebei region; YRD-Yangtze River Delta region; SCB-Sichuan Basin; PRD-Pearl River Delta region; BJ-Beijing; WH-Wuhan; SH-Shanghai; CQ-Chongqing; GZ-Guangzhou); (c) the topography of North China Plain (NCP) and surroundings of Wuhan (TBM-TongBai Mountain, DBM-Dabie Mountain). The two red lines indicate the typical transportation route of air masses in autumn and winter from NCP to Wuhan; (d) the topography of Wuhan, with the Yangtze River flowing from southwest to the northeast and abundant of lakes. The sampling site locates in the city center.

Figure 2 Comparisons of observed SO₄²⁻, NO₃⁻, NH₄⁺, and NH₃ with the predicted values by ISOROPPIA-II.

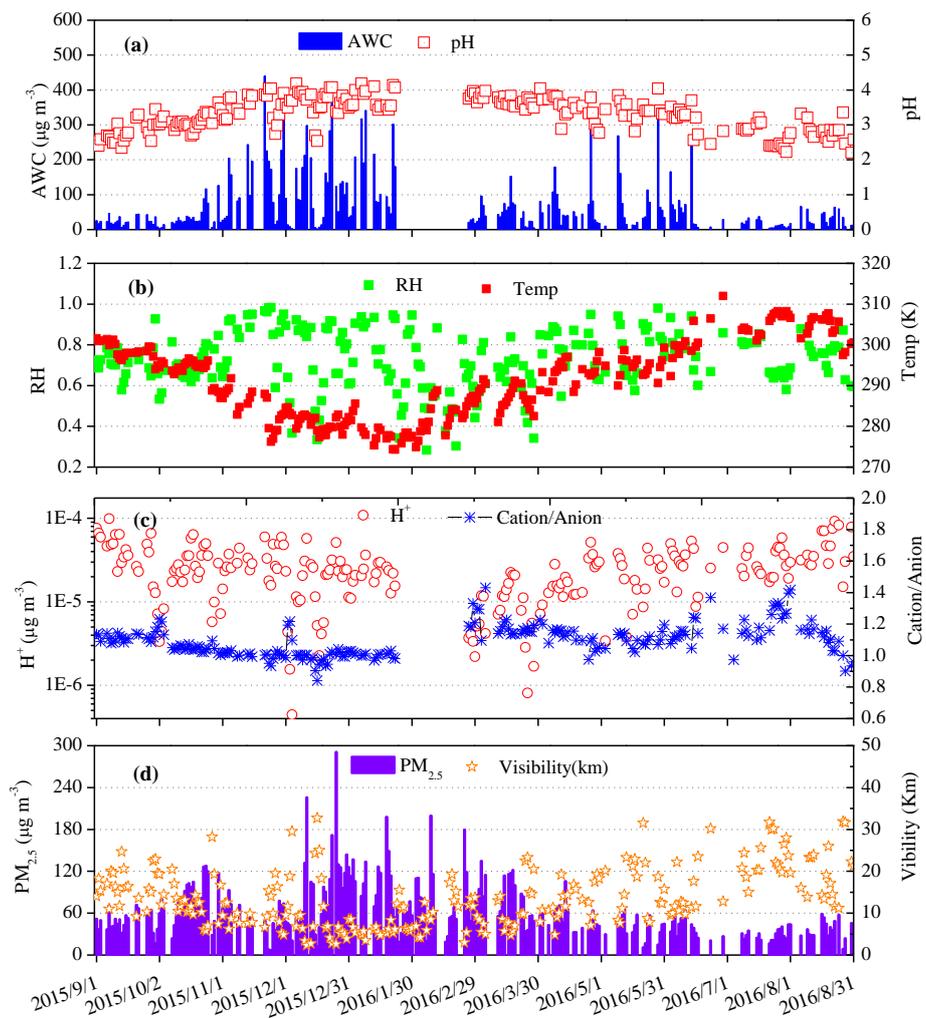

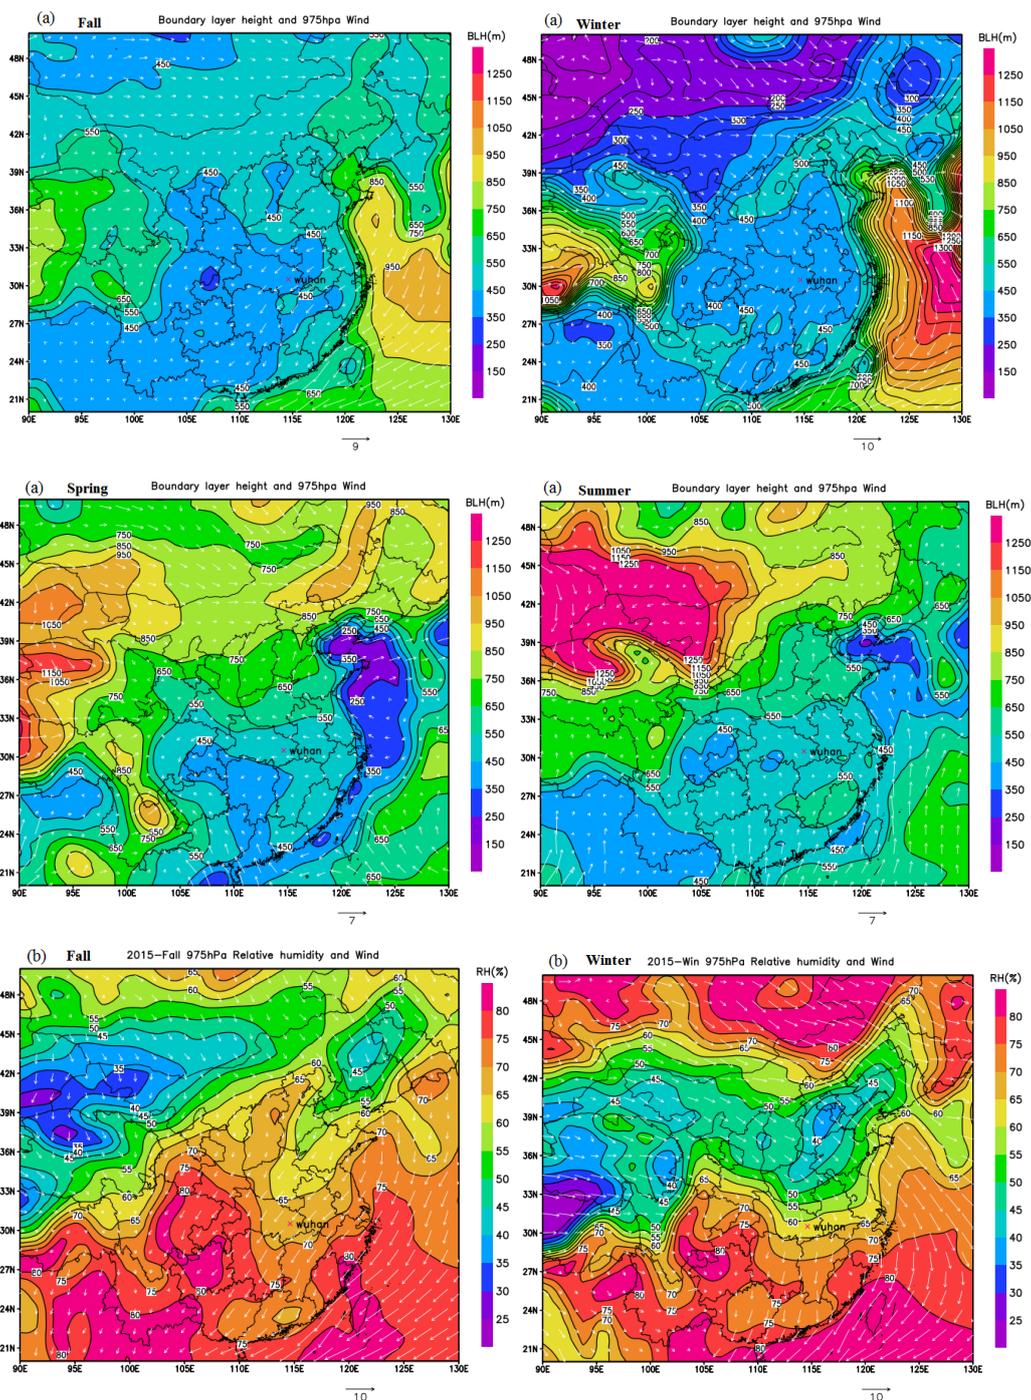

Figure 3 Daily variation of aerosol pH and AWC (a), RH and temperature (b), $[\text{H}^+]$ and cation/anion (c), $\text{PM}_{2.5}$ concentrations and visibility (d) in Wuhan from September 2015 to August 2016.

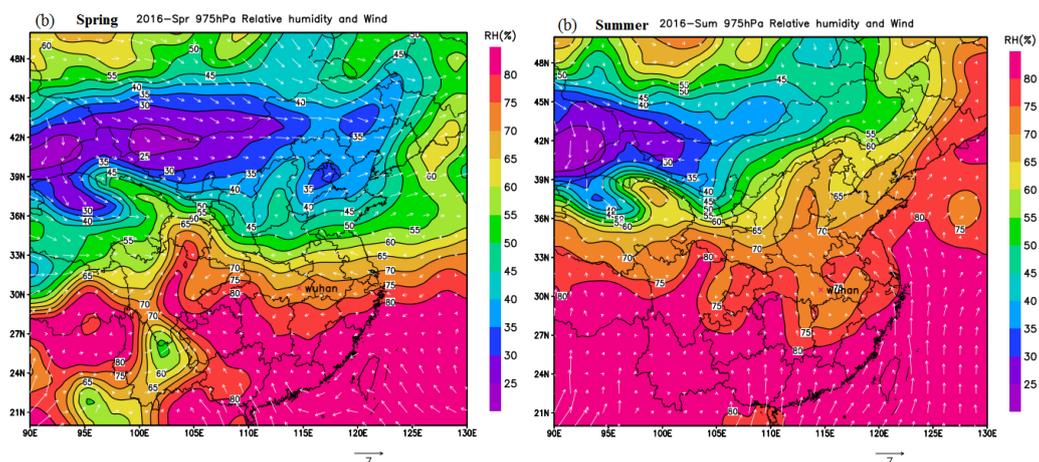

Figure 4 Atmospheric boundary layer height (a), relative humidity (b) and wind field in different seasons of Wuhan.

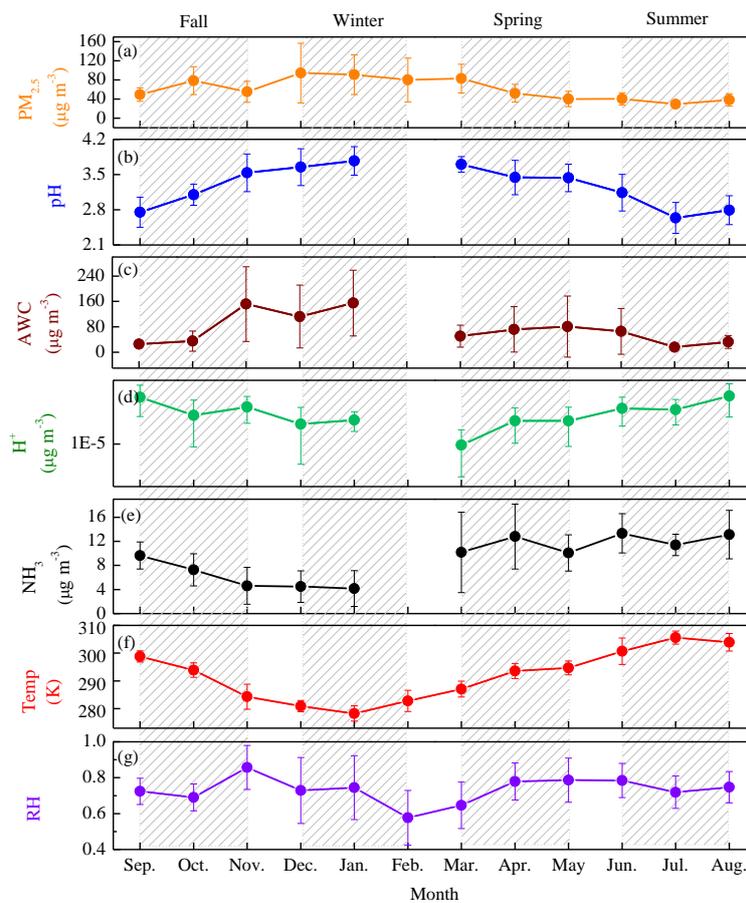

Figure 5 Monthly variation of PM_{2.5} concentrations (a), pH (b), AWC (c), [H⁺] (d), NH₃ (e), temperature (f), RH (g) in Wuhan during September 2015 to August 2016.

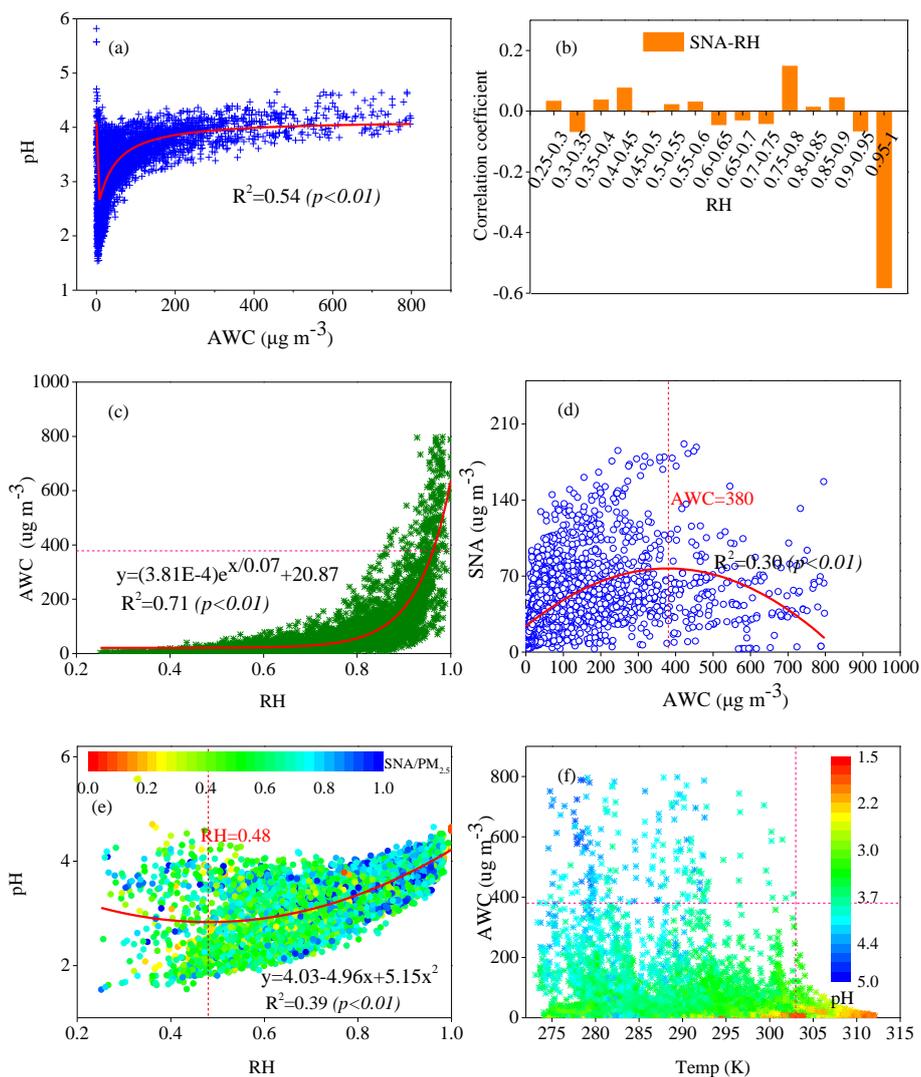

Figure 6 Relationship of pH with aerosol water content (AWC) (a), SNA-RH correlation coefficient with RH (b), AWC with RH (c), SNA with AWC (d), pH with RH (e), AWC with temperature (f) in Wuhan.

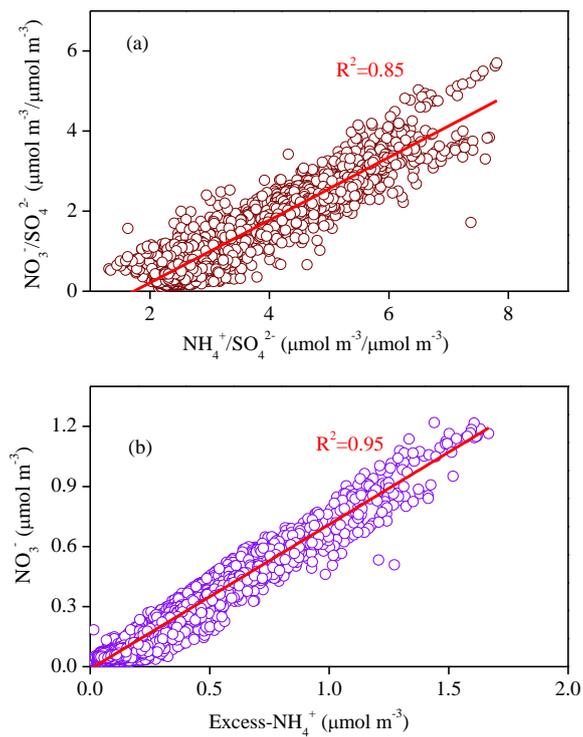

Figure 7 Relationship of $\text{NO}_3^-/\text{SO}_4^{2-}$ with $\text{NH}_4^+/\text{SO}_4^{2-}$ (a) and NO_3^- with excess- NH_4^+ (b).

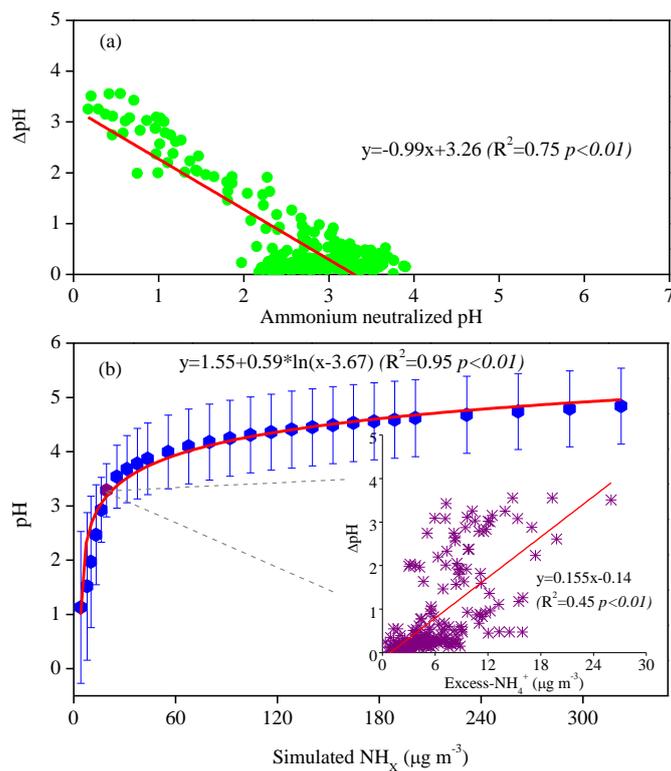

Figure 8 Relationship of pH changes (pH changes between presence and absence of excess NH_4^+) with ammonium neutralized pH (with no excess NH_4^+ case) (a); pH with simulated NH_x ($\text{NH}_x = \text{NH}_3 + \text{NH}_4^+$) (b), the special purple point in the logarithmic curve was the current state in Wuhan.

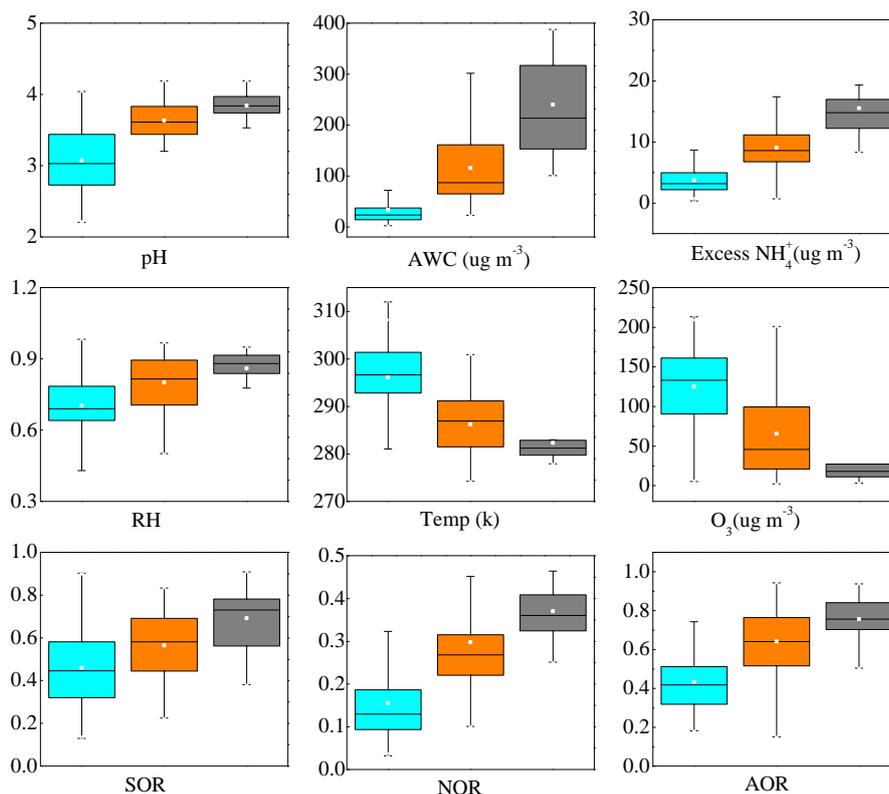

Figure 9 The pH, water content, excess NH_4^+ , meteorological parameters, ozone concentration, SOR (sulfur oxidation rate), NOR (nitrogen oxidation rate) and AOR (ammonia conversion rate) in different pollution episodes. The grey, orange and blue colors indicated the polluted (visibility less than 5 km), transition (visibility 5-10 km) and clean (visibility higher than 10 km) episodes, with the average $\text{PM}_{2.5}$ concentrations of 130, 80 and $42 \mu\text{g m}^{-3}$, respectively. The white dot in the box marks the mean value. The bottom and top vertical line correspond to the 5th and 95th percentiles, respectively. The bottom, middle and top of the horizontal lines of each box represent the 25th, 50th, and 75th percentiles of the data.

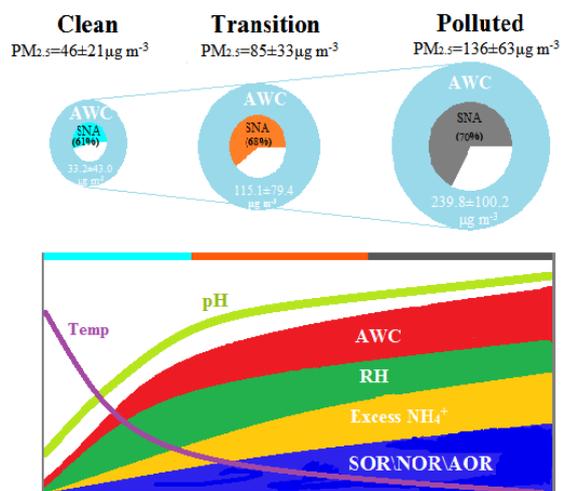

Figure 10 A conceptual schematic for the variations of fine particle mass concentrations and the driving factors impacted on aerosol pH along with the pollution aggravation.

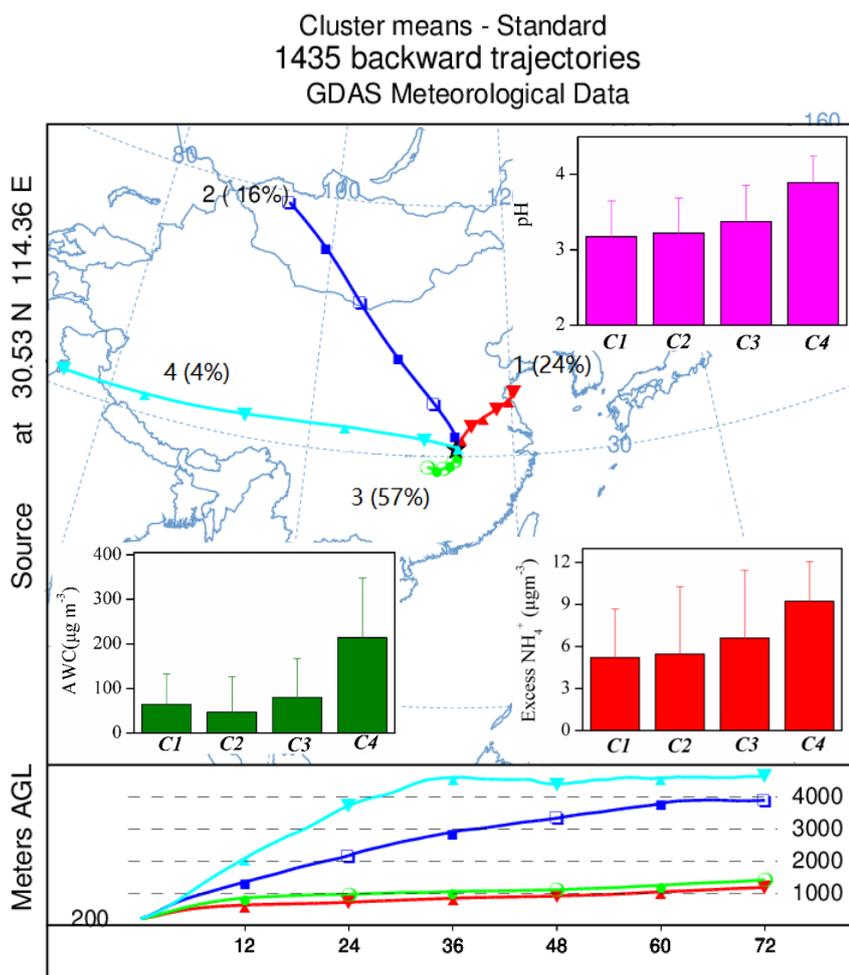

Figure 11 Backward trajectories for each cluster and corresponding pH, water content and excess NH_4^+ .
