29 **Abstract**

30 Atmospheric fine-particle (PM_{2.5}) pollution is frequently associated with the formation
31 of particulate nitrate (*p*NO₃⁻), the end product of the oxidation of NO_x gases (=NO+NO₂)
32 in the upper troposphere. The application of stable nitrogen (N) (and oxygen) isotope
33 analyses of *p*NO₃⁻ to constrain NO_x source partitioning in the atmosphere requires the
34 knowledge of the isotope fractionation during the reactions leading to nitrate formation.
35 Here we determined the δ¹⁵N values of fresh *p*NO₃⁻ (δ¹⁵N-*p*NO₃⁻) in PM_{2.5} at a rural site
36 in Northern China, where atmospheric *p*NO₃⁻ can be attributed exclusively to biomass
37 burning. The observed δ¹⁵N-*p*NO₃⁻ (12.17±1.55‰; n=8) was much higher than the N
38 isotopic source signature of NO_x from biomass burning (1.04±4.13‰). The large
39 difference between δ¹⁵N-*p*NO₃⁻ and δ¹⁵N-NO_x (Δ(δ¹⁵N)) can be reconciled by the net N
40 isotope effect (ε_N) associated with the gas-particle conversion from NO_x to NO₃⁻. For
41 the biomass-burning site, a mean ε_N (≈ Δ(δ¹⁵N)) of 10.99±0.74‰ was assessed through
42 a newly-developed computational quantum chemistry (CQC) module. ε_N depends on
43 the relative importance of the two dominant N isotope exchange reactions involved
44 (NO₂ reaction with OH versus hydrolysis of dinitrogen pentoxide (N₂O₅) with H₂O),
45 and varies between regions, and on a diurnal basis. A second, slightly higher CQC-
46 based mean value for ε_N (15.33±4.90‰) was estimated for an urban site with intense
47 traffic in Eastern China, and integrated in a Bayesian isotope mixing model to make
48 isotope-based source apportionment estimates for NO_x at this site. Based on the δ¹⁵N
49 values (10.93±3.32‰, n=43) of ambient *p*NO₃⁻ determined for the urban site, and
50 considering the location-specific estimate for ε_N, our results reveal that the relative
51 contribution of coal combustion and road traffic to urban NO_x are 32±11% and 68±11%,

52 respectively. This finding agrees well with a regional bottom-up emission inventory of
53 NO_x. Moreover, the variation pattern of OH contribution to ambient pNO₃⁻ formation
54 calculated by the CQC module is consistent with that simulated by the Weather
55 Research and Forecasting model coupled with Chemistry (WRF-Chem), further
56 confirming the robustness of our estimates. Our investigations also show that, without
57 the consideration of the N isotope effect during pNO₃⁻ formation, the observed δ¹⁵N-
58 pNO₃⁻ at the study site would erroneously imply that NO_x is derived almost entirely
59 from coal combustion. Similarly, reanalysis of reported δ¹⁵N-NO₃⁻ data throughout
60 China and its neighboring areas suggests that NO_x emissions from coal combustion may
61 be substantively overestimated (by >30%) when the N isotope fractionation during
62 atmospheric pNO₃⁻ formation is neglected.

63 **1 Introduction**

64 Nitrogen oxides (NO_x = NO + NO₂) are among the most important molecules in
65 tropospheric chemistry. They are involved in the formation of secondary aerosols and
66 atmospheric oxidants, such as ozone (O₃) and hydroxyl radicals (OH), which controls
67 the self-cleansing capacity of the atmosphere (Galloway et al., 2003; Seinfeld and
68 Pandis, 2012; Solomon et al., 2007). The sources of NO_x include both anthropogenic
69 and natural origins, with more than half of the global burden (~40 Tg N yr⁻¹) currently
70 attributed to fossil fuel burning (22.4-26.1 Tg N yr⁻¹) and the rest primarily derived
71 from nitrification/denitrification in soils (including wetlands; 8.9 ± 1.9 Tg N yr⁻¹),
72 biomass burning (5.8 ± 1.8 Tg N yr⁻¹), lightning (2-6 Tg N yr⁻¹), and oxidation of N₂O
73 in the stratosphere (0.1-0.6 Tg N yr⁻¹) (Jaegle et al., 2005; Richter et al., 2005; Lamsal
74 et al., 2011; Price et al., 1997; Yienger and Levy, 1995; Miyazaki et al., 2017; Duncan
75 et al., 2016; Anenberg et al., 2017; Levy et al., 1996). The main/ultimate sinks for
76 NO_x in the troposphere are the oxidation to nitric acid (HNO_{3(g)}) and the formation of
77 aerosol-phase particulate nitrate (pNO₃⁻) (Seinfeld and Pandis, 2012), the partitioning
78 of which may vary on diurnal and seasonal time scales (Morino et al., 2006).

79 Emissions of NO_x occur mostly in the form of NO (Seinfeld and Pandis, 2012; Leighton,

80 1961). During daytime, transformation from NO to NO₂ is rapid (few minutes) and
81 proceeds in a photochemical steady state, controlled by the oxidation of NO by O₃ to
82 NO₂, and the photolysis of NO₂ back to NO (Leighton, 1961):

86 where M is any non-reactive species that can take up the energy released to stabilize
87 O. NO_x oxidation to HNO₃ is governed by the following equations. During daytime:

89 and during nighttime:

93 HNO₃ then reacts with gas-phase NH₃ to form ammonium nitrate (NH₄NO₃) aerosols.
94 If the ambient relative humidity (RH) is lower than the efflorescence relative humidity
95 (ERH) or crystallization relative humidity (CRH), solid-phase NH₄NO₃(s) is formed
96 (Smith et al., 2012; Ling and Chan, 2007):

98 If ambient RH exceeds the ERH or CRH, HNO₃ and NH₃ dissolve into the aqueous
99 phase (aq) (Smith et al., 2012; Ling and Chan, 2007):

101 Whilst global NO_x emissions are well constrained, individual source attribution and
 102 their local or regional role in particulate nitrate formation are difficult to assess due to
 103 the short lifetime of NO_x (typically less than 24 hr), and the high degree of
 104 spatiotemporal heterogeneity with regards to the ratio between gas-phase HNO₃ and
 105 particulate NO₃⁻ (*p*NO₃⁻) (Duncan et al., 2016; Lu et al., 2015; Zong et al., 2017; Zhang
 106 et al., 2003). Given the conservation of the nitrogen (N) atom between NO_x sources and
 107 sinks, the N isotopic composition of *p*NO₃⁻ can be related to the different origins of the
 108 emitted NO_x, and thus provides valuable information on the partitioning of the NO_x
 109 sources (Morin et al., 2008). Such N isotope balance approach works best if the N
 110 isotopic composition of various NO_x sources display distinct ¹⁵N/¹⁴N ratios (reported
 111 as $\delta^{15}\text{N} = \frac{\left(\frac{^{15}\text{N}}{^{14}\text{N}}\right)_{\text{sample}} - \left(\frac{^{15}\text{N}}{^{14}\text{N}}\right)_{\text{N}_2}}{\left(\frac{^{15}\text{N}}{^{14}\text{N}}\right)_{\text{N}_2}} \times 1000$). The $\delta^{15}\text{N}$ -NO_x of coal-fired power
 112 plant (+10‰ to +25‰) (Felix et al., 2012; Heaton, 1990; Felix et al., 2013), vehicle
 113 (+3.7‰ to +5.7‰) (Heaton, 1990; Walters et al., 2015; Felix and Elliott, 2014; Felix et
 114 al., 2013; Wojtal et al., 2016), and biomass burning (-7‰ to +12‰) emissions (Fibiger
 115 and Hastings, 2016), for example, are generally higher than that of lightning (-0.5‰ to
 116 +1.4‰) (Hoering, 1957) and biogenic soil (-48.9‰ to -19.9‰) emissions (Li and Wang,
 117 2008; Felix and Elliott, 2014; Felix et al., 2013), allowing the use of isotope mixing
 118 models to gain insight on the NO_x source apportionment for gases, aerosols, as well as
 119 the resulting nitrate deposition (-15‰ to +15‰) (Elliott et al., 2007; Zong et al., 2017;
 120 Savarino et al., 2007; Morin et al., 2008; Elliott et al., 2009; Park et al., 2018; Altieri et
 121 al., 2013; Gobel et al., 2013). In addition, because of mass-independent fractionation
 122 during its formation (Thiemens, 1999; Thiemens and Heidenreich, 1983), ozone
 123 possesses a strong isotope anomaly ($\Delta^{17}\text{O} \approx \delta^{17}\text{O} - 0.52 \cdot \delta^{18}\text{O}$), which is propagated into
 124 the most short-lived oxygen-bearing species, including NO_x and nitrate. Therefore, the
 125 oxygen isotopic composition of nitrate ($\delta^{18}\text{O}$, $\Delta^{17}\text{O}$) can provide information on the
 126 oxidants involved in the conversion of NO_x to nitrate (Michalski et al., 2003; Geng et
 127 al., 2017). Knopf et al. (2006, 2011) and Shiraiwa et al. (2012) have shown that NO₃
 128 can be taken up efficiently by organic (e.g., levoglucosan) aerosol and may dominate

129 oxidation of aerosol in the polluted urban nighttime (Kaiser et al., 2011). Globally,
130 theoretical modeling results show that nearly 76%, 18%, and 4% of annual inorganic
131 nitrate are formed via pathways/reactions involving OH, N₂O₅, and dimethylsulfide
132 (DMS) or hydrocarbons (HC), respectively (e.g., Alexander et al., 2009). The stable O
133 isotopic composition of atmospheric nitrate is a powerful proxy for assessing which
134 oxidation pathways are important for converting NO_x into nitrate under changing
135 environmental conditions (e.g., polluted, volcanic events, climate change). In the same
136 line, in this study, the average $\delta^{18}\text{O}$ value of $p\text{NO}_3^-$ in Nanjing City was $83.0 \pm 11.2\text{‰}$
137 (see discussion later), suggesting that $p\text{NO}_3^-$ formation is dominated by the pathways
138 of “OH + NO₂” and the heterogeneous hydrolysis of N₂O₅.

139 $\delta^{15}\text{N}$ -based source apportionment of NO_x requires knowledge of how kinetic and
140 equilibrium isotope fractionation may impact $\delta^{15}\text{N}$ values during the conversion of NO_x
141 to nitrate (Freyer, 1978; Walters et al., 2016). If these isotope effects are considerable,
142 they may greatly limit the use of $\delta^{15}\text{N}$ values of $p\text{NO}_3^-$ for NO_x source partition (Walters
143 et al., 2016). Previous studies didn't take into account the potentially biasing effect of
144 N isotope fractionation, because they assumed that changes in the $\delta^{15}\text{N}$ values during
145 the conversion of NO_x to nitrate are minor (without detailed explanation) (Kendall et
146 al., 2007; Morin et al., 2008; Elliott et al., 2007) or relatively small (e.g., +3‰) (Felix
147 and Elliott, 2014; Freyer, 2017). However, a field study by Freyer et al. (1993) has
148 indicated that N isotope exchange may have a strong influence on the observed $\delta^{15}\text{N}$
149 values in atmospheric NO and NO₂, implying that isotope equilibrium fractionation
150 may play a significant role in shaping the $\delta^{15}\text{N}$ of NO_y species (the family of oxidized
151 nitrogen molecules in the atmosphere, including NO_x, NO₃, NO₃⁻, peroxyacetyl nitrate
152 etc.). The transformation of NO_x to nitrate is a complex process that involves several
153 different reaction pathways (Walters et al., 2016). To date, few fractionation factors for
154 this conversion have been determined. Recently, Walters and Michalski (2015) and
155 Walters et al. (2016) used computational quantum chemistry methods to calculate N
156 isotope equilibrium fractionation factors for the exchange between major NO_y
157 molecules and confirmed theoretical predictions that ¹⁵N isotopes enrich in the more

158 oxidized form of NO_y , and that the transformation of NO_x to atmospheric nitrate (HNO_3 ,
159 NO_3 (aq), NO_3 (g)) continuously increases the $\delta^{15}\text{N}$ in the residual NO_x pool.

160 As a consequence of its severe atmospheric particle pollution during the cold season,
161 China has made great efforts toward reducing NO_x emissions from on-road traffic (e.g.,
162 improving emission standards, higher gasoline quality, vehicle travel restrictions) (Li
163 et al., 2017). Moreover, China has continuously implemented denitrogenation
164 technologies (e.g., selective catalytic reduction or SCR) in the coal-fired power plants
165 sector since the mid-2000s, and has been phasing out small inefficient units (Liu et al.,
166 2015). Monitoring and assessing the efficiency of such mitigation measures, and
167 optimizing policy efforts to further reduce NO_x emissions, requires knowledge of the
168 vehicle- and power plant-emitted NO_x to particulate nitrate in urban China (Ji et al.,
169 2015; Fu et al., 2013; Zong et al., 2017). In this study, the chemical components of
170 ambient fine particles ($\text{PM}_{2.5}$) were quantified, and the isotopic composition of
171 particulate nitrate ($\delta^{15}\text{N}\text{-NO}_3^-$, $\delta^{18}\text{O}\text{-NO}_3^-$) was assessed in order to elucidate ambient
172 NO_x sources in Nanjing City of Eastern China. We also investigated the potential
173 isotope effect during the formation of nitrate aerosols from NO_x , and evaluated how
174 disregard of such N isotope fractionation can bias N-isotope mixing model-based
175 estimates on the NO_x source apportionment for nitrate deposition.

176 **2 Methods**

177 **2.1 Field sampling**

178 In this study, $\text{PM}_{2.5}$ aerosol samples were collected on precombusted (450 °C for 6 hr)
179 quartz filters (25 × 20 cm) on a day/night basis, using high-volume air samplers at a
180 flow rate of 1.05 $\text{m}^3 \text{min}^{-1}$ in Sanjiang and Nanjing (Fig. 1). After sampling, the filters
181 were wrapped in aluminum foil, packed in air-tight polyethylene bags and stored at -
182 20 °C prior to further processing and analysis. Four blank filters were also collected.
183 They were exposed for 10 min to ambient air (i.e., without active sampling). $\text{PM}_{2.5}$ mass
184 concentration was analyzed gravimetrically (Sartorius MC5 electronic microbalance)

185 with a $\pm 1 \mu\text{g}$ precision before and after sampling (at 25°C and $45 \pm 5\%$ during
186 weighing).

187

188 **Figure 1.**

189

190 The Sanjiang campaign was performed during a period of intensive burning of
191 agricultural residues between October 8 and 18, 2013, to examine if there is any
192 significant difference between the $\delta^{15}\text{N}$ values of $p\text{NO}_3^-$ and NO_x emitted from biomass
193 burning. The Sanjiang site (in the following abbreviated as SJ; 47.35°N , 133.31°E) is
194 located at an ecological experimental station affiliated with the Chinese Academy of
195 Sciences located in the Sanjiang Plain, a major agricultural area predominantly run by
196 state farms in Northeastern China (Fig. 1). Surrounded by vast farm fields and bordering
197 Far-Eastern Russia, SJ is situated in a remote and sparsely populated region, with a
198 harsh climate and rather poorly industrialized economy. The annual mean temperature
199 at SJ is close to the freezing point, with daily minima ranging between -31 and -15°C
200 in the coldest month January. As a consequence of the relatively low temperatures (also
201 during summer), biogenic production of NO_x through soil microbial processes is rather
202 weak. SJ is therefore an excellent environment where to collect biomass burning-
203 emitted aerosols with only minor influence from other sources.

204 The Nanjing campaign was conducted between 17 December 2014 and 8 January 2015
205 with the main objective to examine whether N isotope measurements can be used as a
206 tool to elucidate NO_x source contributions to ambient $p\text{NO}_3^-$ during times of severe
207 haze. Situated in the lower Yangtze River region, Nanjing is, after Shanghai, the second
208 largest city in Eastern China. The aerosol sampler was placed at the rooftop of a building
209 on the Nanjing University of Information Science and Technology campus (in the
210 following abbreviated as NJ; 18 m a.g.l.; 32.21°N , 118.72°E ; Fig. 1), where NO_x
211 emissions derive from both industrial and transportation sources.

212 2.2 Laboratory analysis

213 The mass concentrations of inorganic ions (including SO_4^{2-} , NO_3^- , Cl^- , NH_4^+ , K^+ , Ca^{2+} ,
214 Mg^{2+} , and Na^+), carbonaceous components (organic carbon or OC, elemental carbon or
215 EC), and water-soluble organic carbon or WSOC were determined using an ion
216 chromatograph (761 Compact IC, Metrohm, Switzerland), a thermal/optical OC/EC
217 analyzer (RT-4 model, Sunset Lab. Inc., USA), and a TOC analyzer (Shimadzu, TOC-
218 VCSH, Japan), respectively. Importantly, levoglucosan, a molecular marker for the
219 biomass combustion aerosols was detected using a DionexTM ICS-5000⁺ system
220 (Thermo Fisher Scientific, Sunnyvale, USA). Chemical aerosol analyses, including
221 sample pre-treatment, analytical procedures, protocol adaption, detection limits, and
222 experimental uncertainty were described in detail in our previous work (Cao et al., 2016;
223 Cao et al., 2017).

224 For isotopic analyses of aerosol nitrate, aerosol subsamples were generated by punching
225 1.4-cm disks out of the filters. In order to extract the NO_3^- , sample discs were placed in
226 acid-washed glass vials with 10 ml deionized water and placed in an ultra-sonic water
227 bath for 30 min. Between one and four disks were used for NO_x extraction, dependent
228 on the aerosol NO_3^- content on the filters, which was determined independently. The
229 extracts were then filtered (0.22 μm) and analyzed the next day. N and O isotope
230 analyses of the extracted/dissolved aerosol nitrate ($^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$) were performed
231 using the denitrifier method (Sigman et al., 2001; Casciotti et al., 2002). Briefly, sample
232 NO_3^- is converted to nitrous oxide (N_2O) by denitrifying bacteria that lack N_2O
233 reductase activity (*Pseudomonas chlororaphis* ATCC# 13985; formerly *Pseudomonas*
234 *aureofaciens*, referred to below as such). N_2O is extracted, purified, and analyzed for
235 its N and O isotopic composition using a continuous-flow isotope ratio mass
236 spectrometer (Thermo Finnigan Delta⁺, Bremen, German). Nitrate N and O isotope
237 ratios are reported in the conventional δ -notation with respect to atmospheric N_2 and
238 standard mean ocean water (V-SMOW) respectively. Analyses are calibrated using the
239 international nitrate isotope standard IAEA-N3, with a $\delta^{15}\text{N}$ value of 4.7‰ and a $\delta^{18}\text{O}$

240 value of 25.6‰ (Böhlke et al., 2003). The blank contribution was generally lower than
241 0.2 nmol (as compared to 20 nmol of sample N). Based on replicate measurements of
242 standards and samples, the analytical precision for $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ was generally better
243 than $\pm 0.2\text{‰}$ and $\pm 0.3\text{‰}$ (1σ), respectively.

244 The denitrifier method generates $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ values of the combined pool of NO_3^-
245 and NO_2^- . The presence of substantial amounts of NO_2^- in NO_3^- samples may lead to
246 errors with regards to the analysis of $\delta^{18}\text{O}$ (Wankel et al., 2010). We refrained from
247 including a nitrite-removal step, because nitrite concentrations in our samples were
248 always $< 1\%$ of the NO_3^- concentrations. In the following $\delta^{15}\text{N}_{\text{NO}_x}$ and $\delta^{18}\text{O}_{\text{NO}_x}$ are thus
249 referred to as nitrate $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ (or $\delta^{15}\text{N}_{\text{NO}_3}$ and $\delta^{18}\text{O}_{\text{NO}_3}$).

250 In the case of atmospheric/aerosol nitrate samples with comparatively high $\delta^{18}\text{O}$ values,
251 $\delta^{15}\text{N}$ values tend to be overestimated by 1-2‰ (Hastings et al., 2003), if the contribution
252 of $^{14}\text{N}^{14}\text{N}^{17}\text{O}$ to the N_2O mass 45 signal is not accounted for during isotope ratio
253 analysis. For most natural samples, the mass-dependent relationship can be
254 approximated as $\delta^{17}\text{O} \approx 0.52 \times \delta^{18}\text{O}$, and the $\delta^{18}\text{O}$ can be used for the ^{17}O correction.
255 Atmospheric NO_3^- does not follow this relationship but inhabits a mass-independent
256 component. Thus, we adopted a correction factor of 0.8 instead of 0.52 for the ^{17}O to
257 ^{18}O linearity (Hastings et al., 2003).

258 **2.3 Calculation of N isotope fractionation value (ϵ_N)**

259 As we described above, the transformation process of NO_x to $\text{HNO}_3/\text{NO}_3^-$ involves
260 multiple reaction pathways (see also Fig. S1) and is likely to undergo isotope
261 equilibrium exchange reactions. The measured $\delta^{15}\text{N}-\text{NO}_3^-$ values of aerosol samples are
262 thus reflective of the combined N isotope signatures of various NO_x sources ($\delta^{15}\text{N}-\text{NO}_x$)
263 plus any given N isotope fractionation. Recently, Walter and Michalski (2015) used a
264 computational quantum chemistry approach to calculate isotope exchange fractionation
265 factors for atmospherically relevant NO_y molecules, and based on this approach, Zong
266 et al. (2017) estimated the N isotope fractionation during the transformation of NO_x to

267 $p\text{NO}_3^-$ at a regional background site in China. Here we adopt, and slightly modify, the
 268 approach by Walter and Michalski (2015) and Zong et al. (2017), and assumed that the
 269 net N isotope effect ε_N (for equilibrium processes $A \leftrightarrow B$: $\varepsilon_{A \leftrightarrow B} =$
 270 $\left(\frac{(\text{heavy isotope/light isotope})_A}{(\text{heavy isotope/light isotope})_B} - 1 \right) \cdot 1000\text{‰}$; ε_N refers to $\varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)}$ in this
 271 study unless otherwise specified) during the gas-to-particle conversion from NO_x to
 272 $p\text{NO}_3^-$ formation ($\Delta(\delta^{15}\text{N})_{p\text{NO}_3^-, \text{NO}_x} = \delta^{15}\text{N}-p\text{NO}_3^- - \delta^{15}\text{N}-\text{NO}_x \approx \varepsilon_N$) can be considered
 273 a hybrid of the isotope effects of two dominant N isotopic exchange reactions:

$$\begin{aligned}
 \varepsilon_N &= \gamma \times \varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}} + (1 - \gamma) \times \varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}} \\
 &= \gamma \times \varepsilon_{N(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{OH}}} + (1 - \gamma) \times \varepsilon_{N(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{H}_2\text{O}}}
 \end{aligned} \quad (1)$$

275 where γ represents the contribution from isotope fractionation by the reaction of NO_x
 276 and photo-chemically produced OH to form HNO_3 (and $p\text{NO}_3^-$), as shown by
 277 $\varepsilon_{N(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{OH}}}$ ($\varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}}$). The remainder is formed by the hydrolysis of N_2O_5
 278 with aerosol water to generate HNO_3 (and $p\text{NO}_3^-$), namely, $\varepsilon_{N(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{H}_2\text{O}}}$
 279 ($\varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}}$). Assuming that kinetic N isotope fractionation associated with the
 280 reaction between NO_x and OH is negligible, $\varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}}$ can be calculated based on
 281 mass-balance considerations:

$$\begin{aligned}
 \varepsilon_{N(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}} &= \varepsilon_{N(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{OH}}} = \varepsilon_{N(\text{NO}_2 \leftrightarrow \text{HNO}_3)_{\text{OH}}} \\
 &= 1000 \times \left[\frac{({}^{15}\alpha_{\text{NO}_2/\text{NO}} - 1)(1 - f_{\text{NO}_2})}{(1 - f_{\text{NO}_2}) + ({}^{15}\alpha_{\text{NO}_2/\text{NO}} \times f_{\text{NO}_2})} \right]
 \end{aligned} \quad (2)$$

283 where ${}^{15}\alpha_{\text{NO}_2/\text{NO}}$ is the temperature-dependent (see equation 7 and Table S1)
 284 equilibrium N isotope fractionation factor between NO_2 and NO , and f_{NO_2} is the
 285 fraction of NO_2 in the total NO_x . f_{NO_2} ranges from 0.2 to 0.95 (Walters and
 286 Michalski, 2015). Similarly, assuming a negligible kinetic isotope fractionation

287 associated with the reaction $\text{N}_2\text{O}_5 + \text{H}_2\text{O} + \text{aerosol} \rightarrow 2\text{HNO}_3$, $\epsilon_{\text{N}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}}$ can be
 288 computed from the following equation:

$$\begin{aligned}
 \epsilon_{\text{N}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}} &= \epsilon_{\text{N}(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{H}_2\text{O}}} = \\
 \epsilon_{\text{N}(\text{NO}_x \leftrightarrow \text{N}_2\text{O}_5)_{\text{H}_2\text{O}}} &= 1000 \times \left({}^{15}\alpha_{\text{N}_2\text{O}_5/\text{NO}_2} - 1 \right) \quad (3)
 \end{aligned}$$

290 where ${}^{15}\alpha_{\text{N}_2\text{O}_5/\text{NO}_2}$ is the equilibrium isotope fractionation factor between N_2O_5 and
 291 NO_2 , which also is temperature-dependent (see equation 7 and Table S1).

292 Following Walter and Michalski (2015) and Zhong et al. (2017), γ can then be
 293 approximated based on the O isotope fractionation during the conversion of NO_x to
 294 $p\text{NO}_3^-$:

$$\begin{aligned}
 \epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)} &= \gamma \times \epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}} + (1 - \gamma) \times \epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}} \quad (4) \\
 &= \gamma \times \epsilon_{\text{O}(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{OH}}} + (1 - \gamma) \times \epsilon_{\text{O}(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{H}_2\text{O}}}
 \end{aligned}$$

296 where $\epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}}$ and $\epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}}$ represent the O isotope effects associated
 297 with $p\text{NO}_3^-$ generation through the reaction of NO_x and OH to form HNO_3 , and the
 298 hydrolysis of N_2O_5 on a wetted surface to form HNO_3 , respectively. $\epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}}$ can
 299 be further expressed as:

$$\begin{aligned}
 \epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{OH}}} &= \epsilon_{\text{O}(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{OH}}} = \frac{2}{3} \epsilon_{\text{O}(\text{NO}_2 \leftrightarrow \text{HNO}_3)_{\text{OH}}} + \frac{1}{3} \epsilon_{\text{O}(\text{NO} \leftrightarrow \text{HNO}_3)_{\text{OH}}} \\
 &= \frac{2}{3} \left[\frac{1000 \left({}^{18}\alpha_{\text{NO}_2/\text{NO}} - 1 \right) (1 - f_{\text{NO}_2})}{(1 - f_{\text{NO}_2}) + \left({}^{18}\alpha_{\text{NO}_2/\text{NO}} \times f_{\text{NO}_2} \right)} + \left(\delta^{18}\text{O-NO}_x \right) \right] + \\
 &\quad \frac{1}{3} \left[\left(\delta^{18}\text{O-H}_2\text{O} \right) + 1000 \left({}^{18}\alpha_{\text{OH}/\text{H}_2\text{O}} - 1 \right) \right] \quad (5)
 \end{aligned}$$

301 and $\epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}}$ can be determined as follows:

302 $\epsilon_{\text{O}(\text{NO}_x \leftrightarrow p\text{NO}_3^-)_{\text{H}_2\text{O}}} = \epsilon_{\text{O}(\text{NO}_x \leftrightarrow \text{HNO}_3)_{\text{H}_2\text{O}}} = \frac{5}{6}(\delta^{18}\text{O}-\text{N}_2\text{O}_5) + \frac{1}{6}(\delta^{18}\text{O}-\text{H}_2\text{O})$ (6)

303 where $^{18}\alpha_{\text{NO}_2/\text{NO}}$ and $^{18}\alpha_{\text{OH}/\text{H}_2\text{O}}$ represent the equilibrium O isotope fractionation
 304 factors between NO_2 and NO , and OH and H_2O , respectively. The range of $\delta^{18}\text{O}-\text{H}_2\text{O}$
 305 can be approximated using an estimated tropospheric water vapor $\delta^{18}\text{O}$ range of -25‰-
 306 0‰. The $\delta^{18}\text{O}$ values for NO_2 and N_2O_5 range from 90‰ to 122‰ (Zong et al. 2017).

307 $^{15}\alpha_{\text{NO}_2/\text{NO}}$ and $^{15}\alpha_{\text{N}_2\text{O}_5/\text{NO}_2}$, $^{18}\alpha_{\text{NO}_2/\text{NO}}$ and $^{18}\alpha_{\text{OH}/\text{H}_2\text{O}}$ in these equations, are dependent
 308 on the temperature, which can be expressed as:

309 $1000(^m\alpha_{X/Y} - 1) = \frac{A}{T^4} \times 10^{10} + \frac{B}{T^3} \times 10^8 + \frac{C}{T^2} \times 10^6 + \frac{D}{T} \times 10^4$ (7)

310 where A, B, C, and D are experimental constants (Table S1) over the temperature range
 311 of 150-450 K (Walters and Michalski, 2015; Walters et al., 2016; Walters and Michalski,
 312 2016; Zong et al., 2017).

313 Based on Equations 4-7 and measured values for $\delta^{18}\text{O}-p\text{NO}_3^-$ of ambient $\text{PM}_{2.5}$, a Monte
 314 Carlo simulation was performed to generate 10000 feasible solutions. The error
 315 between predicted and measured $\delta^{18}\text{O}$ was less than 0.5‰. The range (maximum and
 316 minimum) of computed contribution ratios (γ) were then integrated in Equation 1 to
 317 generate an estimate range for the nitrogen isotope effect ϵ_N (using Equations 2-3).
 318 $\delta^{15}\text{N}-p\text{NO}_3^-$ values can be calculated based on ϵ_N and the estimated $\delta^{15}\text{N}$ range for
 319 atmospheric NO_x , (see section 2.4).

320 **2.4 Bayesian isotope mixing model**

321 Isotopic mixing models allow estimating the relative contribution of multiple sources
 322 (e.g., emission sources of NO_x) within a mixed pool (e.g., ambient $p\text{NO}_3^-$). By explicitly
 323 considering the uncertainty associated with the isotopic signatures of any given source,
 324 as well as isotope fractionation during the formation of various components of a mixture,
 325 the application of Bayesian methods to stable isotope mixing models generates robust

326 probability estimates of source proportions, and are often more appropriate when
327 targeting natural systems than simple linear mixing models (Chang et al., 2016a). Here
328 the Bayesian model MixSIR (a stable isotope mixing model using sampling-
329 importance-resampling) was used to disentangle multiple NO_x sources by generating
330 potential solutions of source apportionment as true probability distributions, which has
331 been widely applied in a number of fields (e.g., Parnell et al., 2013; Phillips et al., 2014;
332 Zong et al., 2017). Details on the model frame and computing methods are given in SI
333 Text S1.

334 Here, coal combustion ($13.72 \pm 4.57\%$), transportation ($-3.71 \pm 10.40\%$), biomass
335 burning ($1.04 \pm 4.13\%$), and biogenic emissions from soils ($-33.77 \pm 12.16\%$) were
336 considered to be the most relevant contributors of NO_x (Table S2 and Text S2). The
337 $\delta^{15}\text{N}$ of atmospheric NO_x is unknown. However, it can be assumed that its range in the
338 atmosphere is constrained by the $\delta^{15}\text{N}$ of the NO_x sources and the $\delta^{15}\text{N}$ of *p*NO₃⁻ after
339 equilibrium fractionation conditions have been reached. Following Zong et al. (2017),
340 $\delta^{15}\text{N}$ -NO_x in the atmosphere was determined performing iterative model simulations,
341 with a simulation step of 0.01 times the equilibrium fractionation value based on the
342 $\delta^{15}\text{N}$ -NO_x values of the emission sources (mean and standard deviation) and the
343 measured $\delta^{15}\text{N}$ -*p*NO₃⁻ of ambient PM_{2.5} (Fig. S2).

344 **3 Results**

345 **3.1 Sanjiang in Northern China**

346 The $\delta^{15}\text{N}$ -*p*NO₃⁻ and $\delta^{18}\text{O}$ -*p*NO₃⁻ values of the eight samples collected from the
347 Sanjiang biomass burning field experiment, ranged from 9.54 to 13.77‰ (mean:
348 12.17‰) and 57.17 to 75.09‰ (mean: 63.57‰), respectively. In this study, atmospheric
349 concentrations of levoglucosan quantified from PM_{2.5} samples collected near the sites
350 of biomass burning in Sanjiang vary between 4.0 and 20.5 μg m⁻³, two to five orders of
351 magnitude higher than those measured during non-biomass burning season (Cao et al.,
352 2017; Cao et al., 2016). Levoglucosan is an anhydrosugar formed during pyrolysis of

353 cellulose at temperatures above 300 °C (Simoneit, 2002). Due to its specificity for
354 cellulose combustion, it has been widely used as a molecular tracer for biomass burning
355 (Simoneit et al., 1999; Liu et al., 2013a; Jedynska et al., 2014; Liu et al., 2014). Indeed,
356 the concentrations of levoglucosan and aerosol nitrate in Sanjiang were highly
357 correlated ($R^2 = 0.64$; Fig. 2a), providing compelling evidence that particulate nitrate
358 measured during our study period was predominately derived from biomass burning
359 emissions.

360 **3.2 Nanjing in Eastern China**

361 The mass concentrations ($mean_{min}^{max} \pm 1\sigma, n = 43$) of $PM_{2.5}$ and pNO_3^- measured in Nanjing
362 City were $122.1_{39.0}^{227.8} \pm 47.9$ and $17.8_{4.0}^{45.2} \pm 10.3$ $\mu g m^{-3}$, respectively. All $PM_{2.5}$
363 concentrations exceeded the Chinese Air Quality Standard for daily $PM_{2.5}$ ($35 \mu g m^{-3}$),
364 suggesting severe haze pollution during the sampling period. The corresponding $\delta^{15}N$ -
365 pNO_3^- values (raw data without correction) ranged between 5.39‰ and 17.99‰,
366 indicating significant enrichment in ^{15}N relative to rural and coastal marine atmospheric
367 NO_3^- sources (Table S4). This may be due to the prominent contribution of fossil fuel-
368 related NO_x emissions with higher $\delta^{15}N$ values in urban areas (Elliott et al., 2007; Park
369 et al., 2018).

370 **4 Discussion**

371 **4.1 Sanjiang campaign: theoretical calculation and field validation of N isotope** 372 **fractionation during pNO_3^- formation**

373 To be used as a quantitative tracer of biomass-combustion-generated aerosols,
374 levoglucosan must be conserved during its transport from its source, without partial
375 removal by reactions in the atmosphere (Hennigan et al., 2010). The mass
376 concentrations of non-sea-salt potassium ($nss-K^+ = K^+ - 0.0355*Na^+$) is considered as
377 an independent/additional indicator of biomass burning (Fig. 2b). The association of
378 elevated levels of levoglucosan with high $nss-K^+$ concentrations underscores that the

379 two compounds derived from the same proximate sources, and that thus aerosol
380 levoglucosan in Sanjiang was indeed pristine and represented a reliable source indicator
381 that is unbiased by altering processes in the atmosphere. Moreover, in our previous
382 work (Cao et al., 2017), we observed that there was a much greater enhancement of
383 atmospheric NO_3^- compared to SO_4^{2-} (a typical coal-related pollutant). This additionally
384 points to biomass burning, and not coal-combustion, as the dominant $p\text{NO}_3^-$ source in
385 the study area, making SJ and ideal “quasi single source” environment for calibrating
386 the N isotope effect during $p\text{NO}_3^-$ formation.

387

388

Figure 2.

389

390 Our $\delta^{18}\text{O}-p\text{NO}_3^-$ values are well within the broad range of values in previous reports
391 (Zong et al., 2017; Geng et al., 2017; Walters and Michalski, 2016). However, as
392 depicted in Fig. 3, the $\delta^{15}\text{N}$ values of biomass burning-emitted NO_3^- fall within the
393 range of $\delta^{15}\text{N}-\text{NO}_x$ values typically reported for emissions from coal combustion,
394 whereas they are significantly higher than the well-established values for $\delta^{15}\text{N}-\text{NO}_x$
395 emitted from the burning of various types of biomass (mean: $1.04 \pm 4.13\text{‰}$, ranging
396 from -7 to $+12\text{‰}$) (Fibiger and Hastings, 2016). Turekian et al. (1998) conducted
397 laboratory tests involving the burning of eucalyptus and African grasses, and
398 determined that the $\delta^{15}\text{N}$ of $p\text{NO}_3^-$ (around 23‰) was 6.6‰ higher than the $\delta^{15}\text{N}$ of the
399 burned biomass. This implies significant N isotope partitioning during biomass burning.
400 In the case of complete biomass combustion, by mass balance, the first gaseous
401 products (i.e., NO_x) have the same $\delta^{15}\text{N}$ as the biomass. Hence any discrepancy between
402 the $p\text{NO}_3^-$ and the $\delta^{15}\text{N}$ of the biomass can be attributed to the N isotope fractionation
403 associated with the partial conversion of gaseous NO_x to aerosol NO_3^- . Based on the
404 computational quantum chemistry (CQC) module calculations, the N isotope
405 fractionation ε_{N} ($mean_{\text{min}}^{\text{max}} \pm 1\sigma$) determined from the Sanjiang data was

406 $10.99_{10.30}^{12.54} \pm 0.74\%$. After correcting the primary $\delta^{15}\text{N-}p\text{NO}_3^-$ values under the
407 consideration of ϵ_{N} , the resulting mean $\delta^{15}\text{N}$ of $1.17_{-1.89}^{2.98} \pm 1.95\%$ is very close to the
408 N isotopic signature expected for biomass burning-emitted NO_x ($1.04 \pm 4.13\%$) (Fig.
409 3) (Fibiger and Hastings, 2016). The much higher $\delta^{15}\text{N-}p\text{NO}_3^-$ values in our study
410 compared to reported $\delta^{15}\text{N-NO}_x$ values for biomass burning can easily be reconciled
411 when including N isotope fractionation during the conversion of NO_x to NO_3^- . Put
412 another way, given that Sanjiang is an environment where we can essentially exclude
413 NO_x sources other than biomass burning at the time of sampling, the data nicely validate
414 our CQC module-based approach to estimate ϵ_{N} .

415

416

Figure 3.

417

418 **4.2 Source apportionment of NO_x in an urban setting using a Bayesian isotopic** 419 **mixing model**

420 Due to its high population density and intensive industrial production, the Nanjing
421 atmosphere was expected to have high NO_x concentrations derived from road traffic
422 and coal combustion (Zhao et al., 2015). However, the raw $\delta^{15}\text{N-}p\text{NO}_3^-$ values ($10.93 \pm$
423 3.32%) fell well within the variation range of coal-emitted $\delta^{15}\text{N-NO}_x$ (Fig. 3). It is
424 tempting to conclude that coal combustion is the main, or even sole, $p\text{NO}_3^-$ source
425 (given the equivalent $\delta^{15}\text{N}$ values), yet, this is very unlikely. The data rather confirm
426 that significant isotope fractionation occurred during the conversion of NO_x to NO_3^-
427 and that, without consideration of the N isotope effect, traffic-related NO_x emissions
428 will be markedly underestimated.

429 In the atmosphere, the oxygen atoms of NO_x rapidly exchanged with O_3 in the NO/NO_2
430 cycle (see equations R₁-R₃) (Hastings et al., 2003), and the $\delta^{18}\text{O-}p\text{NO}_3^-$ values are
431 determined by its production pathways (R₄-R₇), rather than the sources of NO_x

432 (Hastings et al., 2003). Thus, $\delta^{18}\text{O-}p\text{NO}_3^-$ can be used to gain information on the
433 pathway of conversion of NO_x to nitrate in the atmosphere (Fang et al., 2011). In the
434 computational quantum chemistry module used here to calculate isotope fractionation,
435 we assumed that two-thirds of the oxygen atoms in NO_3^- derive from O_3 and one-third
436 from $\bullet\text{OH}$ in the $\bullet\text{OH}$ generation pathway (R_4) (Hastings et al., 2003); correspondingly,
437 five sixths of the oxygen atoms then derived from O_3 and one sixth from $\bullet\text{OH}$ in the
438 $\text{O}_3/\text{H}_2\text{O}$ pathway ($\text{R}_5\text{-R}_7$). The assumed range for $\delta^{18}\text{O-O}_3$ and $\delta^{18}\text{O-H}_2\text{O}$ values were
439 90‰-122‰ and -25‰-0‰, respectively (Zong et al., 2017). The partitioning between
440 the two possible pathways was then assessed through Monte Carlo simulation (Zong et
441 al., 2017). The estimated range was rather broad, given the wide range of $\delta^{18}\text{O-O}_3$ and
442 $\delta^{18}\text{O-H}_2\text{O}$ values used. Nevertheless, the theoretical calculation of the average
443 contribution ratio (γ) for nitrate formation in Nanjing via the reaction of NO_2 and $\bullet\text{OH}$
444 is consistent with the results from simulations using the Weather Research and
445 Forecasting model coupled with Chemistry (WRF-Chem) (Fig. 4; see Text S3 for
446 details). A clear diurnal cycle of the mass concentration of nitrate formed through $\bullet\text{OH}$
447 oxidation of NO_2 can be observed (Fig. S3), with much higher concentrations between
448 12:00 and 18:00, This indicates the importance of photochemically produced $\bullet\text{OH}$
449 during daytime. Yet, throughout our sampling period in Nanjing, the average $p\text{NO}_3^-$
450 formation by the heterogeneous hydrolysis of N_2O_5 ($12.6 \mu\text{g m}^{-3}$) exceeded $p\text{NO}_3^-$
451 formation by the reaction of NO_2 and $\bullet\text{OH}$ ($4.8 \mu\text{g m}^{-3}$), even during daytime, consistent
452 with recent observations during peak pollution periods in Beijing (Wang et al., 2017).
453 Given that the production rates of N_2O_5 in the atmosphere is governed by ambient O_3
454 concentrations, reducing atmospheric O_3 levels appears to be one of the utmost
455 important measures to take for mitigating $p\text{NO}_3^-$ pollution in China's urban
456 atmospheres.

457

458

Figure 4.

459

460 In Nanjing, dependent on the time-dependent, dominant $p\text{NO}_3^-$ formation pathway, the
461 average N isotope fractionation value calculated using the computational quantum
462 chemistry module varied between 10.77‰ and 19.34‰ (15.33‰ on average). Using
463 the Bayesian model MixSIR, the contribution of each source can be estimated, based
464 on the mixed-source isotope data under the consideration of prior information on the
465 site (see Text S1 for detailed information regarding model frame and computing
466 method). As described above, theoretically, there are four major sources, i.e., road
467 traffic, coal combustion, biomass burning, and biogenic soil, potentially contributing to
468 ambient NO_x . As a start, we tentatively integrated all four sources into MixSIR (data
469 not shown). The relative contribution of biomass burning to the ambient NO_x (median
470 value) ranged from 28% to 70% (average 42%), representing the most important source.
471 The primary reason for such apparently high contribution by biomass burning is that
472 the corrected $\delta^{15}\text{N}-p\text{NO}_3^-$ values of $-4.29_{-10.32}^{0.42} \pm 3.66\text{‰}$ are relatively close to the N
473 isotopic signature of biomass burning-emitted NO_x ($1.04 \pm 4.13\text{‰}$) compared to the
474 other possible sources. Based on $\delta^{15}\text{N}$ alone, the isotope approach can be ambiguous if
475 there are more than two sources. The N isotope signature of NO_x from biomass burning
476 falls right in between the spectrum of plausible values, with highest $\delta^{15}\text{N}$ for emissions
477 from coal combustion on the one end, and much lower values for automotive and soil
478 emissions on the other, and will be similar to a mixed signature from coal combustion
479 and NO_x emissions from traffic.

480 We can make several evidence-based pre-assumption to better constrain the emission
481 sources in the mixing model analysis: (1) sampling at a typical urban site in a major
482 industrial city in China, we can assume that the sources of road traffic and coal
483 combustion are dominant, while the contribution of biogenic soil to ambient NO_x
484 should have minimal impact, or can be largely neglected (Zhao et al., 2015); (2) there
485 is no crop harvest activity in Eastern China during the winter season. Furthermore,
486 deforestation and combustion of fuelwood has been discontinued in China's major
487 cities (Chang et al., 2016a). Therefore, the contribution of biomass burning-emitted
488 NO_x during the sampling period should also be minor. Indeed, Fig. S4 shows that the

489 mass concentration of biomass burning-related $p\text{NO}_3^-$ is not correlated with the fraction
490 of levoglucosan that contributes to OC, confirming a weak impact of biomass burning
491 on the variation of $p\text{NO}_3^-$ concentration during our study period.

492 In a second, alternative, and more realistic scenario, we excluded biomass burning and
493 soil as potential source of NO_x in MixSIR (see above). As illustrated in Fig. 5a,
494 assuming that NO_x emissions in urban Nanjing during our study period originated
495 solely from road traffic and coal combustion, their relative contribution to the mass
496 concentration of $p\text{NO}_3^-$ is $12.5 \pm 9.1 \mu\text{g m}^{-3}$ (or $68 \pm 11\%$) and $4.9 \pm 2.5 \mu\text{g m}^{-3}$ (or 32
497 $\pm 11\%$), respectively. These numbers agree well with a city-scale NO_x emission
498 inventory established for Nanjing recently (Zhao et al., 2015). Nevertheless, on a
499 nation-wide level, relatively large uncertainties with regards to the overall fossil fuel
500 consumption and fuel types propagate into large uncertainties of NO_x concentration
501 estimates and predictions of longer-term emission trends (Li et al., 2017). Current
502 emission-inventory estimates (Jaegle et al., 2005; Zhang et al., 2012; Liu et al., 2015;
503 Zhao et al., 2013) suggest that in 2010 NO_x emissions from coal-fired power plants in
504 China were about 30% higher than those from transportation. However, our isotope-
505 based source apportionment of NO_x clearly shows that in 2014 the contribution from
506 road traffic to NO_x emissions, at least in Nanjing (a city that can be considered
507 representative for most densely populated areas in China) is twice that of coal
508 combustion. In fact, due to changing economic activities, emission sources of air
509 pollutants in China are changing rapidly. For example, over the past several years,
510 China has implemented an extended portfolio of plans to phase out its old-fashioned
511 and small power plants, and to raise the standards for reducing industrial pollutant
512 emissions (Chang, 2012). On the other hand, China continuously experienced double-
513 digit annual growth in terms of auto sales during the 2000s, and in 2009 it became the
514 world's largest automobile market (Liu et al., 2013b; Chang et al., 2017; Chang et al.,
515 2016b). Recent satellite-based studies successfully analyzed the NO_x vertical column
516 concentration ratios for megacities in Eastern China and highlighted the importance of
517 transportation-related NO_x emissions (Reuter et al., 2014; Gu et al., 2014; Duncan et

518 al., 2016; Jin et al., 2017). Moreover, long-term measurements of the ratio of NO_3^-
519 versus non-sea-salt SO_4^{2-} in precipitation and aerosol jointly revealed a continuously
520 increasing trend in Eastern China throughout the latest decade, suggesting decreasing
521 emissions from coal combustion (Liu et al., 2013b; Itahashi et al., 2017). Both coal
522 combustion- and road traffic-related $p\text{NO}_3^-$ concentrations are highly correlated with
523 their corresponding tracers (i.e., SO_2 and CO , respectively), confirming the validity of
524 our MixSIR modelling results. With justified confidence in our Bayesian isotopic model
525 results, we conclude that previous estimates of NO_x emissions from
526 automotive/transportation sources in China based on bottom-up emission inventories
527 may be too low.

528

529

Figure 5.

530

531 3.3 Previous $\delta^{15}\text{N}\text{-NO}_3^-$ based estimates on NO_x sources

532 Stable nitrogen isotope ratios of nitrate have been used to identify nitrogen sources in
533 various environments in China, often without large differences in $\delta^{15}\text{N}$ between
534 rainwater and aerosol NO_3^- (Kojima et al., 2011). In previous work, no consideration
535 was given to potential N isotope fractionation during atmospheric $p\text{NO}_3^-$ formation.
536 Here, we reevaluated 700 data points of $\delta^{15}\text{N}\text{-NO}_3^-$ in aerosol ($-0.77 \pm 4.52\text{‰}$, $n = 308$)
537 and rainwater ($3.79 \pm 6.14\text{‰}$, $n = 392$) from 13 sites that are located in the area of
538 mainland China and the Yellow and East and South China Seas (Fig. 1), extracted from
539 the literature (see SI Table S4 for details). To verify the potentially biasing effects of
540 neglecting N isotope fractionation (i.e. testing the sensitivity of ambient NO_x source
541 contribution estimates to the effect of N isotope fractionation), the Bayesian isotopic
542 mixing model was applied a) to the original NO_3^- isotope data set and b) to the corrected
543 nitrate isotope data set, accounting for the N isotope fractionation during NO_x
544 transformation. All 13 sampling sites are located in non-urban areas; therefore, apart

545 from coal combustion and on-road traffic, the contributions of biomass burning and
546 biogenic soil to nitrate needs to be taken into account.

547 Although most of the sites are located in rural and coastal environments, using the
548 original data set without the consideration of N isotope fractionation in the Bayesian
549 isotopic mixing model, fossil fuel-related NO_x emissions (coal combustion and on-road
550 traffic) appear as the largest contributor at all the sites (data are not shown). This is
551 particularly true for coal combustion: Everywhere, except for the sites of Dongshan
552 Islands and Mt. Lumin, NO_x emissions seem to be dominated by coal combustion. Very
553 high contribution from coal combustion (on the order of 40-60%) particularly in
554 Northern China may be plausible, and can be attributed to a much larger consumption
555 of coal. Yet, rather unlikely, the highest estimated contribution of coal combustion (83%)
556 was calculated for Beihuang Island (a full-year sampling at a costal island that is 65 km
557 north of Shandong Peninsula and 185 km east of the Beijing-Tianjin-Hebei region) and
558 not for mainland China. While Beihuang may be an extreme example, we argue that,
559 collectively, the contribution of coal combustion to ambient NO_x in China as calculated
560 on the basis of isotopic analyses in previous studies without the consideration of N
561 isotope fractionation represent overestimates.

562 As a first step towards a more realistic assessment of the actual partitioning of NO_x
563 sources in China in general (and coal combustion-emitted NO_x in particular), it is
564 imperative to determine the location-specific values for ϵ_N . Unfortunately, without
565 $\delta^{18}\text{O}-\text{NO}_3^-$ data in hand, as well as data on meteorological parameters that correspond
566 to the 700 $\delta^{15}\text{N}-\text{NO}_3^-$ values used in our meta-analysis, it is not possible to estimate the
567 ϵ_N values through the above-mentioned CQC module. As a viable alternative, we
568 adopted the approximate values for ϵ_N as estimated in Sanjiang (10.99‰) and Nanjing
569 ($15.33 \pm 4.90\%$). As indicated in Fig. 6, the estimates on the source partitioning is
570 sensitive to the choice of ϵ_N . Whereas with increasing ϵ_N , estimates on the relative
571 contribution of on-road traffic and biomass burning remained relatively stable;
572 estimates for coal combustion and biogenic soil changed significantly, in opposite

573 directions. More precisely, depending on ϵ_N , the average estimate of the fractional
574 contribution of coal combustion decreased drastically from 43% ($\epsilon_N = 0\text{‰}$) to 5% (ϵ_N
575 = 20‰) (Fig. 6), while the contribution from biogenic soil to NO_x emissions increased
576 in a complementary way. Given the lack of better constraints on ϵ_N for the 13 sampling
577 sites, it cannot be our goal here to provide a robust revised estimate on the partitioning
578 of NO_x sources throughout China and its neighboring areas. But we have very good
579 reasons to assume that disregard of N isotope fractionation during $p\text{NO}_3^-$ formation in
580 previous isotope-based source apportionment studies has likely led to overestimates of
581 the relative contribution of coal combustion to total NO_x emissions in China. For what
582 we would consider the most conservative estimate, i.e. lowest calculated value for the
583 N isotope fractionation during the transformation of NO_x to $p\text{NO}_3^-$ ($\epsilon_N = 5\text{‰}$), the
584 approximate contribution from coal combustion to the NO_x pool would be 28%, more
585 than 30% less than N isotope mixing model-based estimates would yield without
586 consideration of the N isotope fractionation (i.e., $\epsilon_N = 0\text{‰}$) (Fig. 6).

587

589

590

591 **4 Conclusion and outlook**

592 Consistent with theoretical predictions, $\delta^{15}\text{N}$ - $p\text{NO}_3^-$ data from a field experiment where
593 atmospheric $p\text{NO}_3^-$ formation could be attributed reliably to NO_x from biomass burning
594 only, revealed that the conversion of NO_x to $p\text{NO}_3^-$ is associated with a significant net
595 N isotope effect (ϵ_N). It is imperative that future studies, making use of isotope mixing
596 models to gain conclusive constraints on the source partitioning of atmospheric NO_x ,
597 will consider this N isotope fractionation. The latter will change with time and space,
598 depending on the distribution of ozone and OH radicals in the atmosphere and the

609 predominant NO_x chemistry. The O-isotope signatures of $p\text{NO}_3^-$ is mostly chemistry-
610 (and not source) driven (modulated by O-isotope exchange reactions in the atmosphere),
611 and thus, O isotope measurements do not allow addressing the ambiguities with regards
612 to the NO_x source that may remain when just looking at $\delta^{15}\text{N}$ values alone. However,
613 $\delta^{18}\text{O}$ in $p\text{NO}_3^-$ will help assessing the relative importance of the dominant $p\text{NO}_3^-$
614 formation pathway. Simultaneous $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ measurements of atmospheric nitrate
615 thus allow reliable information on ϵ_{N} , and in turn on the relative importance of single
616 NO_x sources. For example, for Nanjing, which can be considered representative for
617 other large cities in China, dual-isotopic and chemical-tracer evidence suggest that on-
618 road traffic and coal-fired power plants, rather than biomass burning, are the
619 predominant sources during high-haze pollution periods. Given that the increasing
620 frequency of nitrate-driven haze episodes in China, our findings are critically important
621 in terms of guiding the use of stable nitrate isotope measurements to evaluate the
622 relative importance of single NO_x sources on regional scales, and for adapting suitable
623 mitigation measures. Future assessments of NO_x emissions in China (and elsewhere)
624 should involve simultaneous $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ measurements of atmospheric nitrate and
625 NO_x at high spatiotemporal resolution, allowing us to more quantitatively reevaluate
626 former N-isotope based NO_x source partitioning estimates.

617 **Competing interests**

618 The authors declare that they have no competing interests.

619 **Data availability**

620 Data are available from the corresponding author on request. We prefer not to publish
621 the software of calculating the nitrogen isotope fractionation factor and estimating
622 nitrate source attribution at the present stage in order to avoid compromising the future
623 of ongoing software registration. Readers can download the software through the
624 website atmosgeochem.com after the finish of software registration.
