# **Author's Response**

**1. Comment:** Please do not abbreviate these locations in the text. It greatly harms the readability. The number of instances of these phrases is not so high as to make the manuscript problematically longer. If you want to use these abbreviations in figures and/or tables, that would be more acceptable.

10

Reply: All the unnecessary and improper abbreviations are modified.

**2. Comment:** I think it would be better if you presented all of the data in this section as a figure rather than numbers. Your goal is to compare values, which is very difficult to do from the text. Also, I suggest you use more than ranges to convince the reader that location A is different from location B. Ranges don't use all the data in an effective manner, and are subject to problems with outliers. You could report mean (or median), and 1 and 2 standard deviations of the measurements, for instance. Or percentiles of the distribution of values. I think pretty much anything is better than a pure range. In other words, supplement figure 5 with one or two more figures that lead the reader to the conclusion you desire. Remove most, if not all, of the numbers from this paragraph. It's a very ineffective mode of communication.

**Reply:** We rewrote the chapter 3.3 and chose the mean values and standard deviations to compare the differences between various sources (Line 7-24 in Page 7 and Line 1-6 in Page 8). According to your suggestion, we added two figures in Figure 5.

Figure 5. Frequency distribution of  $\chi_{lf}$  (a, c), bivariate plots of  $\chi_{lf}$  and  $\chi_{fd}$  (b, d) and average values and standard deviations of  $\chi_{lf}$  and  $\chi_{fd}$  (e, f) of NSS in each source and urban dust aerosols, including AD, STD and AP. Frequency distribution statistics of  $\chi_{lf}$  for NSS, AD and STD, and AP were generated using intervals of  $10 \times 10^{-8}$  m<sup>3</sup> kg<sup>-1</sup>,  $100 \times 10^{-8}$  m<sup>3</sup> kg<sup>-1</sup> and  $200 \times 10^{-8}$  m<sup>3</sup> kg<sup>-1</sup>, respectively.

5 **3.** Comment: This is a poor topic sentence for this section. First, mineralogy isn't determined from images, but on spectroscopy. Second, the title of the section is about morphology and mineralogy. You need to edit this beginning section

(Lines 17 in Page 8). Why does this matter? You should use whatever magnification necessary to generate the appropriate data (Lines 18 in Page 8).

**Reley:** We corrected the sentence to "SEM provides morphology information based on gray-scale intensity. The elemental composition is determined by the EDS detector. In order to compare the morphology and mineralogy characteristic of different dust sources, more than 40 fields of views of the representative bulk samples were randomly obtained for various types of particles." (Lines 8-10 in Page 8).

When we observed the particles, we used magnification large enough to make them clear. But we took photos of sample particles from different sources (Figure 7) at the same magnification to demonstrate the differences in their grain sizes and shapes.

**4. Comment:** Please estimate the uncertainty in the derived LC values (from both methods). For example, for LC<sub>X</sub>, the values of 25 and 550 are not exact, but subject to some uncertainty. What, then, does this mean for LC<sub>X</sub>? You should then plot reasonable uncertainty bounds on your figures (Figure 10).

**Reply:** We calculated the standard deviations of both methods as their uncertainty boundaries. The standard deviations of  $LC_{flux}$  and  $LC_x$  mean the fluctuation range of values and can be measured the degree of their dispersion effectively. We added the uncertainty boundaries to be added the uncertainty boundaries of the standard deviation in Figure 10.

15 the uncertainty bounds estimated by standard deviations in Figure 10.

Figure 10. The estimated local anthropogenic contributions by dust flux (a) and  $\chi_{\rm ff}$  (b). From bottom to top: (a) weekly dust flux (pink) and background estimate by the running median with a cross-validated number of window points (k=19) (black), monthly averaged dust flux (blue) and background (brown), average monthly local contribution (red) estimate by dust flux at XA1 and the bounds calculated by standard deviation (gray area); (b) weekly  $\chi_{\rm lf}$  values (light blue), averaged  $\chi_{\rm lf}$  values of natural distant dust (green dotted lines), monthly averaged  $\chi_{\rm lf}$  values (dark red), averaged  $\chi_{\rm lf}$  values of local street dust (orange dotted lines), monthly local contribution (violet) estimate by  $\chi_{\rm lf}$  at XA1 and the uncertainty boundaries calculated by standard deviation (gray area).

**5.** Comment: What does it mean that the two different LC methods generate such varying estimates? Which is more reliable? Or is the average of the two methods better than either one method?

10 **Reply:** Results of the first method ( $LC_{flux}$ ) are used to estimate the different contributions of atmospheric dustfall from distal and local sources, while the second ( $LC_{\chi}$ ) are the estimates of different contributions of atmospheric dustfall from natural and polluted sources. Because of different classifications of dust sources, these estimates are subjected to varying results. Therefore, they are not directly comparable.

6. Comment: All journal titles must be in italics. Please use abbreviated journal names throughout the reference list. Manyof your DOI references are incorrect.

**Reply:** All the references are checked and corrected.

- Abstract. The characteristics of urban dust aerosols and the contributions of their natural and anthropogenic sources are of scientific interest as well as being of substantial sociopolitical and economic concern. Here we present a comprehensive
  study of dust flux, magnetic parameters, and magnetic particulates' morphology and elemental composition of atmospheric dustfall originating from natural dust sources in East Asia and local anthropogenic sources in Xi'an, China. The results reveal a significant inverse relationship between seasonal variations of dust flux and magnetic susceptibility (χ). By comparing dust flux and χ records, the relative contributions of dust from local anthropogenic sources are estimated. Analyses using Scanning Electron Microscopy (SEM) combined with Energy Dispersive Spectroscopy (EDS) indicate that
  magnetic particulates from different sources have distinct morphological and elemental characteristics. Detrital magnetic particles originating from natural sources are characterized by relatively smooth surfaces with Fe and O as the major
- particles originating from natural sources are characterized by relatively smooth surfaces with Fe and O as the major elements and a minor contribution from Ti. The anthropogenic particles have angular, spherical, aggregate, and porous

that this multidisciplinary approach is effective in distinguishing dust derived from distant natural sources and local anthropogenic sources, and for quantitative assessment of contributions from the two end-members.

# **1** Introduction

Urban dust aerosols, comprising both natural and anthropogenic contributions with complex morphological and 5 physiochemical characteristics, have become a focus of studies of global climate change and regional air pollution (Wilson et al., 2002). Natural dust is derived primarily from long-range transport with minor local soil contributions, and often cause dust events, including sandstorm, suspended-dust and blown-sand weather (Sun et al., 2001; Zhang et al., 2003a; Chen et al., 2004; Kan et al., 2007; Baddock et al., 2013), and has a deleterious effect on local air quality (Wang et al., 2004; Ginoux et al., 2004). Anthropogenic dust produced by human activities is characterized by high concentrations of toxic heavy metals

10 (e.g., Pb, Zn, Co, Cr, Ni, As), which has a long-lasting and adverse impact on local environment and human health (Zdanovicz et al., 2006; Qiao et al., 2013; Lu et al., 2014; Lee et al., 2015).

Airborne particulate matter  $< 2.5 \,\mu m$  in diameter (e.g., PM2.5 and PM1) can enter the alveolar region and blood circulatory system leading to health issues and even death (Brunekreef, et al., 2002; Nel et al., 2006; Pickrell et al., 2009; Maher et al., 2013). Moreover, anthropogenic dust is an important medium for the formation of secondary pollutants and plays a significant role in the formation of haze events (Hanisch and Crowley, 2001; Li et al., 2001; Lee et al., 2002; Usher et al., 2002; Finlayson-Pitts et al., 2003; Rubasinghege and Grassian, 2009; Takeuchi et al., 2010; Wu et al., 2011; Huang et al., 2014). Consequently, it is important to distinguish the characteristics and contributions of natural and anthropogenic dust in urban aerosols to formulate effective policies for dust pollution abatement and improving air quality.

20

Natural and anthropogenic contributions to urban dust aerosols are usually assessed quantitatively using geochemical and magnetic methodologies (Gorden, 1988; Xie et al., 1999; Gomez et al., 2004; Spassov et al., 2004; Kim et al., 2009; Feng et al., 2012). Geochemical methods typically involve source apportionment and contribution assessment of representative heavy metal elements using statistical methods such as chemical mass balance (CMB) (Chow et al., 2002; Gupta et al., 2006) and factor analysis (FA) (Harrison et al., 1997a; Salvador et al., 2004). Pb, Fe, Zn, Cr, Cd, Ni, Ba and Sb are frequently used

as marker elements for vehicle emissions (Huang et al., 1994; Adachi et al., 2004; Meza-Figueroa et al., 2007), while Hg, Pb, Mn, Cr, Co, Cu, Cd and Ni are regarded indicative of coal combustion (Vouk and Piver, 1983; Pacyna and Pacyna, 2001; Sushil and Batra, 2006).

Since magnetic measurements are rapid, inexpensive and non-destructive, environmental magnetism is increasingly being used as an effective approach to study urban dust pollution (Maher et al., 1998; Hoffmann et al., 1999). By combining magnetic properties with morphological (Muxworthy et al., 2001; Urbat et al., 2004; Blaha et al., 2008a), heavy metal (Hunt et al., 1984; de Miguel et al., 1997; Blaha et al., 2008b; Maher et al., 2008), and back trajectory characteristics (Wehner et al., 2008; Li et al., 2009; Fleming et al., 2012), the provenance, transport routes and spatial distribution of polluted dust aerosols can be investigated. This multidisciplinary approach is becoming a popular means of urban pollution monitoring and assessment (Jordanova et al., 2014; Stein et al., 2015; Yan et al., 2015; Bourliva et al., 2016).

Using environmental magnetic techniques to assess pollution levels and sources, different forms of urban dust aerosols in East Asia have been studied, including atmospheric dustfall, street dust, leaf dust, inhalable particulate matter, and surface soil. For example, spatial and temporal pollution patterns were quantitatively estimated from seasonal fluctuations of the concentration and grain size of magnetic particles in urban roadside dust (Kim et al., 2007, 2009). A high correlation between

- 15 magnetic parameters (magnetic susceptibility and saturation isothermal remanence, i.e. χ and SIRM) and heavy metal concentrations in street dust, polluted farmland soil and atmospheric dustfall was observed, indicating that these magnetic parameters can be employed as effective proxies to assess heavy metal pollution (Zhang et al., 2011, 2012a, b; Qiao et al., 2013). SIRM characteristics of roadside leaves were shown to reflect spatial variations of magnetic particles in urban dustfall (Quayle et al., 2010; Hansard et al., 2011, 2012; Maher et al., 2013; Kardel et al., 2012). Although morphology, grain size,
- 20

signatures of natural dust, urban dust aerosol and polluted dust from source-to-sink.

This study systematically collected surface sediments from potential dust sources in East Asia, urban dust aerosols in Xi'an, including atmospheric dustfall (over five consecutive years) and street dust, and typical anthropogenic pollutants such as vehicle exhaust and fly ash. Morphology and elemental compositions of magnetic particles in representative samples were

mineral and element analyses were utilized in previous works, there are no studies that systematically compare magnetic

analyzed to facilitate a thorough source-sink comparison. Our results indicate that natural and anthropogenic contributions to urban dust aerosols can be differentiated using a combination of their magnetic, morphological and elemental characteristics.

#### 2 Sampling and methods

#### 2.1 Sampling

- 5 Surface sediments were collected in potential dust source regions of East Asia, including the northern Chinese deserts (including the Badain Juran and Tengger Deserts), Taklimakan Desert, Mongolian Gobi and Tibetan Plateau (Fig. 1a). Fine-grained materials were taken from alluvial fans, dry riverbeds, lake basins, and drainage depressions within Gobi/sandy deserts at intervals of 100 to 200 km (Fig. 2a-d). To better understand the different sedimentary characteristics, 48 samples from the northern Chinese deserts, 50 samples from the Taklimakan Desert, 23 samples from the Mongolian Gobi, and 32 samples from the Tibetan Plateau were selected for measurement. Locations of the samples are shown in Fig. 1. Detailed descriptions were given in Sun et al. (2013).
- Sixty-eight street dust samples were collected from parks, construction sites, commercial streets, and residential areas in Xi'an following a 3×4 km grid spanning approximately 30 km from west to east, and 20 km from north to south (Fig. 1b). The sampling grid covers a range of different functional areas in Xi'an, including the Industrial District, Commercial District,
  Cultural District, Ecological District, and Han Chang'an city ruins Park (Fig. 1b). We also collected four typical anthropogenic pollutant samples in June 2017, including one sample of vehicle exhaust from the exhaust pipes of several vehicles, one sample of fly ash from dust bag of electrostatic precipitators at the Baqiao thermal power plant, one street dust sample from the Bell Tower in downtown Xi'an which experiences daily traffic jams, and one street dust sample near the Baqiao thermal power plant where coal-burning is the leading pollution factor. The locations of these samples are shown in
  Fig. 1.

Atmospheric dustfall collectors were placed on the top of a four-story building at the Institute of Earth Environment, Chinese Academy of Sciences, ~10 m above the ground surface, and a 15-story building inside the Xinxinjiayuan residential community, ~50 m above the ground surface (Fig. 2e-f). The sampling sites situated in southwest Xi'an consist primarily of commercial and residential districts. Samples were collected using the wet-collection method (Qian and Dong, 2004) at time intervals of 3 - 5 days in spring and 6 - 7 days in other seasons. Detailed sampling procedures were reported by Yan et al. (2015a, b). 733 samples were collected from March 2009 to March 2014. Dust flux (DF, g m<sup>-2</sup> day<sup>-1</sup>) is calculated as follows:  $DF=W/(A\times T)$  (1)

where W is the sample weight in g, A is the area in m<sup>2</sup>, and T is sampling duration in days.

5

# 2.2 Methods

Low- and high-frequency magnetic susceptibilities ( $\chi_{lf}$  and  $\chi_{hf}$ , respectively) are measured using a MFK1-FA Kappabridge at frequencies of 976 Hz and 15,616 Hz. Frequency-dependent magnetic susceptibility ( $\chi_{fd}$ ) is calculated as ( $\chi_{lf} - \chi_{hf}$ ) /  $\chi_{lf} \times 100\%$ .

- 10 The temperature dependent susceptibility  $(\chi$ -T) are measured in an argon atmosphere (the flow rate is 50 ml/min) at a frequency of 976 Hz from room temperature up to 700 °C and back to room temperature using a MFK1-FA Kappabridge equipped with a CS-3 high-temperature furnace. The susceptibility of each sample is corrected for background (furnace tube correction) using the CUREVAL 8.0 program .
- Hysteresis loops and first-order reversal curve (FORC) diagrams are measured by vibrating sample magnetometer 15 (VSM3900) to a maximum applied field of 1 T. Hysteresis parameters, including the saturation magnetization ( $M_s$ ), saturation remanent magnetization ( $M_{rs}$ ), and coercivity ( $B_c$ ), are obtained after subtracting the paramagnetic contribution. The remanence coercivity ( $B_{cr}$ ) is obtained by demagnetizing samples from +1 T back to -1 T. The hysteresis ratios  $M_{rs}/M_s$  vs.  $B_{cr}/B_c$  are used to construct a Day plot.
- The FORC diagrams are measured with the averaging time of 200 ms and produced using FORCinel software (Harrison and Feinberg, 2008). The total of 18 samples are used for detailed iron oxide analyses, including 2 samples from each natural dust source with modal  $\chi_{lf}$  values, 4 dustfall samples and 2 street dust samples with high  $\chi_{lf}$  and low  $\chi_{lf}$ , and the 2 samples of vehicle exhaust and fly ash.

The magnetic components of these representative samples are separated from the bulk samples using a 1 T magnet sealed in a polyethylene bag. To confirm their mineral, morphological and elemental characteristics, direct observations and measurements of the samples and their extracted magnetic particles are performed using a ZEISS EVO-18 Scanning Electron Microscopy (SEM), equipped with Bruker XFlash 6130 Energy Dispersive Spectroscopy (EDS). Samples are mounted on SEM stub with double-sided carbon tape and then coated with a thin gold film. The specified resolution of the SEM is < 5 nm. The EDS detector is capable of detecting elements with atomic numbers  $\geq 5$  and the detection sensitivity can reach 0.1 wt%. Bulk samples and magnetic extracts are characterized by randomly selecting 3 to 4 fields of view and examining all the particles observed within the selected fields. All the measurements are made at the Institute of Earth Environment, Chinese Academy of Sciences, Xi'an.

# **3** Results

5

# 3.1 Magnetic mineralogy

- 10  $\chi$ -T is used to identify magnetic mineral composition. All the  $\chi$ -T heating curves (Fig. 3a-f) are characterized by a major susceptibility decrease at 580 °C, i.e. the Curie temperature of magnetite, which identifies magnetite as the major contributor to  $\chi$ . All the samples are irreversible with cooling paths above heating trajectories due to the neoformation of magnetite (Jordanova et al., 2004; Kim et al., 2009). The  $\chi$ -T heating curve of the vehicle exhaust displays a decreasing  $\chi$  between 580 and 700 °C (Fig. 3b), suggesting the presence of hematite.
- 15 All samples have similar slightly wasp-waisted hysteresis loops (Fig. 3g-l). Magnetic saturation is generally reached at a magnetic field of about 300 mT. This is a clear indication of the predominance of low coercivity ferrimagnetic minerals in all samples.

# 3.2 Hysteresis properties

The Day plot and FORC diagram are powerful methods to identify the domain state distribution of magnetic materials

20 (Day et al., 1977; Pike et al., 1999; Roberts et al., 2000; Dunlop 2002a, b). All the samples agree well with single-domain + multi-domain admixture curves in the pseudo-single-domain range of the Day plot (Fig.4 a). The FORC diagrams for street dust (Fig. 4d), and anthropogenic pollutant (Fig. 4e) have divergent contours that are characteristic of multi-domain grains. The FORC diagram for natural surface sediments (Fig. 4b) seems to be characteristic of pseudo-single-domain and multi-domain behavior, whose outer contours display divergent pattern and inner contours are somewhat less divergent. The FORC distributions of atmospheric dustfall (Fig. 4c) appear to have a mixed set of contours. The outer contours have a divergent pattern that would be expected for multi-domain particles, while the inner distribution with closed contours represent single-domain grains.

# 3.3 Spatial and temporal variation of $\chi$

5

10

15

Magnetic susceptibilities of all bulk samples were measured to estimate concentrations of magnetic minerals, which are largely controlled by concentrations of ferromagnetic minerals (Dunlop et al., 1997; Evans et al., 2003; Liu et al., 2012).  $\chi_{fd}$  is sensitive to the superparamagnetic component. There are virtually no superparamagnetic grains when  $\chi_{fd}$  is < 2 %, while a mixture of superparamagnetic and coarser grains is indicated with  $\chi_{fd}$  in the range of 2 - 10% (Dearing et al. 1994). The peaking of  $\chi_{lf}$  frequency distribution curve indicates the  $\chi_{lf}$  values are most distributed in this interval. Both  $\chi_{lf}$  and  $\chi_{fd}$  exhibit a distinctive distribution pattern in different sources.

 $\chi_{\rm lf}$  values from Taklimakan Desert and northern Chinese deserts samples exhibit unimodal distribution (Fig. 5a), and those from Mongolian Gobi exhibit a bimodal distribution. However,  $\chi_{\rm lf}$  have a multimodal distribution in the Tibetan Plateau (Fig. 5a). Different distribution patterns and peak values of  $\chi_{\rm lf}$  (Fig. 5a) indicate the assemblage of magnetic minerals may differ in these four natural sources. Average  $\chi_{\rm lf}$  in individual sources shows a decreasing trend from the Mongolian Gobi, to northern Chinese deserts and Tibetan Plateau, and then to Taklimakan Desert (Fig. 5e). The mean values of  $\chi_{\rm fd}$  in different natural

- sources show a decreasing trend of superparamagnetic component from the Taklimakan Desert to Mongolian Gobi and Tibetan Plateau, and then to northern Chinese deserts (Fig. 5f).
- The frequency distributions of  $\chi_{lf}$  for the street dust and atmospheric dustfall are both unimodal (Fig. 5c). The average  $\chi_{lf}$ and  $\chi_{fd}$  value of the street dust are higher than those of the atmospheric dustfall and natural surface sediments (Fig. 5c). Low  $\chi_{lf}$  (  $< 500 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$ ) occurs in the Ecological District, Han Chang'an city ruins Park, and Cultural District, while samples with intermediate  $\chi_{lf}$  values (500 -  $800 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$ ) are from the moderately developed Industrial District and the periphery of the Commercial District. In contrast, the central areas of the Industrial District and the Commercial District (particularly

the area of high traffic density at the Bell Tower) are characterized by relatively high  $\chi_{1f}$  values (> 800×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup>).  $\chi_{1f}$  of atmospheric dustfall from XA1 and XA2 exhibit significant and consistent seasonal variations (Fig. 6). The lowest (highest)  $\chi_{1f}$  values correspond to highest (lowest) dust flux in spring (autumn).

The representative anthropogenic pollutants, i.e. the vehicle exhaust, fly ash, and nearby street dust at the Bell Tower and 5 thermal power plant, have high  $\chi_{\rm lf}$  and  $\chi_{\rm fd}$  (Fig. 5c, 5d ). The  $\chi_{\rm lf}$  and  $\chi_{\rm fd}$  of vehicle exhaust and fly ash are higher than the mean values of other sources of dust (Fig. 5e, 5f).

# 3.4 Morphology and mineralogy of the dust samples

10

SEM provides morphology information based on gray-scale intensity. The elemental composition is determined by the EDS detector. In order to compare the morphology and mineralogy characteristic of different dust sources, more than 40 fields of views of the representative bulk samples were randomly obtained for various types of particles. The morphologies and mineral compositions of the natural surface sediments, street dust, and atmospheric dustfall with low and high  $\chi_{lf}$ , are illustrated in Fig. 7. The particles are typically angular and irregularly shaped in the surface sediments, with a broad size range (around 1 - 100 µm). Based on the EDS analysis for each particles of the selected field, clay minerals, quartz, calcite, dolomite and magnetic grains (Fig. 7a) were clearly identified (Welton et al., 2012).

15 The SEM-DES analysis shows that the morphology and constituents of the particles in the street dust are complex and heterogeneous. Three categories of particles can be morphologically differentiated, including irregular and aggregate mineral particles, spherical particles, and anomalous particles with porous and loose structures (Fig. 7b). Particles with irregular shapes are mainly minerals and commonly present in street dust samples. Compared to the natural surface sediments, the grain size of mineral particles in the street dust is finer, and mostly ranges from 1 - 50 µm, with some up to 80 µm. Spherical particles are mainly amorphous silicon-aluminum and iron-rich spheres, whose grain size varies mostly from 1 - 20 µm with some up to 50 µm. There are a small number of anomalous particles with diameters of 10 - 100 µm.

The morphology and mineral composition of atmospheric dustfall are similar to those of the street dust, except that atmospheric dustfall with low  $\chi_{lf}$  has a higher content of irregularly-shaped detrital minerals (Fig. 7c), while that with high  $\chi_{lf}$  contains more spherical and anomalous particles (Fig. 7d).

#### 3.5 Elemental compositions of mineral particles

Since the elemental compositions of mineral particles can be clearly distinguished using SEM-EDS analysis (Blanco et al., 2003; Barbara et al., 2006), a street dust sample dominated by anthropogenic inputs, which has the highest  $\chi_{lf}$  in the street dust samples, was selected for analysis. A field of view is shown in Fig. 8. The various mineral particles exhibit distinct chemical compositions. The plate-like aggregates (labeled a) with high levels of Si and Al, and low levels of K, Ca, Mg and Fe are clay minerals composed of crystalline sheet-structure silicates with a small particle size (Fig. 8a). The angular and sharp-edged particle (labeled b) with high Si and O is quartz (Fig. 8b). The angular particle consisting of Si, Al, and K is potassium feldspar (Fig. 8c). Particles with the high levels of Ca and Mg are calcite (Fig. 8d) and dolomite (Fig. 8e).

10 The irregular particles (labeled f) which are abundant in Fe are identified as magnetic grains (Fig. 8f), although some of the particles show low levels of crustal elements, including Si, Al, Ca, and K. Two types of spheres were observed. One (labeled g) is an amorphous alumino-silicate particle (Fig. 8g) with predominant Si and Al and lesser amounts of K, Mg, Na and Ti. The other (labeled h) is an iron-rich sphere (Fig. 8h), which is mainly composed of Fe. These particles exhibit various surface textures. In addition, almost all particles contain O and C.

## 15 4 Discussion

20

5

# 4.1 Contributions of local anthropogenic sources estimated by dust flux and $\chi_{\rm ff}$

On the bivariate-plot of  $\chi_{\rm lf}$  vs.  $\chi_{\rm fd}$ , atmospheric dustfall is intermediate between the surface sediments and street dust (Fig.9b), implying that atmospheric dustfall is a mixture of distal natural dust and local anthropogenic dust, but much closer to the latter. The local anthropogenic contribution (LC) is mainly derived from local stable and sustained pollutant sources, including vehicle emissions and fly ash. Considering that natural dust comes primarily from natural dust sources with a minor local soil contribution (Wang et al., 2004; Ginoux et al., 2012), we attribute the natural contribution entirely to the distal natural dust.

The dust flux background can be taken as the average input from the end member of LC. The time-dependent background

estimation was calculated using:

5

10

20

$$x(i)_{bg} = \operatorname{MED}_{j=i-k}^{j=i+k}(x(j))$$
(2)

 $i=k+1,..., n-k, x(i)_{bg}$  is the background of x(i) at time t(i).  $MED_{j=i-k}^{j=i+k}(x(j))$  is the running median with window points of 2k+1 ( $k \le (n-1)/2$ ) (Härdle and Steiger, 1995); cross-validation can be used to choose k. We used two such criterions: median criterion (Zhen and Yan, 1988) and L<sub>1</sub>-norm (Marron, 1987; Dodge, 2012):

$$CV_m(k) = \operatorname{median}\left\{ \left| x(i) - \operatorname{MED}_{j=i-k, j\neq i}^{j=i+k} \left( x(j) \right) \right| \right\}$$
(3)

$$CV_{1}(k) = \left[\sum_{i=1}^{n} \left| x(i) - \operatorname{MED}_{j=i-k, j\neq i}^{j=i+k} \left( x(j) \right) \right| \right] / n$$
(4)

where  $MED_{j=i-k, j\neq i}^{j=i+k}(x(j))$  is the delete-one background estimate. The cross-validation functions are to measure the average performance of the delete-one estimate to predict the observation x(i). Optimal k values should minimize  $CV_m(k)$  or  $CV_1(k)$  (Mudelsee, 2006).

Through the cross-validation calculation on the dust flux series of atmospheric dustfall, we find that cross-validated number of window width (Eq. (3)) is k =19. On this basis, we calculate the monthly LC using the ratio of monthly background and total dust flux as the following:

$$LC_{flux} = x(j)_{bg} / DF \times 100\%$$
(5)

15 where  $LC_{flux}$  is the percentage of the monthly local anthropogenic contribution estimated by dust flux (Fig. 10a). Note that when the background is larger than the dust flux, LC is taken to be 100%.

 $M_s$  of representative samples (Fig.3h-m) are measured to identify concentration of ferrimagnetic minerals. We find that the averaged values of  $M_s$  in different sources show a rising trend from the natural surface sediments (0.04 Am<sup>2</sup>/kg) to atmospheric dustfall (0.81 Am<sup>2</sup>/kg) and street dust (1.03 Am<sup>2</sup>/kg), and then to anthropogenic pollutant (1.58 Am<sup>2</sup>/kg), which correspond to the characteristics of averaged  $\chi_{lf}$  in different sources. This indicates that the high  $\chi_{lf}$  of urban dust is caused by the ferrimagnetic mineral from local anthropogenic source. In consequence, the LC contribution could also be estimated by the peak values of  $\chi_{lf}$  frequency distribution, with 20 -  $30 \times 10^{-8}$  m<sup>3</sup> kg<sup>-1</sup> in the distant natural surface sediments and 500 -

 $600 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$  in local street dust (Fig. 9a). On this basis, we calculate the average LC using the following equation:  $\text{LC}_{\tau} = (\chi_{\text{m}} - 25) / (550 - 25) \times 100\%$ 

where  $LC_{\chi}$  is the percentage of the monthly local contribution estimated by  $\chi_{lf}$  (Fig. 10b), and  $\chi_m$  is the monthly average  $\chi_{lf}$  value in 10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup>. 25 × 10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup> and 550 × 10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup> are the averages  $\chi_{lf}$  values of surface sediments from source regions and local street dust, respectively. Note that when  $\chi_m$  is larger than the average  $\chi_{lf}$  of the street dust, LC is taken to be 100%.

The LC<sub>flux</sub> and LC<sub> $\chi$ </sub> values have the same trend and show a distinctive seasonal pattern (Fig. 10a-b), with the maximum in autumn (92.4 %, 92.3%), followed by winter (90.8 %, 74.7 %), summer (83.5 %, 71 %), and spring (73.0 %, 53.1%). Both the LC<sub>flux</sub> and LC<sub> $\chi$ </sub> are the lowest in spring, implying that distant natural dust input makes a great contribution to atmospheric dustfall during this period.

The LC variation exhibits a similar seasonal pattern with  $\chi_{lf}$ , but opposite trend to that of dust flux (Fig. 10a-b). This suggests that the major sources of atmospheric dustfall varied seasonally between the distant natural sources in spring and local anthropogenic sources in other seasons. In spring, dust is emitted from the natural sources by strong winds, and after long-range transport it contributes to the elevated dust flux in Xi'an, and decreases the LC in atmospheric dustfall. However, from summer to winter, dust input from local anthropogenic sources is low and stable as indicated by the high LC.

#### 4.2 Magnetic characteristics of anthropogenic particles

SEM-EDS analysis shows that the extracted magnetic particles from the street dust and atmospheric dustfall can be divided into detrital and anthropogenic types (Fig. 11a-c). Detrital particles are angular and characterized by relatively smooth surfaces with Fe and O as the major elements and minor amount of Ti (Fig. 11d), indicating the presence of magnetite, hematite, and titanomagnetite (Maher et al.,1991; Liu et al, 2015). Anthropogenic particles include angular particles with coarse surface textures, spherules, aggregates, and porous particles with complex internal structures. The major elements identified in these particles are Fe and O, which indicate the occurrence of magnetite or hematite, consistent with previously identified anthropogenic magnetic particles (Kim et al., 2007; Koukouzas et al., 2007; Maher et al., 2009). Minor concentrations of S, Zn, Cu and Cr were also observed in this type of particle, which is typically attributed to anthropogenic

<sup>15</sup> 

activities (Fig. 11d). The relatively weaker signal intensity of Fe in the EDS spectra of porous particles indicates a much lower Fe concentration (maximum less than 10 %), while their concentrations of Si, Al, Ca, Ti and Mn are higher.

SEM-EDS analysis shows that the morphology and concentration of magnetic materials in urban dust aerosols varied with sampling sites and over time. Among more than 20 images of analyzed magnetic extracts from urban dust samples, angular particles with coarse surface textures were the most frequently observed (> 50 %, some up to 80 %), with a wide range of grain size (1 - 100 µm). Spherules were also commonly observed in all samples, ranging from 10 - 40 %, mainly with diameters from 10 - 30 µm. The aggregates with diameters of 5 - 30 µm account for less than 10 %. Detrital particles, characterized by smooth surfaces, range from 1 - 5 % and have small diameters (10 - 20 µm). Porous particles are the least observed magnetic particles (< 1 %) with diameters of 30 - 120 µm. The SEM-EDS data show that the morphology and concentration of magnetic particulates in atmospheric dustfall with high χ<sub>lf</sub> values are similar to those of the street dust, whereas atmospheric dustfall with low χ<sub>lf</sub> contains more angular-subangular magnetic particles of detrital origin.

# 4.3 Potential sources of anthropogenic magnetic particles

Anthropogenic magnetic particles in the urban environment are mainly derived from the combustion of fossil fuels (Flanders, 1994; Matzka and Maher, 1999; Muxworthy et al., 2001), vehicle emissions (Harrison et al., 1997b; Moreno et al., 2003; Diapoui et al., 2008; Pant et al., 2013; Maher et al., 2013), and industrial activities (Hanesch et al., 2003; Desenfant et al., 2004). To clarify potential sources, microscopic and elemental investigations of magnetic extracts from anthropogenic pollutants were performed using SEM-EDS. Compared with the magnetic particles in atmospheric dustfall (Fig. 12a-d), those from vehicle exhaust consist of only three types of particles, including angular particles with coarse surface textures, spherules and aggregates (Fig. 12e-g), while all magnetic particle types in dustfall samples were identified in fly ash (Fig. 12h-k). The EDS analysis showed that the major elements of the same three types of magnetic particles in vehicle exhaust and fly ash are Fe and O, consistent with elemental features of those in atmospheric dustfall (Fig. 12l-n). This suggests that vehicle exhaust and fly ash are the main pollutant sources of the dustfall. However, there are some differences in compositions of the minor elements in the three types of particles between vehicle exhaust and fly ash. Angular particles with coarse surface textures from vehicle exhaust contain more S, Cr, Cu, Zn and Mn, while those from fly ash have more Ca and Mn. Aggregates consist of more Cr, Zn and S in vehicle exhaust, whereas Ca and S are enriched in fly ash. Spherules from vehicle exhaust contain higher amounts of heavy metals (Cr, Ni Mn and Zn), while those from fly ash have higher Ca and Mn. Coarse-grained porous magnetic particles were only observed in fly ash, which are relatively low in Fe and high in crustal elements (e.g. Si, Al, K, Ca, Mg, and Ti).

5 The EDS elemental data clearly indicate that the magnetic particles from vehicle exhaust contain higher concentrations of a greater range of elements from anthropogenic activities (S, Cr, Cu, Zn, Ni and Mn) than those from fly ash, whose EDS spectra show a substantial peak of Ca. The χ<sub>lf</sub> (925.7×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup>) and M<sub>s</sub> (2.5 Am<sup>2</sup>/Kg) values of vehicle exhaust are significantly higher than those of the fly ash (769.9×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup> and 0.66 Am<sup>2</sup>/Kg), indicating a higher content of ferrimagnetic contaminants. In summary, the magnetic particles emitted by vehicle exhaust and thermal power plants can be distinguished by a combination of morphological and elemental characteristics, which indicates that SEM-EDS can be used to trace the sources of anthropogenic pollutants in Xi'an.

#### **5** Conclusions

15

By comparing the magnetic properties of surface sediments in natural dust sources in East Asia and various urban dust samples in Xi'an, we found that distal natural dust and local anthropogenic dust have different magnetic, morphological and elemental characteristics. We take natural surface sediments as the representative of distal natural dust, and background atmospheric dustfall and polluted street dust as representatives of local anthropogenic dust. Based on this end-member configuration, relative contributions of local anthropogenic sources to urban atmospheric dustfall can be quantitatively estimated.

The results show that local anthropogenic contribution decreases in spring and increases in other seasons. Local anthropogenic contribution variation exhibits a similar seasonal pattern to  $\chi_{lf}$ , but opposite trend to that of dust flux with the maximum in spring. This means that a great amount of distant natural dust input with less magnetic content makes a great contribution to atmospheric dustfall in spring, which results minimum  $\chi_{lf}$  and anthropogentic contributions during this period. Hence, the local contribution is reduced as a result of increasing natural dust flux. SEM-EDS analysis of urban dust indicates that magnetic particles produced by anthropogenic activities have distinct morphological and elemental characteristics. The anthropogenic particles exhibit angular, spherical, aggregate, and porous shapes, and contain distinctive marker elements such as S, Cr, Cu, Zn, Ni, Mn and Ca. The porous particles are likely derived from the thermal power plant, while others may be attributed to both vehicle exhaust and the thermal power plant. Our results suggest that magnetic signatures combined with morphological and elemental compositions can be used to quantitatively estimate the local and anthropogenic contributions to urban dust aerosols.

5 Figure 1. Locations of natural surface sediments (NSS) in the East Asian sources (a) and urban dust samples in Xi'an (b). NCD - northern Chinese deserts, MG - Mongolian Gobi, TD - Taklimakan Desert, and TP - Tibetan Plateau. Black diamonds are STD sampling sites; blue dots are samples of consecutive AD (XA1 at the Institute of Earth Environment, Chinese Academy of Sciences; XA2 at the Xinxinjiayuan residential community); red triangles are typical heavily-polluted sites, including the Bell Tower in an area of high traffic density, and the Baqiao thermal power plant.

Figure 2. Sampling sites of NSS in a dry riverbed (a), desert margin (b), drainage depressions within sandy desert (c), and Gobi deserts (d), and AD at XA1 (e) and XA2 (f).

Figure 3.  $\chi$ -T heating (red line) and cooling (blue line) curves (a-f) and magnetic hysteresis loops (g-l) of representative samples of NSS (MG0907), atmospheric dustfall (AD, 2013.7.18 and 2010.4.30), street dust (STD, L5-10) and anthropogenic pollutant (AP): fly ash (DCYH) and vehicle exhaust (QCWQ).

Figure. 4 (a) Day-plot of the ratios  $M_{rs}/M_s$  and  $B_{cr}/B_c$  for representative samples from NSS, AD, STD, and AP, grain size boundaries and the single-domain+multi-domain matrix line are according to Dunlop (2002b). Percentages in the Day plot represent the concentrations of multi-domain in the single-domain+multi-domain mixture; (b-e) FORC diagrams for representative samples of NSS, AD, STD, and AP.

Figure 5. Frequency distribution of χ<sub>lf</sub> (a, c), bivariate plots of χ<sub>lf</sub> and χ<sub>fd</sub> (b, d) and average values and standard deviations of χ<sub>lf</sub> and χ<sub>fd</sub> (e, f)
 of NSS in each source and urban dust aerosols , including AD, STD and AP. Frequency distribution statistics of χ<sub>lf</sub> for NSS, AD and STD, and AP were generated using intervals of 10×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup>, 100×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup> and 200×10<sup>-8</sup> m<sup>3</sup> kg<sup>-1</sup> respectively.

Figure 6. Time series of magnetic susceptibility and dust flux of AD at XA1 and XA2, from 2009 to 2014.

5 Figure 7. Morphology and mineralogy of representative samples of the NSS (a), STD (b), AD with low  $\chi_{lf}$  (c) and high  $\chi_{lf}$  (d). Qtz - quartz, Fsp - feldspar, Cal - calcite, Dol - dolomite, Cm - clay minerals, Dmm - detrital magnetic mineral, Irs - iron-rich sphere, As aluminosilicate sphere, An - anomalous particles with a poriferous and loose structure.

Figure 8. SEM photograph and elemental spectra for a typical sample of STD. In the subplots the green plus symbols denote the locations of the beam used in the EDS analysis.

Figure 9. Frequency distributions of  $\chi_{lf}$  (a) and bivariate-plots of  $\chi_{lf}$  versus  $\chi_{fd}$  (b) of NSS, STD, AD, and AP.

5 Figure 10. The estimated local anthropogenic contributions by dust flux (a) and  $\chi_{lf}$  (b). From bottom to top: (a) weekly dust flux (pink) and background estimate by the running median with a cross-validated number of window points (k=19) (black), monthly averaged dust flux (blue) and background (brown), average monthly local contribution (red) estimate by dust flux at XA1 and the bounds calculated by standard deviation (gray area); (b) weekly  $\gamma_{\rm ff}$  values (light blue), averaged  $\gamma_{\rm ff}$  values of natural distant dust (green dotted lines), monthly averaged  $\chi_{If}$  values (dark red), averaged  $\chi_{If}$  values of local street dust (orange dotted lines), monthly local contribution (violet) estimate by  $\chi_{\rm lf}$  at XA1 and the uncertainty boundaries calculated by standar deviation (gray area).

Figure 11. SEM images and typical elemental spectra (d) of magnetic extracts from STD(a), AD with high  $\chi_{\rm f}$  (b) and low  $\chi_{\rm f}$  (c). From left to right, the particle morphologies represent detrital particles with relatively smooth surfaces from natural source regions, and anthropogenic particles with angular shapes and coarse surface textures, aggregates, spherules, and porous feature.

Figure 12. SEM images and elemental spectra of magnetic extracts from AD (a-d), vehicle exhaust (e-g) and fly ash (h-k). Black lines are elemental spectra of AD. Blue and red lines are elemental spectra for vehicle exhaust and fly ash.
