## Abstract

10 Secondary organic aerosol (SOA) is a complex mixture of hundreds of semi-volatile to extremely low-volatility organic compounds that are chemically processed in the atmosphere, including via heterogeneous oxidation by gas-phase radicals. Relative humidity (RH) has a substantial impact on particle phase, which can affect how SOA evolves in the atmosphere. In this study, SOA from dark  $\alpha$ -pinene ozonolysis is heterogeneously aged by OH radicals in a flowtube at low and high RH. At high RH (RH = 89%) there is substantial loss of particle volume (~60%) at an equivalent atmospheric OH exposure of 3 weeks. In contrast, at low RH (RH = 15 25%) there is little mass loss (<20%) at the same OH exposure. Mass spectra of the SOA particles were measured as a function of OH exposure using a vacuum ultraviolet aerosol mass spectrometer (VUV-AMS). The mass spectra observed at low RH overall exhibit minor changes with oxidation and negligible further changes above an OH exposure =  $2 \times 10^{12}$  20 molecule  $\text{cm}^{-3}$  s, suggesting limited impact of oxidation on the particle composition. In contrast, the mass spectra observed at high RH exhibit substantial and continuous changes as a function of OH exposure. Further, at high RH clusters of peaks in the mass spectra exhibit unique decay patterns, suggesting different responses of various species to oxidation. A 25 model of heterogeneous oxidation has been developed to understand the origin of the difference in aging between the low and high RH experiments. Differences in diffusivity of the SOA between the low and high RH experiments alone can explain the difference in compositional change but cannot explain the difference in mass loss. Instead, the difference in mass loss is attributable to RH-dependent differences in the OH uptake coefficient and/or 30 the net probability of fragmentation, with either or both larger at high RH compared to low

RH. These results illustrate the important impact of relative humidity on the fate of SOA in the atmosphere.

## 1. Introduction

Organic aerosol (OA) is ubiquitous in the atmosphere and makes up a large fraction of submicron particulate matter (Zhang et al., 2007). OA includes primary organic aerosol (POA) particles that are emitted directly into the atmosphere and secondary organic aerosol (SOA), which is formed in the atmosphere through oxidation of volatile organic compounds (VOCs) and yields less-volatile products that partition to the particle phase (Hallquist et al., 2009). SOA is often found to dominate OA mass (Jimenez et al., 2009), and thus can have a large impact on the ability of particles to affect climate and air quality. Despite the importance of SOA, understanding its full lifecycle—involving formation, chemical evolution and removal processes—remains challenging due to its complex and variable composition (Hallquist et al., 2009).

Heterogeneous oxidation is an important process during the lifecycle of OA in the atmosphere. Heterogeneous oxidation of OA involves the reaction of gas-phase oxidants, such as OH and O<sub>3</sub>, with compounds in the condensed phase. Heterogeneous oxidation can alter the composition of organic particles through two general pathways, functionalization and fragmentation (Kroll et al., 2009; Donahue et al., 2012; Lambe et al., 2012; Nah et al., 2013; Wiegel et al., 2015). Functionalization leads to formation of more oxygenated species in the particles (Smith et al., 2009; Ruehl et al., 2013) while fragmentation generally leads to production of more volatile species (Slade and Knopf, 2013). Heterogeneous oxidation can alter the optical properties (Cappa et al., 2011; Dennis-Smith et al., 2012), hygroscopicity (Petters et al., 2006; George et al., 2009; Cappa et al., 2011; Dennis-Smith et al., 2012; Harmon et al., 2013; Slade et al., 2015), density (George et al., 2007; Kroll et al., 2009; Nah et al., 2014), thermal properties (Emanuelsson et al., 2014; Hu et al., 2016) and the particle size (George et al., 2009; Dennis-Smith et al., 2012; Donahue et al., 2012; Kroll et al., 2015) of OA.

Various laboratory experiments have considered heterogeneous oxidation by OH of OA particles or films of OA proxies; these have typically focused on single compound systems (e.g. George et al., 2007; McNeill et al., 2008; Hennigan et al., 2010; Nah et al., 2013; Slade and Knopf, 2013; Chan et al., 2014; Davies and Wilson, 2015; Fan et al., 2015; Kroll et al., 2015; Lai et al.,

2015). In general, heterogeneous oxidation leads to an increase in the bulk-average oxygen-to-carbon ratio (or the average carbon oxidation state) as a function of photochemical age (Kroll et al., 2015). Heterogeneous oxidation by OH can also lead to varying amounts of OA mass loss, from negligible to more than 30% for OH exposures equivalent to 1 weeks of  
5 typical ambient OH (Kroll et al., 2015).

One important consideration in understanding the impact of heterogeneous oxidation on OA properties is the influence of relative humidity and particle-phase water. The phase of OA particles depends on the OA composition and the relative humidity (Koop et al., 2011;Renbaum-Wolff et al., 2013). For SOA in general, particles at low RH tend to have very  
10 high viscosity, with the particles behaving as if solid or semi-solid, although the exact behavior depends on the SOA precursor gas, oxidant and concentration (Virtanen et al., 2010). At high RH, however, the viscosity of SOA is generally much lower, with the particle phase being more liquid-like (Bateman et al., 2015). Diffusion coefficients ( $D_{org}$ ) of molecules within particles are related to viscosity according to Stokes-Einstein relation, with lower diffusion coefficients  
15 corresponding to higher viscosity. The molecular diffusivity is further related to the mixing timescale ( $\tau$ ) of the particle. The relationship between  $D_{org}$  and  $\tau$  is approximately  $\tau = d_p^2/4\pi^2 D_{org}$ , where  $d_p$  is the particle diameter. For reference, the  $\tau$  of a 100-nm particle is  $\sim 2.5$  seconds when  $D_{org} = 1 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ , corresponding to a more “liquid-like” particle, while  $\tau$  is  $\sim 40$  min when  $D_{org} = 1 \times 10^{-15} \text{ cm}^2 \text{ s}^{-1}$ , typical of “semi-solid” particles. Because RH impacts  $D_{org}$   
20 and mixing timescales, variations in RH have the potential to impact particle reactivity (Kuwata and Martin, 2012;Li et al., 2015b;Wang et al., 2015) and thus the evolution of particles in the atmosphere.

To address this, recent experimental studies have considered the effect of RH on heterogeneous oxidation by OH radicals, typically using model (single-component) OA  
25 systems. Some studies have observed slower loss of the model compound (Chan et al., 2014;Davies and Wilson, 2015;Fan et al., 2015;Chim et al., 2017b), or smaller gas-phase uptake coefficients (Slade and Knopf, 2014) under lower RH conditions. A number of model simulations have suggested the smaller OH uptake coefficient and longer photochemical lifetime of OA under dry conditions are driven by limited diffusion in highly viscous particles  
30 (Arangio et al., 2015;Houle et al., 2015). However, other single-component studies report no effect of RH, or even a decrease in the loss of parent species and OH uptake (Park et al., 2008;Lai et al., 2014;Slade and Knopf, 2014), with suggestions that the existence of a water

film at the surface hinders uptake of gas-phase oxidants. Given these contrasting results, it is difficult to extrapolate from these model systems to understand how RH might influence the reactivity of chemically complex SOA. We are aware of only one study that has probed the influence of RH on reactivity of SOA. Hu et al. (2016) examined the dependence on RH of heterogeneous oxidation of ambient isoprene-epoxydiol-derived (IEPOX) SOA by OH over the RH range 40 – 100%. They observed mass loss of IEPOX-SOA upon heterogeneous oxidation at all RH investigated. The extent of IEPOX-SOA loss was independent of RH for RH < 90%. However, at RH > 90% they found that the loss was somewhat enhanced, most likely as a result of an increase in particle surface area and not as a result of changes to particle phase because viscosity of the IEPOX-SOA particles was likely sufficiently low that the particles exhibited liquid-like behavior at all RH conditions considered. Thus, the specific influence of SOA phase on heterogeneous reactivity remains unclear.

To address this gap, we have conducted heterogeneous OH oxidation experiments under low and high RH conditions using SOA formed from dark ozonolysis of  $\alpha$ -pinene. We selected  $\alpha$ -pinene SOA because oxidation of monoterpenes, including  $\alpha$ -pinene, is an important source of SOA globally (Guenther et al., 1995; Guenther et al., 2012; Ziemann and Atkinson, 2012). In addition, the composition, phase state and photochemical aging of  $\alpha$ -pinene SOA have been extensively investigated, although the impact of phase on photochemical aging has not been characterized. Here we establish the effect of RH on photochemical aging of the  $\alpha$ -pinene SOA in terms of the influence on aerosol mass and compositional change. A simplified multiphase oxidation model that couples reaction and diffusion is used to understand the RH-dependent factors that impact photochemical aging.

## 2. Methods

In the experiments here (Cappa et al., 2018), SOA is formed initially under dry conditions and these SOA particles are then heterogeneously oxidized by OH at either a low or high RH. The experimental setup is shown in **Figure 1**. Four parts are highlighted: SOA formation, RH control, heterogeneous oxidation and SOA measurements. SOA particles were first produced chemically in one flow tube under dry conditions (the SOA formation flow tube). The airstream was then humidified to the desired level, and the SOA particles were reacted heterogeneously with OH radicals in a second flow tube (the OH flow tube). The size

distribution and chemical composition of the particles were then characterized. Each of these steps is described below.

## 2.1 SOA formation

SOA was formed from homogeneous nucleation of products from dark ozonolysis of  $\alpha$ -pinene in a stainless steel flowtube reactor in the absence of seed particles and  $\text{NO}_x$ .  $\alpha$ -pinene (98%, Sigma-Aldrich) was constantly injected into a stream of clean, dry  $\text{N}_2$  (at  $1.0 \mu\text{l hr}^{-1}$ ) using two parallel syringe pumps.  $\text{O}_3$  was produced by passing the  $\text{N}_2/\text{O}_2$  mixture through a cell lit by Hg pen-ray lamp (UVP, LLC). These two flows were introduced into a 25 cm long, 1.2 cm diameter stainless steel tube containing two helical static mixers (StaMixCo, LLC) and then passed into a 170 cm long, 2.5 cm diameter flow tube reactor. This step-wise increase in diameter facilitated mixing of the reactants and limited dead volume in the main flow tube. The typical residence time of the flow tube was around 80 seconds. The  $\text{O}_3$  concentration was measured using an  $\text{O}_3$  monitor (Model 108L, 2B Technologies) while the  $\alpha$ -pinene concentration is estimated based on flow rates and infusion rate. No OH scavenger was used during SOA formation. Detailed information of each experiment is summarized in **Table 1**. Downstream of the flowtube was a Carulite 200 (Carus) denuder followed by a Charcoal denuder to remove residual hydrocarbons and oxidants in the gas-phase. Previous experiments have shown negligible mass loss of SOA particles due to scavenging of vapors in denuders on the time scales relevant to our experiments (Cappa and Wilson, 2011). Therefore, the gas-phase oxidation of evaporated semi-volatile organics in the second flowtube is likely limited.

As shown in **Table 1**, mass concentrations of SOA were  $\sim 1000 \mu\text{g m}^{-3}$ , which is substantially higher than typical ambient aerosol concentrations, by two orders of magnitude (depending on the environment). However, the high initial concentrations are needed to allow for robust chemical characterization of the particles by the VUV-AMS at the much lower concentrations encountered after particles have lost much of their mass at high OH exposures.

## 2.2 RH control

Particles were reacted with gas-phase OH radicals in a second flow tube at two distinct RH conditions: high RH and low RH. Grayson et al. (2016) summarize a variety of experimental observations of the influence of RH on the phase state of  $\alpha$ -pinene SOA. Although there are

discrepancies in the exact values of  $D_{\text{org}}$  for  $\alpha$ -pinene SOA in the literature, the observations generally indicate that  $D_{\text{org}} < 10^{-14} \text{ cm}^2 \text{ s}^{-1}$  below RH = 30% and  $D_{\text{org}} > 10^{-12} \text{ cm}^2 \text{ s}^{-1}$  above RH = 70%. Based on this, the experiments here were conducted at RH = 25% for low RH experiments and at RH = 89% for high RH experiments. A dry  $\text{N}_2$  stream, a  $\text{N}_2$  stream humidified by a water bubbler and the stream containing the SOA particles were combined after the denuders. Three steps were used to achieve the desired RH range in the OH flow tube. First, the fraction of dry and humidified  $\text{N}_2$  was varied, with no dry  $\text{N}_2$  for high RH experiments. Second, the SOA particle stream was passed through a Nafion humidifier (Perma Pure, LLC) for high RH experiments, but through a bypass line for low RH experiments. Third, the humidifier was heated to slightly above ambient temperatures (to  $\sim 35 - 36^\circ \text{C}$ ) to increase the absolute water vapor concentration in the flow for high RH experiments. At this temperature and given the very short residence time in the humidifier, evaporation of SOA should be minimal (Kolesar et al., 2015). Condensation between the humidifier and the OH flowtube was avoided by maintaining the connecting tubing at the same temperature as humidifier.

RH and temperature were monitored both at the inlet and outlet of the OH flow tube using Omega temperature controllers (CNi Series) and Newport humidity probes (iTHP-5), and temperature in the OH flow tube was measured by a thermocouple (5SC-TT-K-30-36, Omega). Temperature in the OH flow tube was usually a few degrees higher than room temperature due to heating from the UV lamps,  $26 - 27^\circ \text{C}$  compared to  $24 - 25^\circ \text{C}$ , respectively. The temperature at the flow tube outlet was controlled to be equal as the temperature in the OH flow tube such that the RH measured at the outlet was representative of the RH in the OH flow tube.

### 2.3 Heterogeneous oxidation

The SOA was heterogeneously oxidized by OH radicals in a 130 cm long quartz flow tube. The residence time was 38 s at the flow rate of  $1.0 \text{ L min}^{-1}$ . Four continuous output 130 cm long Hg lamps ( $\lambda = 254 \text{ nm}$ ; Sankyo Denki) were positioned outside of the quartz flowtube. OH radicals were generated by the following reactions:

At a fixed condition (dry vs. wet), the concentration of OH was varied by changing the input O<sub>3</sub> concentration (Figure S1). O<sub>3</sub> was generated using a corona discharger (Model Y, Ozone Services). The O<sub>3</sub> concentration generated can be varied from 20 – 1000 ppm, which corresponds to 1 – 50 ppm after dilution into the OH flow tube. The O<sub>3</sub> concentration was measured by an O<sub>3</sub> monitor (Model 202M, 2B Technologies) before dilution into the flow tube.

To estimate the OH exposure in the flowtube, a tracer compound, acetone (H<sub>3</sub>CC(O)CH<sub>3</sub>), was added to the flow. Acetone reacts with OH along the length of the flow tube with a known rate coefficient, *k*<sub>Ace+OH</sub>. We used the average temperature-dependent rate constant from Wollenhaupt et al. (2000); and Gierczak et al. (2003). The observed decay of acetone was used to calculate the OH exposure:

$$\frac{\ln([H_3CC(O)CH_3]/[H_3CC(O)CH_3]_0)}{-k_{Ace+OH}} = \int_0^t [OH] dt = \langle OH \rangle_t \cdot t = OH \text{ exposure} \quad (1)$$

where [H<sub>3</sub>CC(O)CH<sub>3</sub>]<sub>0</sub> and [H<sub>3</sub>CC(O)CH<sub>3</sub>] are the initial and final concentrations of acetone, respectively, [OH] is the time-dependent concentration of OH,  $\langle OH \rangle_t$  is the time-averaged concentration of OH, and *t* is the residence time in the quartz flow tube, which is fixed at 38 seconds (Figure S1). The acetone concentration was measured using a gas chromatograph (Model 8610c, SRI Instruments). A cylinder of 50 ppm acetone balanced in N<sub>2</sub> was prepared and used. After dilution, the initial concentration of acetone entering the OH flow tube was ~ 750 ppb.

Water vapor was removed from the airstream that exited the OH flow tube (after the RH was measured) by a diffusion dryer and any remaining gas-phase hydrocarbons and oxidants were removed by a Carulite denuder.

## 2.4 SOA characterization

Both particle size and composition were characterized after the OH flow tube. The size distributions of the SOA particles were characterized by a scanning mobility particle sizer (SMPS; TSI Inc.), composed of a differential mobility analyzer (DMA; Model 3085) and a condensation particle counter (CPC; Model 3772). The SOA volume concentration at each OH exposure was calculated from the volume-weighted distribution. These volume concentrations (*V*<sub>p</sub>) were normalized by the measured particle number concentration to

account for variations in particle losses that result from changes in particle size upon heterogeneous oxidation. By comparing the number-normalized  $V_p$  values at a given OH exposure to that at no OH exposure, the extent of bulk volume (mass) loss as a function of OH exposure is obtained.

5           The composition of the SOA particles was characterized using the time-of-flight (ToF) vacuum ultraviolet aerosol mass spectrometry (VUV-AMS) at beamline 9.0.2 at the Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory. A detailed description of the instrument has been reported elsewhere (Gloaguen et al., 2006). Briefly, particles are sampled into the instrument and focused into a particle beam through an aerodynamic lens.  
10   The particles impact onto a heater block that is maintained at 120 – 125 °C and evaporate. The evaporated molecules are photoionized using 10.5 eV radiation. The resulting ions are extracted and directed into a ToF mass spectrometer for detection. Each particle measurement is coupled with a background measurement. The background spectra are measured by sampling air into the VUV-AMS through a particle filter before the particle  
15   measurements. All the mass spectra reported here are background corrected. While the resolution of the VUV-AMS is  $m/\Delta m \sim 2000$ , the mass spectra reported here are in unit mass resolution.

## 2.5 Multilayer Heterogeneous Oxidation Model

We developed a simplified multilayer heterogeneous oxidation model that is based on  
20   both the KM-SUB, KM-GAP model (Shiraiwa et al., 2010; Shiraiwa et al., 2012) and a stochastic model (Wiegel et al., 2015; Wiegel et al., 2017). The model is used to develop understanding of the factors that influence the particle bulk behavior and compositional change under different RH conditions. Our model treats particles as 2D spheres having a fixed-depth surface layer and  $n$  variable-depth, sub-surface bulk layers, as illustrated in **Figure 2**. The depths of all  
25   sub-surface layers are assumed equal. Diffusion and chemical reactions are coupled in the model to simulate evolution of SOA.

Reactions of gas-phase  $\text{HO}_x$  (OH and  $\text{HO}_2$ ) radicals with condensed-phase organic species are assumed to occur only in the surface layer. Unlike the KM-SUB model and the stochastic model, the physical processes of adsorption and desorption of  $\text{HO}_x$  radicals are not  
30   explicitly simulated in the model. Production of  $\text{HO}_x$  radicals from reactions that occur within the condensed phase is also not considered. Therefore, reactions involving  $\text{HO}_x$  radicals are

assumed to happen only at the surface, and not in the sub-surface bulk layers. This is a reasonable assumption because HO<sub>x</sub> radicals are very reactive species and they likely primarily react within 1 nm from the surface in organic aerosols (Arangio et al., 2015) with the probability of reaction falling off rapidly with distance into the particle (Houle et al., 2015).

5 The OH and HO<sub>2</sub> reaction rates are thus calculated by using a single uptake coefficient ( $\gamma$ ) that characterizes the fraction of collisions that lead to reaction of HO<sub>x</sub> radicals with organic molecules at the surface, as illustrated by Eqn. (2) (Smith et al., 2009):

$$\frac{d[Y]}{dt} = -\gamma_{OH}^Y \cdot f_Y \cdot J_{coll} \cdot C_p \cdot A \quad (2)$$

10

where Y is any reactive stable organic species in the surface layer that can react with OH,  $\gamma_{OH}^Y$  is the uptake coefficient of OH radicals by species Y,  $f_Y$  is the fraction of Y molecules in the surface layer,  $C_p$  is the particle number concentration and  $A$  is the particle surface area of one particle.  $J_{coll}$  is the OH radicals flux at the particle surface, calculated as:

15

$$J_{coll} = \bar{c} \cdot [OH]_{gs}/4 \quad (3)$$

where  $\bar{c}$  is the mean speed of gas-phase OH and  $[OH]_{gs}$  is the near-surface concentration of gas-phase OH. The relationship between  $[OH]_{gs}$  and  $[OH]_g$ , the concentration far away from

20 the particle surface, can be described as:

$$[OH]_{gs} = C_{g,OH} [OH]_g \quad (4)$$

where  $C_{g,OH}$  is a gas-phase diffusion correction factor suggested by Pöschl et al. (2007):

25

$$C_{g,OH} = \frac{1}{1 + \gamma_{OH}^Y \frac{0.75 + 0.28 Kn_{OH}}{Kn_{OH}(1 + Kn_{OH})}} \quad (5)$$

$Kn_{OH}$  is the Knudsen number approximated as:

$$30 \quad Kn_{OH} = \frac{6 D_{g,OH}}{\bar{c} D_p s} \quad (6)$$

where  $D_{g,OH}$  is the OH gas phase diffusion coefficient and  $D_{p,s}$  is the surface-weighted particle diameter. This correction is needed to account for gas-phase diffusion especially when high uptake of gas-phase OH leads to strong local depletion of OH near particle surface.

5 The same calculations for reaction rates are applied to reactions involving gas-phase HO<sub>2</sub> radicals. The gas phase concentrations of HO<sub>x</sub> radicals ( $[OH]_g$  and  $[HO_2]_g$ ) are assumed constant throughout the flow tube for a given OH exposure. At each OH exposure, the OH concentration is set equal to the time-averaged concentration as calculated from the specified OH exposure divided by total reaction time (38 s). The concentration of HO<sub>2</sub> is  
 10 assumed to be same as that of OH. Using the reaction scheme of Li et al. (2015a) to simulate the more detailed gas-phase chemical reactions, it was determined that this was a reasonable assumption.

Since HO<sub>x</sub> radicals are assumed to react at the surface, the depth of the surface layer is set to 0.76 nm, corresponding to an effective molecular diameter of typical SOA components.  
 15 This value is estimated assuming an average molecular weight of 175 g mole<sup>-1</sup> and density of 1.3 g cm<sup>-3</sup> for α-pinene SOA (Renbaum and Smith, 2009). The depth of the surface layer is assumed independent of the total particle size, i.e. is constant.

A generalized reaction scheme of OH oxidation of alkanes suggested by Ruehl et al. (2013) and Wiegel et al. (2015) is used to simulate the compositional change of particles, as  
 20 shown in **Figure 2b**. It is assumed that all of the initial (unreacted) SOA molecules react identically. It is also assumed that all functionalized stable products formed are reactive towards OH, and up to three generations of products are considered. The general reaction scheme for both SOA parent species and for stable product species (written as P<sub>x</sub>, where x indicates the generation number, from 0 – 3) can be written as:

25

The stable product species that can go on to react are the ROOH and ROH species. The above scheme illustrates that oxidation is initiated by H-abstraction from a stable species (parent or product) by OH (R3), leading to production of an organic peroxy radical (RO<sub>2</sub>·). It is implicitly assumed that the alkyl radical (R·) that proceeds RO<sub>2</sub>· formation reacts rapidly with O<sub>2</sub>. The RO<sub>2</sub>· radicals can then react with either HO<sub>2</sub> or RO<sub>2</sub>·. Reaction with HO<sub>2</sub> (R4) leads to production of organic hydroperoxides (ROOH). Reaction of RO<sub>2</sub>· with another RO<sub>2</sub>· can lead to production of either functionalized stable products (alcohols or ketones; R5a) or alkoxy radicals (RO·; R5b). All stable product species produced from RO<sub>2</sub>· self-reactions are lumped into the generation-specific generic product species ROH<sub>x</sub>, where x indicates the generation. The RO· can either react with O<sub>2</sub> (R6b) or other stable species (R6c) to produce stable products (ROH) or can decompose to produce two fragmentation products (F<sub>1</sub> and F<sub>2</sub>; R6a). The fragmentation products are assumed to have low molecular weight and high volatility, and thus evaporate from the particles leading to mass loss. The stable products can further react with OH radicals in the surface layer and lead to the next generation of products. Formation of ROOH and ROH is known as functionalization. Here, the net effect of R5 (RO<sub>2</sub>· + RO<sub>2</sub>· reactions) and R6 (the fate of RO·) is treated in a simplified manner. In particular, RO· is not treated explicitly. Instead, the overall probability that RO<sub>2</sub>· + RO<sub>2</sub>· ultimately leads to production of functionalized products or fragmentation products is considered as a lumped probability (*p*<sub>frag</sub>). The parameter *p*<sub>frag</sub> accounts for both the branching ratio of RO<sub>2</sub>· + RO<sub>2</sub>· reactions and the fractional loss of RO· from decomposition (R6a) versus functionalization (R6b and R6c). The overall reaction for RO<sub>2</sub>· + RO<sub>2</sub>· can then be written as:

where F indicates all fragmentation products. The fragmentation products are assumed non-reactive towards OH and are the only species that can evaporate. This simplification of the reaction scheme serves to overcome lack of knowledge regarding the actual branching ratios and rate coefficients associated with RO· decomposition and reaction with O<sub>2</sub> and other stable species. The value of *p*<sub>frag</sub> is not known *a priori*, but can be varied to establish the sensitivity of the model to functionalization versus fragmentation, and how this might differ depending

on the RH (and particle phase state). It is assumed that  $\gamma_{OH}$ ,  $\gamma_{HO_2}$ , the rate coefficients for self-reaction of  $RO_2\cdot$  radicals ( $k_{RO_2+RO_2}$ ), and  $p_{frag}$  are the same for all generations. Generation-specific products are tracked through three generations of reaction. Subsequent reaction of 3<sup>rd</sup> generation species are assumed to reform 3<sup>rd</sup> generation species.

5           Reactions occur within layers, and diffusion occurs between neighbor layers. The diffusion rates are calculated based on the equations used in the KM-SUB model (Shiraiwa et al., 2010). The diffusion coefficient ( $D_{org}$ ) is assumed the same for parent compounds and functionalization products (both stable products and radical intermediates), and are dependent upon the RH. The  $D_{org}$  for fragments is assumed to be 1.4 times larger than for the  
10 other species to account for their smaller sizes. The model results are not sensitive to reasonable variations in  $D_{org}$  of the fragments.

          Only fragmentation products are assumed to be sufficiently volatile to evaporate. All other species are assumed effectively non-volatile. The evaporation of fragmentation products is treated in a simplified manner wherein once these compounds reach the surface  
15 layer (either because they are directly produced in that layer or diffuse up from lower layers), they evaporate instantaneously. The change of particle size is calculated based on loss of fragments assuming a linear relation between molecule number and particle volume. As particles shrink, the thickness of the sub-surface bulk layers (including the radius of the inner core) decreases based on the new particle size and constant total layer number, and the  
20 volume of each layer and molecular density of each species in each layer are recalculated. Density and averaged molecular weight of the aerosol are assumed to be constant over the process of oxidation.

          Both the particle volume and composition after 38 seconds (the residence time of the quartz flow tube) of reaction are calculated as a function of OH concentration. The evolution  
25 of the particle volume and composition with OH exposure are then determined from the individual model results at each OH concentration. The simulated volume fraction remaining (VFR) of particles as a function of OH exposure can be directly and quantitatively compared to the observed VFR while the simulated compositional changes can be qualitatively compared to the measurement of spectral change.

30           Water uptake affects the SOA in various ways. Water uptake can engender a change (decrease) in the SOA viscosity, cause the particle size to increase with a corresponding dilution of the organic molecules, impact the uptake of OH (i.e.  $\gamma$ ), or alter the oxidation

chemistry in the condensed phase (i.e.  $p_{\text{frag}}$ ). The impact of viscosity changes are considered in the model by systematically varying the  $D_{\text{org}}$  while assuming a constant, RH-independent size, composition,  $\gamma$  and  $p_{\text{frag}}$  (Section 3.3.1). The impact of the size increase and dilution are considered together by using an increased particle surface area and a decreased molecular density of organic compounds for high RH simulations, where the extent of growth, characterized by the hygroscopic growth factor ( $GF$ ) is constrained by literature observations (Section 3.3.2). In these simulations, the hygroscopicity of the products is assumed the same as the parent species, and thus the assumed growth factor is constant with oxidation. The impact of variations in either  $\gamma$  or  $p_{\text{frag}}$  between low and high RH conditions are considered together (Section 3.3.3). These parameters are tuned one at a time for low and high RH conditions (using RH-dependent  $D_{\text{org}}$  and size) to achieve good agreement with the measurements.

### 3. Results and Discussion

#### 3.1 Bulk Behavior

The heterogeneous oxidation of  $\alpha$ -pinene SOA by OH leads to mass loss and particle shrinking for both the low and high RH condition. However, the extent of shrinkage at a given OH exposure differs between low and high RH (**Figure 3**). An example of the change in the size distributions before and after heterogeneous oxidation at the same OH exposure ( $= 4.7 \times 10^{12}$  molecule  $\text{cm}^{-3}$  s) is shown for both low and high RH (**Figure 3b**). The general broadening of the size distribution after exposure to OH is due to the slower overall reaction for larger particles resulting from their smaller surface-to-volume ratio. The variation in the volume loss with OH exposure between low and high RH is shown in **Figure 3a**. At an OH exposure  $= 4.7 \times 10^{12}$  molecule  $\text{cm}^{-3}$  s, only 20% of particle volume (or mass assuming constant particle density) is lost at low RH, compared to more than 60% volume loss at high RH. These observations clearly indicate that particles shrink to a much greater extent under high RH. These observations may have implications for the lifetime of SOA with respect to heterogeneous oxidation in the atmosphere. Assuming a typical atmospheric  $[\text{OH}]$  of  $2 \times 10^6$  molecules  $\text{cm}^{-3}$ , it would take 4 weeks for  $\alpha$ -pinene SOA to lose 20% of volume under dry conditions but only a few days to lose the same amount of volume under wet conditions. These observations

suggest that SOA mass loss due to heterogeneous OH oxidation may vary substantially throughout the atmosphere, dependent on variations in ambient RH.

Our observations for SOA can be compared to various single-component observations from the literature. Fan et al. (2015) reported the mass fraction remaining for methyl  $\beta$ -D-glucopyranoside (a cellulose oligomer surrogate) nanoparticles after photochemical aging by OH radicals at RH = 10 – 30%. The extent of mass loss was observed to increase with RH to a small extent in this range. Chan et al. (2014) have also observed that aqueous (high RH) succinic acid particles lost volume to a greater extent than solid (low RH) succinic acid particles at the same OH exposure. However, they observed no further change in volume above OH exposure  $\sim 0.8 \times 10^{12}$  molecule  $\text{cm}^{-3}$  s for aqueous droplets, different from our observation of continuous volume loss at high RH. This is likely a result of the different chemical systems used. Davies and Wilson (2015) reported the change in diameter of citric acid particles as a function of OH lifetimes for RH= 20 – 90%. For all RH conditions, they observed that the particle diameter initially increased but then peaked and decreased as the number of oxidation lifetimes was increased. Their oxidation lifetime values can be converted to equivalent, RH-dependent OH exposures using the reported rate constant. We find that there is a greater change in particle diameter for a given OH exposure for their experiments when RH is higher, with greater overall volume loss at high RH. Additionally, the initial, small increase in diameter occurs at relatively low OH exposures ( $< 1.5 \times 10^{12}$  molecules  $\text{s cm}^{-3}$ ), and the general effects of RH on particle volume loss with OH exposure are reasonably consistent with our observations. In addition to the single component studies, our results can also be compared to the observations of Hu et al. (2016), who reported the mass fraction remaining for IEPOX-SOA in the ambient environment as a function of OH exposure. As noted in the introduction, they observed faster decay of particle mass at 90 – 100 % RH compared to  $< 90$  % RH, but no further variation with RH at  $< 90\%$ . However, they also observed a larger surface area concentration under 90 – 100 % RH, due to particle growth, which was postulated to facilitate faster OH uptake. An increase in surface area is unlikely to explain our observation because the water uptake of  $\alpha$ -pinene SOA at RH = 90% is small (Varutbangkul et al., 2006) and the dry particle size distributions of our non-oxidized particles are nearly identical between the two RH conditions (Fig. 3b). Further, the increase in surface area is offset by a decrease in the mole fraction of the organic species due to the presence of water, which will be examined in Section 3.3.2.

### 3.2 Spectral Changes

The composition of SOA generated from ozonolysis of  $\alpha$ -pinene has been well-studied using both online and offline mass spectrometry (e.g. Tolocka et al., 2006; Shilling et al., 2009; Camredon et al., 2010; Putman et al., 2012; Yasmineen et al., 2012; Hall et al., 2013; Kristensen et al., 2014; Kristensen et al., 2016; Zhang et al., 2017). The mass spectrum obtained depends on the measurement method used. For example, mass spectra of  $\alpha$ -pinene SOA obtained using high-temperature evaporation ( $> 600$  °C) coupled with electron impact ionization at 70 eV (the typical operating conditions of the Aerodyne AMS) have very few ions with  $m/z > 100$  having substantial intensity (Shilling et al., 2009). In contrast, mass spectra obtained using electrospray ionization (ESI), typically considered a softer ionization method, typically show that dimers or oligomers (nominally those compounds having molecular weights more than twice higher than that of parent compound, 136 amu for  $\alpha$ -pinene) comprise a substantial fraction of the particle (Kristensen et al., 2014; Zhang et al., 2017). Mass spectra for  $\alpha$ -pinene SOA obtained using the VUV-AMS, used here, exhibit peaks spanning the range  $m/z = 50 - 300$ , although with much lower intensity ions at  $m/z > 200$  amu (**Figure 4**). In the VUV-AMS spectra, ions in range  $m/z = 50 - 200$  are likely a combination of monomers (especially above  $m/z = 140$ ), fragments of monomers (especially below  $m/z = 140$ ) and fragments of dimers. For example, characteristic fragment ions of monomers such as cis-pinonic acid and pinic acid, known products of  $\alpha$ -pinene ozonolysis (Yu et al., 1999; Kristensen et al., 2014), have been previously identified in VUV-AMS mass spectra of non-oxidized particles (Mysak, 2006) and are observed here with high intensity in the non-oxidized particles. The characteristic ions are observed at  $m/z = 98, 114, 125, 166$  for cis-pinonic acid ( $m/z = 184$ ) and at  $m/z = 100, 114, 140, 168$  for pinic acid ( $m/z = 186$ ), respectively. However, some of the odd-numbered, high-intensity ions that were observed in the non-oxidized particles, such as  $m/z = 125, 141$  and  $169$  (**Figure 4**), may be fragments of dimers based on Kristensen et al. (2016), although they used a different mass spectrometry technique (ESI). This is consistent with the peaks in the VUV-AMS spectrum of  $\alpha$ -pinene SOA consisting of contributions of monomers, fragments of monomers and fragments of dimers. Dimers and oligomers are likely underrepresented in VUV-AMS spectra of  $\alpha$ -pinene SOA, although they may comprise more than 50% of the aerosol mass (Kristensen et al., 2016). This underrepresentation is probably attributable to substantial fragmentation of dimers during

the ionization process and/or the slow desorption of dimers from the heater block, leading to low sensitivity of VUV-AMS towards dimers and oligomers.

The relative changes of the  $\alpha$ -pinene SOA mass spectra are considered as a function of OH exposure. We define non-oxidized particles as particles that passed through the OH flowtube with the lights on but with no added O<sub>3</sub>. As such, all changes to the observed spectra are attributable to chemical oxidation of the particles, not photolysis. We note that there is no difference in the mass spectra for non-oxidized particles for tests done with the lights on versus lights off in the absence of O<sub>3</sub> for low RH conditions ( $R^2 = 0.997$ ; Figure S2). This indicates that direct photolysis of the SOA had no influence on the SOA spectra for the short exposure timescale (38 s) here. We also observe that the mass spectrum of non-oxidized particles at low and high RH are identical ( $R^2 = 0.999$ ), indicating that photolysis does not differ between low and high RH conditions in these experiments. Thus, the differences in spectral changes between the two RH conditions are driven by chemical oxidation only.

The mass spectra observed at four different OH exposures are shown for low RH (**Figure 4a**) and high RH (**Figure 4b**). There are distinct RH-dependent differences in the spectral evolution. At low RH, the four most abundant ions in the non-oxidized particle spectra ( $m/z = 98, 125, 141$  and  $169$ ), are still among the most abundant at the highest OH exposure. In contrast, at high RH the relative signal intensities of these four ions decreases substantially with increasing OH exposure.

The overall similarity of the oxidized spectra to the non-oxidized spectra can be considered by calculating the  $R^2$  between the spectra (Lanz et al., 2007). Smaller  $R^2$  values indicate greater spectral differences (lower similarity). The  $R^2$  between the mass spectra of oxidized particles and non-oxidized particles are calculated at each OH exposure for both the low and high RH experiments. Only ions that contribute more than 0.5% to the total signals are included in the calculation. As shown in **Figure 5**, changes in the  $R^2$  differ substantially between low and high RH. At low RH, the  $R^2$  decreases reasonably fast below OH exposure =  $2 \times 10^{12}$  molecule cm<sup>-3</sup> s, although to a limited total extent, only to  $R^2 = 0.78$ . Above this value, further decreases in  $R^2$  are small. In contrast, at high RH the  $R^2$  exhibits a rapid decrease below OH exposure =  $1 \times 10^{12}$  molecule cm<sup>-3</sup> s to near zero. The very small  $R^2$  values at high RH indicates that the composition of the oxidized particles differs substantially from the non-oxidized particles.

The decay of each individual  $m/z$  ion in the mass spectrum (from  $m/z = 15 - 350$ ) with OH exposure is shown in **Figure 6**. The intensity of each ion has been first normalized by the particle number concentration to account for changes in intensity due to variations in physical loss of particles in the flow tube, which likely result from changes in the particle size distribution with OH exposure. The number-normalized intensities were then normalized by the observed intensity at zero OH exposure to assess the relative change. This resulting normalized intensities are also referred to here as the signal fraction remaining (*SFR*). The decay of the average *SFR* (calculated from the individual *SFR* curves) and the weighted-average *SFR* (equal to total signal fraction remaining) are also shown in **Figure 6**. The difference in the average *SFR* decay between low and high RH conditions and the absolute magnitude of decay are consistent with the observed volume loss. However, the weighted-average *SFR* decays to a greater extent than the average *SFR* decay or mass loss under both low and high RH conditions. Ideally, loss of total signal should be equivalent to loss of particle mass if detection sensitivity towards all the species are the same. One possible explanation of this difference is that the VUV-AMS exhibits a lower sensitivity towards product species compared to parent species. Another possibility is the underrepresentation of dimers and oligomers in VUV-AMS spectra, as mentioned above. If the latter is true, it also indicates that dimers should decay more slowly than monomers to account for the difference between mass loss and total signal loss.

There is substantially greater spread in the *SFR* between individual ions at high RH compared to low RH at a given OH exposure. In other words, at low RH the intensities of the individual ions all decay to a similar extent. However, at high RH the intensity of some ions decrease by nearly a factor of 100 at the highest OH exposure while the intensity of others remains similar to the non-oxidized particles. This is consistent with the differences in  $R^2$  versus OH exposure between low and high RH, indicating distinctly different compositional change.

We focus first on the high RH ion decay curves. To further understand differences between ions that decay rapidly versus slowly under high RH conditions, the ions have been grouped by their extent of decay (**Figure 7a**). Four groups have been established. Group 1 includes ions that exhibit the fastest and most substantial decay, with the average *SFR* for this group equal to 0.04 at the highest OH exposure. This group contains most of the ions that have the greatest signal intensity in the non-oxidized particle spectrum and includes markers

from known products of  $\alpha$ -pinene ozonolysis, such as cis-pinonic acid and pinic acid. Also, the odd ions with  $m/z = 125, 141, 169$  that might be markers of oligomers as discussed above are also in Group 1. Nearly all of the ions in Group 1 have  $m/z < 200$  (**Figure 7b**), suggesting that Group 1 primarily consists of either monomeric species or fragments thereof, and signature fragments from dimers (or larger oligomers). That these ions exhibit a rapid, continuous decay indicates that they are chemically transformed, producing either new functionalized products or fragments that evaporated, and are not produced during heterogeneous oxidation.

Group 2 includes the ions that decay relatively slowly, albeit still to a substantial extent, with the average  $SFR = 0.3$  for this group at the highest OH exposure. Group 2 has the greatest number of ions, containing many ions with  $m/z < 200$  and, notably, almost all the ions with  $m/z > 200$  (**Figure 7c**). The Group 2 ions with  $m/z < 200$  have generally smaller percentage contributions to the total signal in the non-oxidized particles than the Group 1 ions. This suggests that they are either less characteristic minor ions for major parent compounds or characteristic ions for minor parent compounds in the non-oxidized particles. The Group 2 ions with  $m/z > 200$  are contributed by very highly oxygenated products, dimer fragments and dimers. The comparably slow decay of Group 2 ions indicates either that they react substantially more slowly than the Group 1 species (which are likely monomers) or that production offsets some of the chemical loss during the aging process. It is difficult to determine which is more likely.

Group 3 includes ions that exhibited little decay with oxidation. The Group 3 ions all have  $m/z < 50$  (**Figure 7d**), and thus are small ion fragments that could result from any of the particle-phase compounds, both parent and product species. The relative intensity of the Group 3 ions is overall extremely small. That their intensity remains relatively constant suggests that these ion fragments are produced to a greater extent from oxidation products than from the molecules comprising the non-oxidized SOA. In other words, production is offsetting loss. Group 4 includes the one ion ( $m/z = 17$ ) that exhibits an increase in signal intensity. The relative intensity of this ion is very small, contributing only 0.01% to total signal in non-oxidized particles. However, at the highest OH exposure the percentage contribution of this ion increases to nearly 1%. Since these experiments were performed under  $\text{NO}_x$  free conditions,  $m/z = 17$  most likely corresponds to  $\text{OH}^+$  ions. In general, the formation of  $\text{OH}^+$  ions from photoionization is unfavorable, which explains the extremely low intensity of this ion in the mass spectra. However, the increase in the intensity of this ion with oxidation is

likely still meaningful and could be a result of product species of increasing generation number having a greater number of -OH groups. Alternatively, it could indicate that the functional groups produced from oxidation are more likely to generate OH ions compared to the parent species, due to differences in bond dissociation energies. Most likely, the increase in intensity of this ion is a result of functionalization.

Considering now the low RH experiment (**Figure 6a**), all the ions visually appear to decay to similar extents. However, building on the results from the high RH experiment above, the mass spectrum has been split into the same  $m/z$  groups (**Figure 8**). It is found that the Group 1 ions collectively decay to the greatest extent for the low RH experiment, consistent with the high RH experiment. This provides additional evidence that Group 1 ions are mainly contributed from monomeric species that are chemically degraded and are not produced through heterogeneous oxidation. The Group 2 ions decay on average to a lesser extent than Group 1 ions at low RH, consistent with the high RH experiment. There is, however, a fair amount of variability in the individual ions for this group (mainly driven by low intensity ions). The Group 3 ions exhibit, on average, slightly less decay than Group 2 ions, although with a fair amount of variability driven by the low ion intensities. The one Group 4 ion ( $m/z = 17$ ) may increase slightly with OH exposure, but the overall behavior is difficult to discern given the small change and low ion intensity.

The mean *SFR* of Group 1 ions equals 0.4 at low RH compared to 0.05 at high RH at the same high OH exposure ( $= 4.7 \times 10^{12}$  molecule  $\text{cm}^{-3}$  s). This difference is comparable to the observed differences in decay of parent ions for model (single-component) OA particles upon heterogeneous oxidation by OH under low versus high RH conditions (Chan et al., 2014; Davies and Wilson, 2015). As discussed above, ions in Group 1 are likely representative of monomeric species in parent compounds. With the assumption that Group 1 ions are only lost through heterogeneous oxidation, and not formed, the mean signal decay of Group 1 ions could be considered as the lower limit of decay of “parent species” for  $\alpha$ -pinene SOA. The lower limit of the reaction rate coefficient of  $\alpha$ -pinene SOA with OH,  $k_{\text{SOA}+\text{OH}}$ , can be estimated based on the signal loss rate of Group 1 ions by fitting the decay of the average *SFR* of Group 1 ions with an exponential function:

$$SFR = \exp(-k_{\text{SOA}+\text{OH}} \cdot \text{OH exposure}) \quad (4)$$

The derived  $k_{\text{SOA+OH}}$  is  $2.3 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  for low RH and  $\sim 1.3 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  for high RH conditions. This difference in rate constants is similar to the difference reported by Davies and Wilson (2015) for citric acid and Hu et al. (2016) for IEPOX-SOA for a similar RH difference. The latter study reported an approximately linear relation between the rate coefficient and the wet particle surface area for the RH conditions examined. However, as discussed above,  $\alpha$ -pinene SOA only takes up small amount of water at RH = 90%, leading to an increase in surface area of only  $\sim 20\%$ , which cannot explain the more than 5 times higher rate constant under high RH.

Overall, it has been observed that substantially larger changes are observed at high RH than at low RH both in terms of the extent of mass loss and the change in the particle composition with increasing OH exposure. It has also been observed that under low RH conditions the composition of SOA stops changing (based on consideration of the  $R^2$ ) above certain oxidation level while mass loss continues slowly. In contrast, both compositional change and mass loss occur continuously and dramatically under high RH conditions.

### 3.3 Model simulation: Dependence on RH

The model is used here to establish the factors that primarily lead to the observed difference in heterogeneous oxidation under different RH in terms of both mass loss and compositional change. Heterogeneous oxidation of organic aerosol has several key steps, as discussed above and shown in **Figure 2**. These include sticking and uptake of gas-phase  $\text{HO}_x$  radicals, chemical reactions of different species and diffusion of the species in the bulk. All of the steps can be affected by RH, and in particular the influence of RH on viscosity plays important roles in these steps.

For the uptake process, there are a variety of reasons that the reactivity of  $\text{HO}_x$  radicals may differ between low and high RH conditions. The existence of water at the surface might lead to more efficient sticking of gas-phase  $\text{HO}_x$  radicals due to enhanced hydrogen bonding to water (Chan et al., 2014). However, the greater abundance of water vapor at high RH also might decrease the available sites for adsorption of gas-phase  $\text{HO}_x$  radicals due to competitive co-adsorption (Kaiser et al., 2011). After adsorbing/sticking to the surface, gas-phase  $\text{HO}_x$  radicals are mobile on surfaces prior to reaction (Slade and Knopf, 2013). Since different sites have different reactivity depending on their bonding environment (Kwok and Atkinson, 1995), the reaction probability of gas-phase  $\text{HO}_x$  radicals with surface species can be affected by

molecular orientation and the mobility of the radicals. The orientation of the SOA molecules can potentially be affected by RH. At low RH the SOA molecules are likely less mobile and their particular orientation and alignment at the surface relatively static compared to high RH (Moog et al., 1982). It is possible that a difference in orientation and mobility of surface molecules between low and high RH affects the probability that an OH radical reacts versus desorbs after colliding with and sticking to the surface.

The viscosity of particles could also have an influence on the chemical pathways and products formed from  $RO_2 \cdot + RO_2 \cdot$  reactions within the bulk by affecting either the (i) reaction probability or (ii) branching ratio, or both. Denisov and Afanas'ev (2005) proposed that  $RO_2 \cdot + RO_2 \cdot$  react to form an unstable tetroxide, which then decomposes to produce a ketone and an alcohol (the Russell mechanism), two ketones and  $H_2O_2$  (the Bennett-Summers mechanism), or two  $RO \cdot$  radicals. They also indicated that the decomposition rate constant of the tetroxide intermediate decreases with an increase in viscosity of the surrounding phase. The products formed from decomposition of the tetroxide depends on the structure of the transition state and, in the condensed phase, on further reaction of radical products within a solvent cage. The presence of a solvent cage and the stability of the cage can potentially influence the branching ratio towards production of  $RO \cdot$  radicals relative to stable, functionalized product species. This is important because  $RO \cdot$  radicals are the only species that lead to fragmentation.

Another impact of an RH-dependent viscosity is on the mixing timescales for condensed phase species. The mixing timescale for particles depends on the condensed phase diffusivity, which is related to viscosity. For example, for  $D_{org} = 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ , the mixing timescale for a 100 nm particle is about 2 seconds (Koop et al., 2011). Thus, the particle can be generally considered well-mixed and liquid-like. However, for  $D_{org} = 10^{-15} \text{ cm}^2 \text{ s}^{-1}$  the mixing timescale for a 100 nm particle is ~40 minutes. In this case, mixing is slow and the particle can be considered as having a more semi-solid phase. As discussed above, the diffusion coefficient (and viscosity) of  $\alpha$ -pinene SOA vary continuously with RH. In general, at >70% RH, the diffusivity of  $\alpha$ -pinene SOA is large ( $D_{org} > 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ ) while at low RH the diffusivity is comparably small ( $D_{org} < 10^{-14} \text{ cm}^2 \text{ s}^{-1}$ ). Given this, for our experiments it is expected that the particles at low RH (~30%) are semi-solid while at high RH (~90%) they are liquid-like. When the particles are more viscous (semi-solid), reaction of the organic radicals generated from reaction with OH will be primarily constrained to surface layers. In contrast, when the particles are less viscous (liquid-like), reaction of radicals may occur throughout the entire

particle. Therefore, there is reason to think that the impact of heterogeneous oxidation on both distribution of parent and product species in the particles and mass loss should depend on RH.

In the model simulations, the influence of RH on the above processes is examined by systematically varying five input parameters: (i) the growth factor (*GF*), (ii) the OH uptake coefficient ( $\gamma$ ), (iii) bulk diffusivity ( $D_{\text{org}}$ ), (iv) the  $\text{RO}_2\cdot + \text{RO}_2\cdot$  reaction rate constant ( $k_{\text{RO}_2+\text{RO}_2}$ ), and (v) the combined branching ratio and fragmentation probability ( $p_{\text{frag}}$ ). A summary of simulation parameters is shown in **Table 2**.

### 3.3.1 Impact of variations in bulk diffusivity

The ability of differences in the bulk diffusivity alone, and thus in the location of reactions, to explain the observed low versus high RH dependence is considered first. We perform simulations where  $\gamma$ ,  $k_{\text{RO}_2+\text{RO}_2}$ , and  $p_{\text{frag}}$  are all held constant while  $D_{\text{org}}$  is varied over a range constrained by the literature, from  $10^{-16}$  to  $10^{-11}$   $\text{cm}^2 \text{s}^{-1}$  by factors of 10 (Song et al., 2015). (The  $\gamma$ ,  $k_{\text{RO}_2+\text{RO}_2}$  and  $p_{\text{frag}}$  were all specified to produce model results generally consistent with the observations.) For these simulations it is assumed that the size of the particles is independent of RH (discussed in Section 3.3.2). We find that substantial differences in the extent of mass loss between simulations with low  $D_{\text{org}}$  (corresponding to low RH) and high  $D_{\text{org}}$  (corresponding to high RH), as was observed, can only be achieved if the  $k_{\text{RO}_2+\text{RO}_2}$  is assumed to be  $< 10^{-21}$   $\text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ , an unreasonably low value (**Figure 9**). When  $k_{\text{RO}_2+\text{RO}_2}$  is this low, the  $\text{RO}_2\cdot + \text{HO}_2$  reaction (which leads to functionalization) becomes competitive in the surface layer at low RH and at high OH ( $\text{HO}_2$ ) exposure. This leads to a build-up for ROOH species in the surface layer and limits the fragmentation pathway. At high RH, the  $\text{RO}_2\cdot$  rapidly diffuse away from the surface into the bulk, where they primarily react with each other and can produce  $\text{RO}\cdot$  radicals that can subsequently decompose and the fragments can evaporate. This leads to a suppression of fragmentation at low RH compared to high RH especially at higher OH ( $\text{HO}_2$ ) exposure. However, the  $k_{\text{RO}_2+\text{RO}_2}$  in this case is orders of magnitude lower than reported in the literature for various  $\text{RO}_2\cdot + \text{RO}_2\cdot$  reactions (Denisov and Afanas'ev, 2005).

When a more reasonable value of  $k_{\text{RO}_2+\text{RO}_2}$  is used ( $1 \times 10^{-15}$   $\text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ ), only very small differences in the calculated VFR versus OH exposure curves between the two RH conditions (i.e. when  $D_{\text{org}}$  is varied) are found no matter the values of  $\gamma$  and  $p_{\text{frag}}$ , assuming

these are RH-independent (**Figure 10a**). For these calculations, the  $\gamma$  and  $p_{\text{frag}}$  are selected to provide good model/measurement agreement with the VFR versus OH exposure curve for high RH conditions. (A similar negligible dependence of the VFR on  $D_{\text{org}}$  is predicted when  $\gamma$  and  $p_{\text{frag}}$  are selected to fit the low RH observations.) It should be noted that the particular  $\gamma$  and  $p_{\text{frag}}$  used here do not provide a unique solution; various combinations give similar results. Thus, we conclude that differences in  $D_{\text{org}}$  alone cannot explain the differences between the low and high RH experiments in terms of the overall mass loss. Simulations also show that the overall reaction rate of  $\text{RO}_2\cdot + \text{RO}_2\cdot$  in the particle is at least three orders of magnitudes higher than the rate of  $\text{RO}_2\cdot + \text{HO}_2$  regardless of the bulk diffusivity or  $\gamma$  and  $p_{\text{frag}}$  used. Even if we assume that  $[\text{HO}_2] = 10[\text{OH}]$  instead of  $[\text{HO}_2] = [\text{OH}]$ , as suggested by some oxidation flow reactor studies (Li et al., 2015a; Peng et al., 2015), loss of  $\text{RO}_2\cdot$  by reaction with  $\text{HO}_2$  is still negligible compared to loss by reaction with  $\text{RO}_2\cdot$ . This result suggests that the uptake of  $\text{HO}_2$  and formation of hydroperoxides are not particularly important during the heterogeneous oxidation of the SOA system considered here. This agrees with a previous study by Lakey et al. (2016), who put an upper limit of 0.001 to the uptake coefficient of  $\text{HO}_2$  by  $\alpha$ -pinene SOA.

However, although the VFR versus OH exposure curves using different  $D_{\text{org}}$  are very similar, there are substantial differences in terms of the calculated compositional changes for the different  $D_{\text{org}}$  considered (**Figure 10b**). In particular, the fractional contribution of model parent species in the oxidized particles depends on  $D_{\text{org}}$ , with larger contributions at smaller  $D_{\text{org}}$ . For example, when  $D_{\text{org}} = 1 \times 10^{-15} \text{ cm}^2 \text{ s}^{-1}$  (low RH), parent compounds make up more than 90% of the total molecules at highest OH exposure (**Figure 10c**). In contrast, when  $D_{\text{org}} = 1 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$  (high RH), oxidation products make up nearly all of the particle at the highest OH exposure (**Figure 10g**). This is consistent with the observation of more dramatic spectral change occurs under high RH conditions when particles are expected to have low viscosity. The reason for this results from differences in the rate of exchange between the bulk and surface at the different RH values. At high RH, parent molecules exchange rapidly between the surface and the bulk layers. Therefore, OH can access all of the parent molecules in the particle, leading to rapid change of particle composition. In contrast, at low RH the OH radicals cannot effectively access parent molecules in below-surface layers due to the high viscosity/low diffusivity. In this case, the surface becomes highly oxidized while the bulk of the particle volume remains largely unoxidized, corresponding to minimal change of the

spectra with OH exposure under dry conditions. Large differences in the overall particle composition between low and high RH conditions do not require additional differences in either  $\gamma_{\text{OH}}$  or the fragmentation probability, unlike for volume loss. This is because of the compensating effects of reaction location and oxidation extent of the products. Every time a stable species reacts with OH, there is a probability of fragmentation. Therefore, the net probability of fragmentation increases with higher generations of products, i.e. when species are more oxidized. At low RH, reactions are limited to the surface layer, leading to more highly oxidized products that have gone through more generations of reaction, with the difference more evident at lower OH exposures in particular (**Figure 10**). While the net probability of fragmentation is therefore increased for these surface-layer molecules, they also inhibit reaction with the bulk of the particle and will be, on average, more oxidized. Ultimately, at low RH the volume loss proceeds through layer-by-layer oxidation and evaporation of the surface. In contrast, at high RH OH radicals can react with the entirety of the particle bulk as these molecules mix to the surface. The average extent of oxidation at high RH is therefore comparably lower than that in the surface-layer at low RH. However, a greater fraction of molecules have some probability of fragmenting and evaporating. The net effect is that the overall extent of volume loss is reasonably independent of RH and the particle bulk diffusivity, although clearly the reason for the volume loss (highly oxidized surface versus lightly oxidized bulk) depends on RH.

The model results also indicate that there is a threshold  $D_{\text{org}}$  above which bulk compositional changes are large and below which they are small, with the threshold  $D_{\text{org}} \sim 10^{-13} \text{ cm}^2 \text{ s}^{-1}$ . Above or below this value the model results are relatively insensitive to further changes in  $D_{\text{org}}$  (e.g. similar results are obtained for  $D_{\text{org}} = 10^{-15} \text{ cm}^2 \text{ s}^{-1}$  and  $10^{-14} \text{ cm}^2 \text{ s}^{-1}$ , or for  $D_{\text{org}} = 10^{-12} \text{ cm}^2 \text{ s}^{-1}$  and  $10^{-11} \text{ cm}^2 \text{ s}^{-1}$ ). The particular threshold is related to the mixing time scale of the particles. For a 125 nm diameter particle (as used here), the mixing time scale when  $D_{\text{org}} = 10^{-13} \text{ cm}^2 \text{ s}^{-1}$  is about 40 seconds, which is comparable to the experimental time scale. Thus, above  $D_{\text{org}} = 10^{-13} \text{ cm}^2 \text{ s}^{-1}$  the particles are effectively well-mixed and further increases in  $D_{\text{org}}$  have limited influence, and at lower  $D_{\text{org}}$  the particles do not mix.

Our observations and modeling indicate that the phase state affects the distribution and oxidation level of the organic species in the particles upon photochemical aging. Slade et al. (2017) oxidized Suwannee River fulvic acid (SRFA) particles above and below the glass transition temperature ( $T_g$ ) up to OH exposures of  $7 \times 10^{11} \text{ molecule cm}^{-3} \text{ s}^{-1}$ , an order or

magnitude lower than our highest value. Above  $T_g$  the  $D_{org}$  is much larger than below the  $T_g$ , with an approximate transition from highly viscous to liquid like around 295-300 K. As such, these T-dependent experiments are complementary to the RH-dependent experiments here. While they did not measure the particle composition, using the KM-GAP model (Shiraiwa et al., 2010; Shiraiwa et al., 2012) they concluded that oxidation at low temperatures (<295 K; semi-solid) engendered compositional changes primarily at the particle surface, while at high temperatures (>300 K; liquid like) changes occurred throughout the particle, consistent with our results. Consequently, for the low-T experiments they predicted that the extent of oxidation of molecules in the near-surface layers, specifically, was much greater than occurred throughout the entire particle in the high-T experiments, also consistent with our conclusions. Associated, we find that the concentration of highly oxidized (3<sup>rd</sup> or higher generation) species in the surface layer rapidly increases in the low-RH (low  $D_{org}$ ) simulations (**Figure S3**). In contrast, for the high RH simulations the concentration of highly oxidized molecules increases only slowly, but continuously, and ultimately reaches a higher concentration than for the low RH simulations (**Figure S3**). However, we note that these highly oxidized molecules in our low-RH experiments make up only a small fraction of the total molecules comprising the particle (**Figure 10**), which is somewhat inconsistent with the conclusion of Slade et al. (2017) that large changes to the average molecular weight of the organic species comprising the particle occur.

### 3.3.2 Impact of size change

Besides affecting particle phase (i.e.  $D_{org}$ ), uptake of water at high RH also leads to an increase of particle size and dilution of organic compounds. The growth factor ( $GF$ ) of  $\alpha$ -pinene SOA at RH = 90% is around 1.1 (Varutbangkul et al., 2006), corresponding to 21% and 33% increase in particle surface area and volume, respectively. The impact of this size increase is examined here by assuming that  $GF = 1.1$  for high RH conditions and  $GF = 1.0$  for low RH conditions, while all the other parameters are assumed RH independent. Multiple simulations are run for different combinations of  $\gamma$ ,  $D_{org}$ ,  $k_{RO_2+RO_2}$  and  $p_{frag}$  (**Table 2**). We find that there are negligible differences between simulations that account for size growth ( $GF = 1.1$ ) and those that do not ( $GF = 1.0$ ) in terms of both the volume loss and compositional change of the particles for all combinations of the other parameters (i.e.  $\gamma$ ,  $D_{org}$ ,  $k_{RO_2+RO_2}$  and  $p_{frag}$ ) explored. Example results are shown in **Figure S4**. The reason for the insensitivity to  $GF$

is that the increase in the surface area is offset by the decrease in the molecular density of organic compounds.

### 3.3.3 Influence of variations in OH uptake and condensed-phase reactions

Given that variations in  $D_{\text{org}}$  alone cannot simultaneously explain the differences in  
5 observed mass loss and chemical changes at low versus high RH, coupled with the insight that  
the difference in hygroscopic growth for low/high RH has a negligible impact on the  
simulations, the impact of varying either  $\gamma$  or  $p_{\text{frag}}$  with RH is considered. For all calculations  
that follow it is assumed that  $D_{\text{org}} = 10^{-12} \text{ cm}^2 \text{ s}^{-1}$  for high RH and  $D_{\text{org}} = 10^{-14} \text{ cm}^2 \text{ s}^{-1}$  for low RH,  
based on the discussion in the Section 3.3.1. It is also assumed that  $GF = 1.1$  for high RH and  
10 that  $GF = 1.0$  for low RH simulations. The model is successful in predicting bulk behavior, i.e.  
mass loss of particles over the full range of OH exposure ( $= 0 - 7 \times 10^{12} \text{ molecule cm}^{-3} \text{ s}$ ), when  
RH-specific values of  $D_{\text{org}}$  and  $GF$  are used along with RH-specific values of either  $\gamma$  or  $p_{\text{frag}}$   
(**Figure 11a**). For both conditions  $k_{\text{RO}_2+\text{RO}_2} = 1 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  is used. For each  
condition, various combinations of  $\gamma$  and  $p_{\text{frag}}$  yield the same VFR versus OH exposure curves.  
15 As shown in **Figure 11b**,  $\gamma$  and  $p_{\text{frag}}$  have an inverse relationship, with increasing  $\gamma$  accompanied  
by decreasing  $p_{\text{frag}}$  (to achieve the same fit to the observations). It is also observed that slopes  
of linear fits to  $\log(\gamma)$  versus  $\log(p_{\text{frag}})$  for high and low RH conditions are identical, although  
the absolute values of  $\gamma$  and  $p_{\text{frag}}$  differ. This indicates that the relationship between either  $\gamma_{\text{dry}}$   
and  $\gamma_{\text{wet}}$  or  $p_{\text{frag,dry}}$  and  $p_{\text{frag,wet}}$  required for good model-measurement agreement are  
20 independent of the absolute  $\gamma$  and  $p_{\text{frag}}$ . In other words, when  $p_{\text{frag}}$  is assumed  
RH-independent, the  $\gamma_{\text{OH}}$  always needs to be nearly five times faster at high RH conditions to  
reproduce the observed greater mass loss compared to low RH. Alternatively, when  $\gamma$  is  
assumed RH-independent, the combined probability of fragmentation ( $p_{\text{frag}}$ ) needs to be  
around four times higher at high RH to explain the difference in VFR between two conditions.

25 Although similar VFR versus OH exposure curves are obtained using various (RH-specific)  
combinations of  $\gamma$  and  $p_{\text{frag}}$ , the predicted variation in composition with OH exposure depends  
on the pair of  $\gamma$  and  $p_{\text{frag}}$  used. At high RH when  $\gamma$  is small and  $p_{\text{frag}}$  is large, the loss of parent  
molecules is relatively slow but with most reactions with OH leading to fragmentation and  
evaporation of the products. Consequently, there is little build-up of stable products in the  
30 particles (**Figure 11c**). In contrast, when  $\gamma$  is large and  $p_{\text{frag}}$  is small the parent compounds

react away faster but with a much larger fraction of stable products forming. Consequently, product species build up in the particles to a greater extent (**Figure 11d**). However, the net production rate of fragments in these two cases are the same, with the decrease in reaction rate offsetting the increase in fragmentation probability (or vice versa). The co-variation of  $\gamma$  and  $p_{\text{frag}}$  has a similar impact on the compositional changes for low RH conditions (**Figure 11e,f**), although the overall compositional changes are much smaller due to the high viscosity of the particles, as discussed above. Based on the above, we conclude that for high RH conditions the  $\gamma$  must be greater than ca. 0.5 and  $p_{\text{frag}}$  must be less than ca. 0.3 to achieve both substantial changes in the particle composition and substantial volatilization, as observed. This range of  $g$  determined based on the overall bulk behavior is generally supported by comparison of the modeled decay of the parent compounds with the decay of the Group 1 ions (**Figure S5**). If  $\gamma_{\text{wet}}$  is assumed to be  $\leq 1$ , then  $p_{\text{frag,wet}}$  can be further constrained to be  $> 0.18$ . Given that  $\gamma_{\text{wet}} \sim 5\gamma_{\text{dry}}$  or  $p_{\text{frag,wet}} \sim 4p_{\text{frag,dry}}$ , as established above, the parameters at low RH are constrained to be  $1.0 > \gamma_{\text{dry}} > 0.1$  and  $0.3 > p_{\text{frag,dry}} > 0.04$ .

### 3.4 Comparison with single-component studies

#### 3.4.1 OH Uptake

The results from our SOA experiments and model simulations can be compared with OH oxidation experiments performed on various single-component systems. Interestingly, some of these studies find that increasing RH can enhance the effective uptake coefficient while others find that increasing RH reduces the effective uptake coefficient. The uptake coefficient can be calculated in two ways: (i) by measuring the loss rate of reacting particle-phase species, or (ii) by measuring the loss rate of gas-phase OH radicals. The first method may include loss due to secondary reactions in the condensed phase, in addition to direct loss from reaction with OH, and is generally referred to as the effective OH uptake coefficient,  $\gamma_{\text{OH,eff}}$ . The latter method characterizes loss of OH only, and is referred to here as the OH uptake coefficient,  $\gamma_{\text{OH}}$ .

Some studies have observed a general increase in  $\gamma_{\text{OH}}$  or  $\gamma_{\text{OH,eff}}$  with RH when going from very dry conditions to higher RH (40 – 70%). For example, Davies and Wilson (2015) reported that  $\gamma_{\text{OH,eff}}$  for citric acid particles increases by a factor of 3 when RH is increased from 20% to 50%, although there is a slight decrease in  $\gamma_{\text{OH,eff}}$  (by 30%) as RH is increased further to 90%

RH. Chim et al. (2017b) similarly observed a continuous increase in  $\gamma_{\text{OH,eff}}$  from RH = 30% to 70% (from 1.9 to 2.6) and a small decrease at higher RH (to 2.4) for OH oxidation of particles composed of 2-methylglutaric acid. The increase in  $\gamma_{\text{OH,eff}}$  with RH at the lower RH range was explained by a decrease in viscosity and faster mixing. This allows OH radicals to react directly more often with the parent species, rather than producing highly oxidized molecules at the surface. The decrease of  $\gamma_{\text{OH,eff}}$  at the higher RH range was explained, in part, by a decrease in the relative concentration of parent compounds due to dilution by water. Nevertheless, both studies indicate  $\gamma_{\text{OH,eff}}$  is generally larger at high RH (~90%) than at low RH (~30%). Slade and Knopf (2014) determined that  $\gamma_{\text{OH}}$  (as opposed to  $\gamma_{\text{OH,eff}}$ ) for levoglucosan particles increased with RH over the range 0 – 40%, from approximately 0.2 to 0.7. While the exact reason for this increase was not identified—although suggested to result from differences in phase state and mixing timescale—if the reaction products formed are less reactive towards OH than the levoglucosan, this could explain the increase in  $\gamma_{\text{OH}}$  with RH because the products would build up to a lesser extent at the surface when particle mixing is faster. Alternatively, it may be that the reaction of OH with levoglucosan molecules at the particle surface depends on the orientation of the levoglucosan molecules. At very low RH the levoglucosan molecules may be fixed in unfavorable orientations (on average), and as RH is increased the levoglucosan may be able to adopt more favorable orientations. Finally, it may be that the sticking probability of OH radicals increases with RH. Regardless of the exact reason, the above single-component studies are consistent with our determination that  $k_{\text{SOA+OH}}$  for the Group 1 (parent) ions is greater at high RH.

However, some single-component studies have reported a negative effect of RH on the uptake coefficient or reaction rate constant, with increasing RH leading to smaller  $\gamma$  or  $k$ . Slade and Knopf (2014) observed a decrease in  $\gamma_{\text{OH}}$  from 0.2 to 0.05 for methyl-nitrocatechol (MNC) particles when RH was increased from 0% to 30%. It was argued that because MNC has a low solubility in water the decrease was likely a result of the competition for adsorption between OH radicals and water at the surface; this differs from levoglucosan, which is moderately soluble. The SOA here is moderately soluble, due to the highly oxygenated nature of the organic compounds, and thus most comparable to the levoglucosan experiments. Lai et al. (2014) reported a strong, negative effect of RH on the loss rate of levoglucosan after exposure to OH, in direct contrast to Slade and Knopf (2014). Lai et al. (2015) separately reported that

the loss rate of *cis*-pinonic acid decreased, by a small amount, as RH increased from 20 – 80%. However, there is an important distinction between the (2014);Lai et al. (2015) and Slade and Knopf (2014) experiments. Whereas Slade and Knopf (2014) used suspended particles, (2014);Lai et al. (2015) exposed thin films (<1 nm thickness) of the parent organic species to OH. Because the film was so thin the impact of diffusive exchange of molecules was effectively eliminated and the increase in RH served only to dilute the levoglucosan and decrease the loss rate. These results suggest that the experimental method used (e.g. suspended particles versus thin films) can strongly impact the apparent influence of RH on heterogeneous oxidation processes. While experiments using suspended particles are more directly relevant to the atmosphere, the combination of thin film and suspended particle experiments can help to isolate the influence of mixing on reactive uptake and loss.

### 3.4.2 Reaction pathways

The influence of RH on the fate of the parent species from heterogeneous oxidation has also been considered by several studies. Following from faster loss of the parent species, Chan et al. (2014) observed faster formation of both functionalization and fragmentation products for reaction of succinic acid in aqueous droplets compared to solid aerosol, i.e. at high versus low RH. As a result, they observed a more dramatic change in the mass spectrum after OH exposure under high RH conditions, consistent with our observation. However, the ions formed after oxidation were identical for the aqueous and solid succinic acid particles. That is, while the product species form faster at high RH, there was no indication that this had a major influence on the reaction pathways. Chim et al. (2017b) and Davies and Wilson (2015) similarly observed that, even though the reaction rates are different, the oxidation products formed are independent of RH. Furthermore, Chim et al. (2017b) observed that for 2-MGA the relative abundances of several important functionalization and fragmentation ions was independent of RH, when considered at the same 2-MGA lifetime (which accounts for RH variations), indicating similar chemical pathways of oxidation regardless of RH.

In a chemical system containing carboxylic acids that are hydrophilic in nature, acid-base chemistry in the particles may need consideration in addition to free-radical chemistry when an aqueous phase is present. Liu et al. (2017) developed a model that couples both acid-base and free-radical chemistry in the oxidation of aqueous citric acid aerosol by OH radicals. They compared their simulation results to the observations of Davies and Wilson (2015). The

inclusion of acid-base chemistry in the simulations did not alter the decay rate of citric acid nor the variation in H/C and O/C as a function of OH exposure. However, a significant increase in the abundance of fragmentation products were predicted only when acid-base chemistry is considered. One key reason is the enhanced unimolecular fragmentation rate of alkoxy radical anions compared to the neutral form. Hydration in the aqueous phase can also enable the decarboxylation of certain acyloxy radicals. Consistent with the simulations, Davies and Wilson (2015) reported that the abundance of  $N_c = 6$  product species (the same carbon number as citric acid) was smaller while the abundance of  $N_c = 3 - 5$  product species (fragments or decarboxylation compounds) was larger at RH = 65% (corresponding liquid phase) compared to RH = 20%, although the differences were not significant. It is possible that acid-base chemistry, which we do not include in our simulations, contributes to the difference in oxidation between the low- and high-RH SOA experiments here. Considering that acids can comprise a substantial fraction of  $\alpha$ -pinene SOA, it is possible that accelerated decomposition of alkoxy radicals in their anion form contributes to greater fragmentation under high RH conditions in the chemically complex system studied here. However, citric acid is substantially more hygroscopic than  $\alpha$ -pinene SOA. The growth factor for citric acid at RH = 20% is similar to that of  $\alpha$ -pinene SOA at RH = 90%. As such, it is unclear to what extent acid-base chemistry might be playing a role in the oxidation of the  $\alpha$ -pinene SOA at RH = 90% and it may be negligible.

OH radicals can also be produced in the condensed phase through decomposition of organic peroxides (ROOH). ROOH molecules can contribute as much as 50% to the total mass of  $\alpha$ -pinene+O<sub>3</sub> SOA (Docherty et al., 2005) but are unstable and with some observed to have half-lives less with respect to decomposition of than an hour at room temperature (Krapf et al., 2016). The decomposition products of ROOH—RO and OH radicals—both facilitate the formation of small molecular weight products that lead to volatilization. Although this chemical pathway is unlikely to contribute substantially to our experiments given the short timescale (38 s), it may influence the rate of aerosol mass loss under ambient conditions and longer timescales, especially under high RH conditions where appreciable amount of liquid water in the particles accelerates the decomposition of ROOH (Tong et al., 2016).

Regardless, RH-dependent differences in  $p_{frag}$ , and thus the oxidation products formed, can explain the difference in VFR and in the particle composition for SOA considered here

based on our simulation results. Differences in viscosity of the particles has the potential to influence reaction rate and product branching ratio, and the importance of this may differ in the more chemically complex SOA compared to the single-component experiments. Comparison with the single-component experiments suggests that the key difference  
5 between the low and high RH SOA experiments is more likely from the RH-dependence of  $\gamma_{OH}$ , although the role of variations in oxidation pathways ( $p_{frag}$ ) cannot be completely ruled out.

## 4. Conclusions

The influence of RH on the heterogeneous oxidation of  $\alpha$ pinene SOA by gas-phase OH radicals is investigated for the first time. There is a substantial difference in the extent of  
10 aerosol volume loss that results from photochemical aging between experiments conducted at low versus high RH (28% versus 90%), with much greater loss for high RH experiments. At low RH, the SOA particles are estimated to lose 80% of their volume over  $\sim 4$  weeks of aging at typical atmospheric OH levels. In contrast, at high RH it takes only a few days for the same amount of shrinking to occur. At high RH, substantial changes are observed in the mass  
15 spectrum of the SOA as the particles are oxidized. Nearly all peaks in the spectrum decrease in intensity as aging occurs, although to varying extents. Grouping of the peaks in the mass spectrum according to their individual extents of decay suggests that monomeric parent species exhibit the fastest decay. The decay of peaks that are attributable to dimers (or higher order oligomers) is comparably slower, yet still substantial. Under low RH conditions, limited  
20 changes in the mass spectrum with oxidation are observed for the SOA particles. However, if the decay groups identified for the high RH experiment are applied to the low RH experiments, there is a general consistency between the low- and high-RH results, with slightly faster decay of the monomeric compounds compared to the dimer compounds.

The RH dependence of the observed volume loss and compositional change of the SOA  
25 particles was assessed using a multiphase chemical-oxidation model in which variations in the bulk diffusivity, OH uptake coefficient and net probability of fragmentation were considered. Differences in the bulk diffusion coefficient alone, which affects mixing timescales within the particles, are found to have a negligible impact on the overall volume loss. However, the calculated variation in particle composition was highly sensitive to the bulk diffusion  
30 coefficient and whether it was larger or smaller than a threshold value of  $D_{org} \sim 10^{-13} \text{ cm}^2 \text{ s}^{-1}$ . At  $D_{org}$  larger than the threshold value (faster mixing), substantial changes in the particle

composition can occur as oxidation proceeds, whereas at  $D_{\text{org}}$  smaller (slower mixing) than the threshold the particle composition remains approximately constant. The difference in volume loss between low and high RH are shown to result from either the OH uptake coefficient or the net fragmentation probability (or both) being RH dependent, with larger values for high RH conditions. Considering the volume loss and compositional changes together, these two parameters are constrained to be  $1.0 > \gamma_{\text{dry}} > 0.1$  and  $0.3 > p_{\text{frag,dry}} > 0.04$  for low RH conditions and  $1.0 > \gamma_{\text{wet}} > 0.5$  and  $0.3 > p_{\text{frag,wet}} > 0.16$  for high RH conditions when  $\gamma_{\text{OH}}$  is assumed to be less than 1. Comparison with studies of single compound systems suggests that variations in  $\gamma_{\text{OH}}$  is more likely responsible for the difference in low versus high RH experiments, although the possibility of different chemical pathways (i.e. differences in  $p_{\text{frag}}$ ) due to difference in viscosity and the presence of water cannot be ruled out. Further work is necessary to establish which parameter,  $\gamma$  or  $p_{\text{frag}}$ , is more sensitive to variations in RH, especially in chemically complex systems.

Overall, our work indicates that RH has a substantial impact on the evolution of the size and composition, and potentially related physical properties, of  $\alpha$ -pinene SOA upon photochemical aging. Particle phase-dependent differences in oxidation—including the importance of functionalization of fragmentation at the surface or throughout the bulk of a particle—can impact how the hygroscopicity of organic particles evolves (Chim et al., 2017a;Slade et al., 2017). Additionally, our observations suggest that the lifetime of SOA with respect to heterogeneous OH oxidation is significantly shorter at high RH and that this loss mechanism should be considered in regional and global models. Although the mass concentrations of SOA we use here are 1 – 3 orders of magnitudes higher than ambient concentrations, the above conclusions are likely to hold true. Recent studies have demonstrated an increase in SOA viscosity with a decrease in mass loadings under low RH conditions (Grayson et al., 2016;Jain et al., 2018). However, under high RH conditions the SOA particles are likely to stay liquid-like independent of mass concentration. (Renbaum-Wolff et al., 2013;Kidd et al., 2014;Bateman et al., 2015). Thus, the difference in particle viscosity of several orders of magnitude between low and high RH conditions will almost certainly persist—and perhaps increase—at typical ambient SOA concentrations. Consequently, the influence of RH on SOA aging is likely important even at ambient SOA concentrations.

Ultimately, additional studies with other types of SOA (e.g. that formed from other biogenic or anthropogenic precursors) are needed to fully establish the effect of RH on SOA sensitivity to OH oxidation and to help further elucidate the underlying physical and chemical mechanisms. However, the results of the current study clearly point to the important role of  
5 RH in the heterogeneous oxidation of SOA.

## 5. Data Availability

The data associated with this paper have been submitted for archiving at the UC Davis DASH data repository (<https://dash.ucdavis.edu>) at <https://doi.org/10.25338/B8ZK5X> (Cappa et al., 2018).

## Tables

**Table 1.** Experimental conditions for SOA generation and heterogeneous oxidation

	SOA precursors			SOA conditions			Experimental conditions	
	$\alpha$ -pinene ( $\mu\text{l hr}^{-1}$ )	$\alpha$ -pinene (ppm)	O <sub>3</sub> (ppm)	$D_{p,s}^*$ (nm)	$N_p$ (# cm <sup>-3</sup> )	$M_p$ ( $\mu\text{g m}^{-3}$ )	RH (%)	Humidifier T (°C)
Exp. 1	1.0	4.3	17	125	1.04e6	1120	89	35-36
Exp. 2	1.0	4.3	17	126	1.12e6	1200	92	35-36
Exp. 3	1.0	4.3	17	124	0.93e6	970	29	24-25
Exp. 4	1.0	4.3	17	124	0.92e6	950	28	24-25

\* $D_{p,s}$  is the surface-weighted middle diameter of initial dry particles

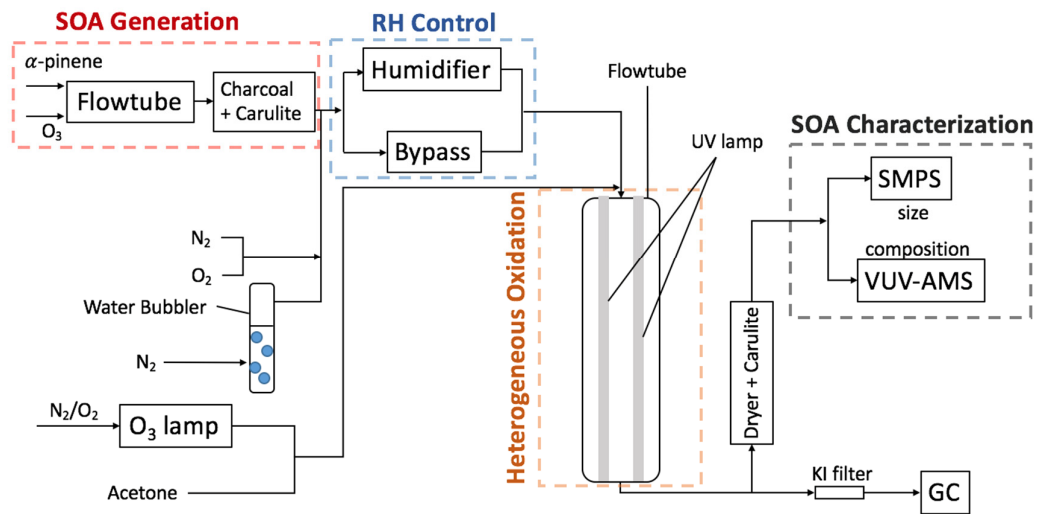

5

**Table 2.** Summary of values or ranges of values for parameters used in the model simulation

Parameter	Description	Value
Condensed phase		
$D_{p,s}$	Surface-weighted middle diameter of initial dry particles	125 nm (initial)
$\rho_p$	Density of SOA	1.3 g cm <sup>-3</sup>
$MW_p$	Molecular weight of SOA	175 g mol <sup>-1</sup>
$GF$	Hygroscopic growth factor	1.1 (high RH) or 1.0 (low RH)
$\gamma$	Uptake coefficient of OH and HO <sub>2</sub>	0 – 1
$p_{frag}$	A combined probability for fragmentation	0 – 1
$k_{RO_2+RO_2}$	Reaction rate coefficient of RO <sub>2</sub> · + RO <sub>2</sub> ·	1×10 <sup>-21</sup> – 1×10 <sup>-15</sup> cm <sup>3</sup> molecule <sup>-1</sup> s <sup>-1</sup>
$d_{SL}$	Depth of surface layer	0.76 nm
$D_{org}$	Bulk diffusivity of SOA compound	1×10 <sup>-16</sup> – 1×10 <sup>-11</sup> cm <sup>2</sup> s <sup>-1</sup>
Gas phase		
[OH] <sub>g</sub>	OH concentration along the flowtube	0 – 1.84×10 <sup>11</sup> molecule cm <sup>-3</sup> -air
[HO <sub>2</sub> ] <sub>g</sub>	HO <sub>2</sub> concentration along the flowtube	Same as [OH]
$\bar{C}_{OH}$	Mean speed of OH radicals	610 m s <sup>-1</sup>
$\bar{C}_{HO_2}$	Mean speed of HO <sub>2</sub> radicals	440 m s <sup>-1</sup>
$D_{g,OH}$	Diffusion coefficient of OH radicals	0.21 cm <sup>2</sup> s <sup>-1</sup>
$D_{g,HO_2}$	Diffusion coefficient of HO <sub>2</sub> radicals	0.25 cm <sup>2</sup> s <sup>-1</sup>

## Figures

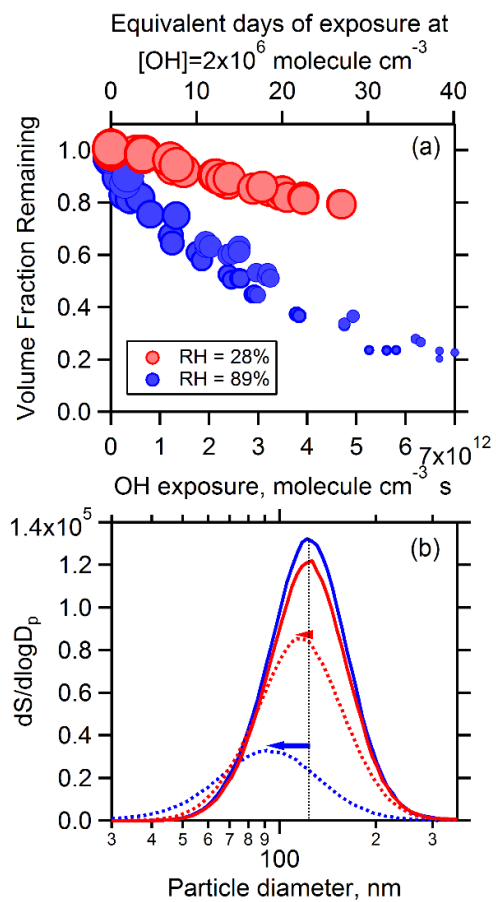

**Figure 1.** A schematic of the experimental setup for heterogeneous oxidation of SOA.

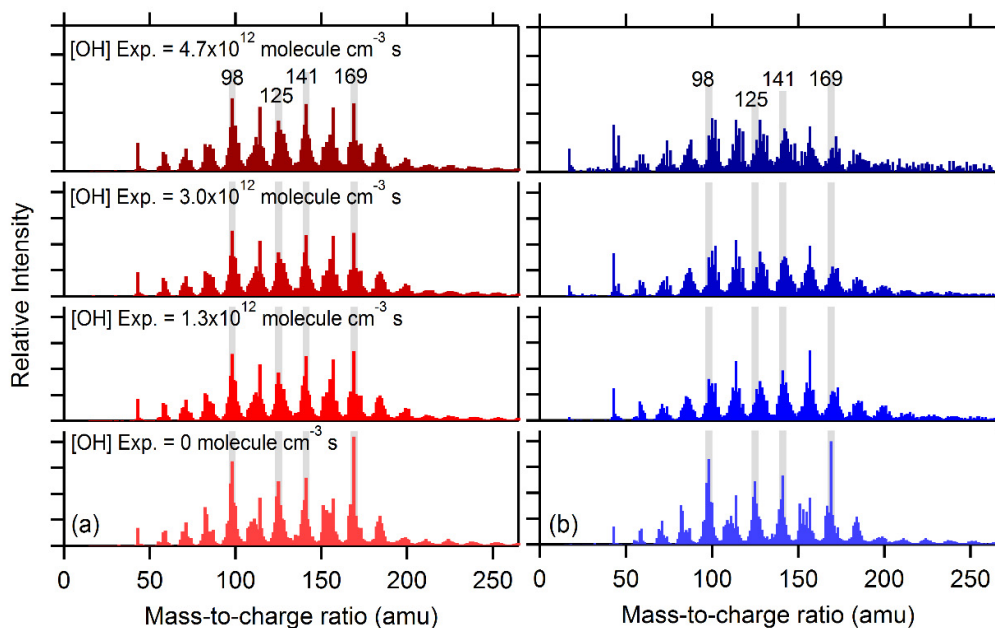

5

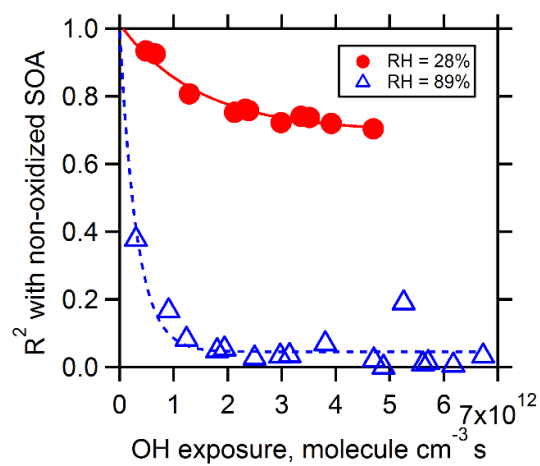

**Figure 2.** Overview of the simplified model. (a) The particle is treated as a sphere stacked with a fixed-depth surface layer and multiple bulk layers with dynamic depths that evolve as the particle evaporates. (b) A generalized reaction scheme of the oxidation process. Oxidation is initiated by H-abstraction of parent compounds that generate organic peroxy radicals ( $\text{RO}_2^\cdot$ ), which react to form peroxides ( $\text{ROOH}$ ), alcohols or ketones, or alkoxy radicals ( $\text{RO}^\cdot$ ).  $\text{RO}^\cdot$  radicals can react to form fragments or stable functionalized products. The net probability of fragmentation is treated implicitly in the model by combining the probability of alkoxy radical formation and their fragmentation. Uptake of  $\text{HO}_x$  radicals and evaporation of fragments occurs only at the surface layer.

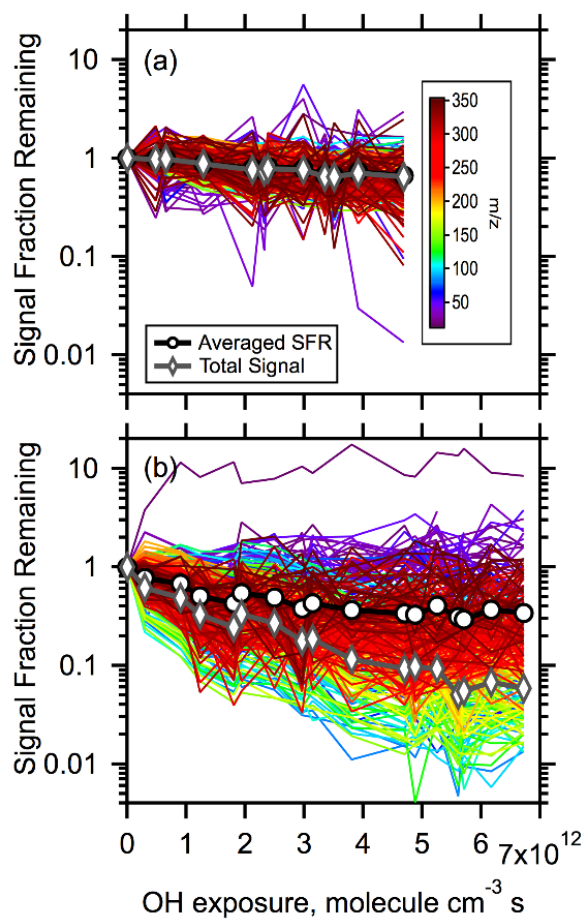

5 **Figure 3.** Influence of photochemical aging on SOA volume for low RH (red) or high RH (blue) conditions. (a) The volume fraction remaining as a function of OH exposure. Sizes of markers correspond to particle size. (b) Example surface-weighted size distributions of particle before OH exposure (solid lines) and after oxidation at an OH exposure =  $4.7 \times 10^{12}$  molecule cm<sup>-3</sup> s (dashed lines).

5 **Figure 4.** Example mass spectra of SOA as a function of OH exposure for (a) low RH (red, left panels) and (b) high RH (blue, right panels) conditions. OH exposure increases from the bottom to the top panels, with values listed in the panels. Vertical gray bars highlight four ions that exhibited a dramatic decay at high RH, but only small changes at low RH. The mass-to-charge ratio of these four ions are indicated in the figure.

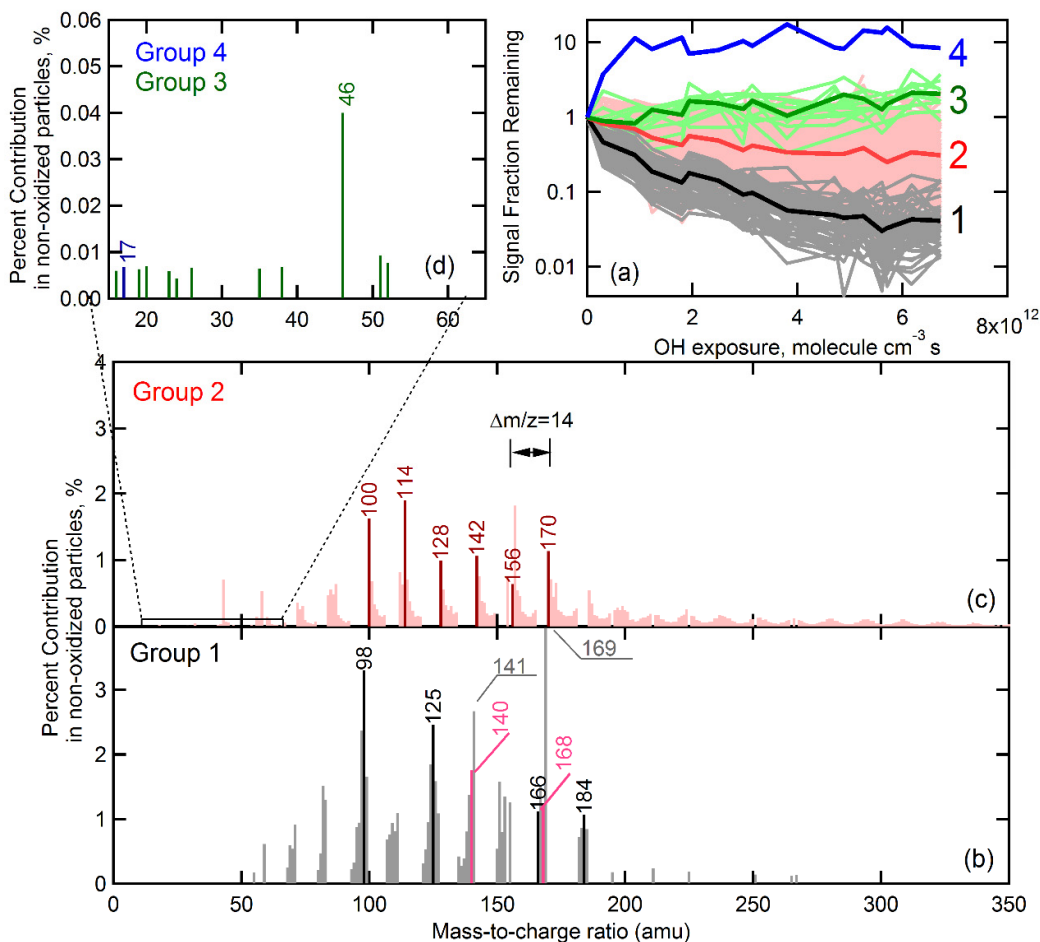

5 **Figure 5.** Coefficient of determination ( $R^2$ ) between spectra of oxidized SOA and non-oxidized SOA as a function of OH exposure for dry (red circles) and wet (blue triangles) conditions. Spectra are filtered by excluding ions that have percentage contribution to total signal below 0.5 %. Lines are exponential fits, and presented only as visual guides.

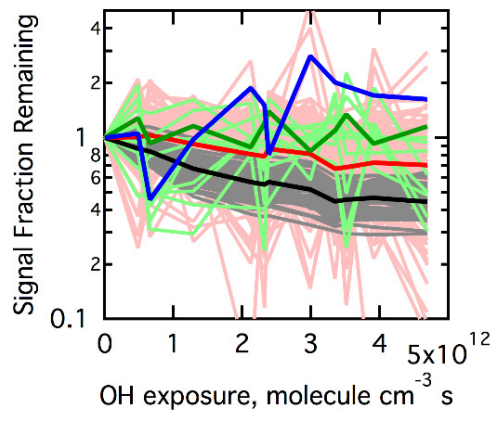

5 **Figure 6.** Signal decay of all peaks observed above background in the mass-to-charge range of 15 – 350 amu as a function of OH exposure for (a) low RH and (b) high RH conditions. Colors denote mass-to-charge of a given peak. The black open circles and line denote the unweighted averaged decay of all the peaks. The dark gray open diamonds and line denote the total signal fraction remaining (i.e. the signal weighted average of all peaks). Note that log scale for the y-axis.

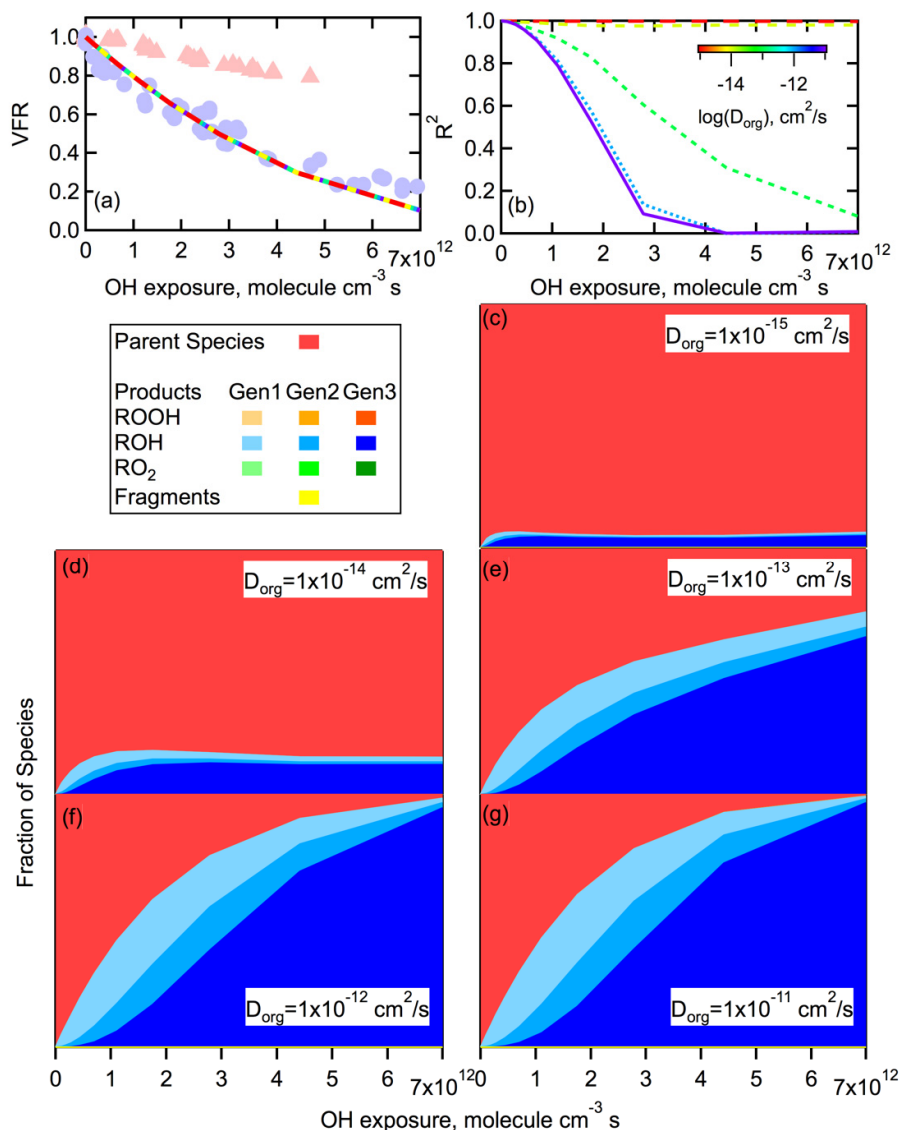

**Figure 7.** (a) Categorization of peaks according to their decay with OH exposure for high RH experiments. The peaks were classified into four groups. Peaks in Group 1 (gray) exhibit the fastest decay with the average shown as the solid black curve. The peaks in Group 2 (red) exhibit the second fastest decay, with the average shown in dark red curve. The peaks in Group 3 (green) exhibit negligible decay, with the average shown in dark green. Group 4 (blue) contains only one peak. (b) Spectrum of the peaks in Group 1. Group 1 contains markers from *cis*-pinonic acid (black peaks) and pinic acid (pink peaks). (c) Spectrum of the peaks in Group 2. Group 2 contains patterns of repeating peaks separated by  $\Delta m/z = 14$ , illustrated by dark red peaks. (d) A zoomed-in view of the peaks of Group 3 and Group 4. These peaks have very small intensities.

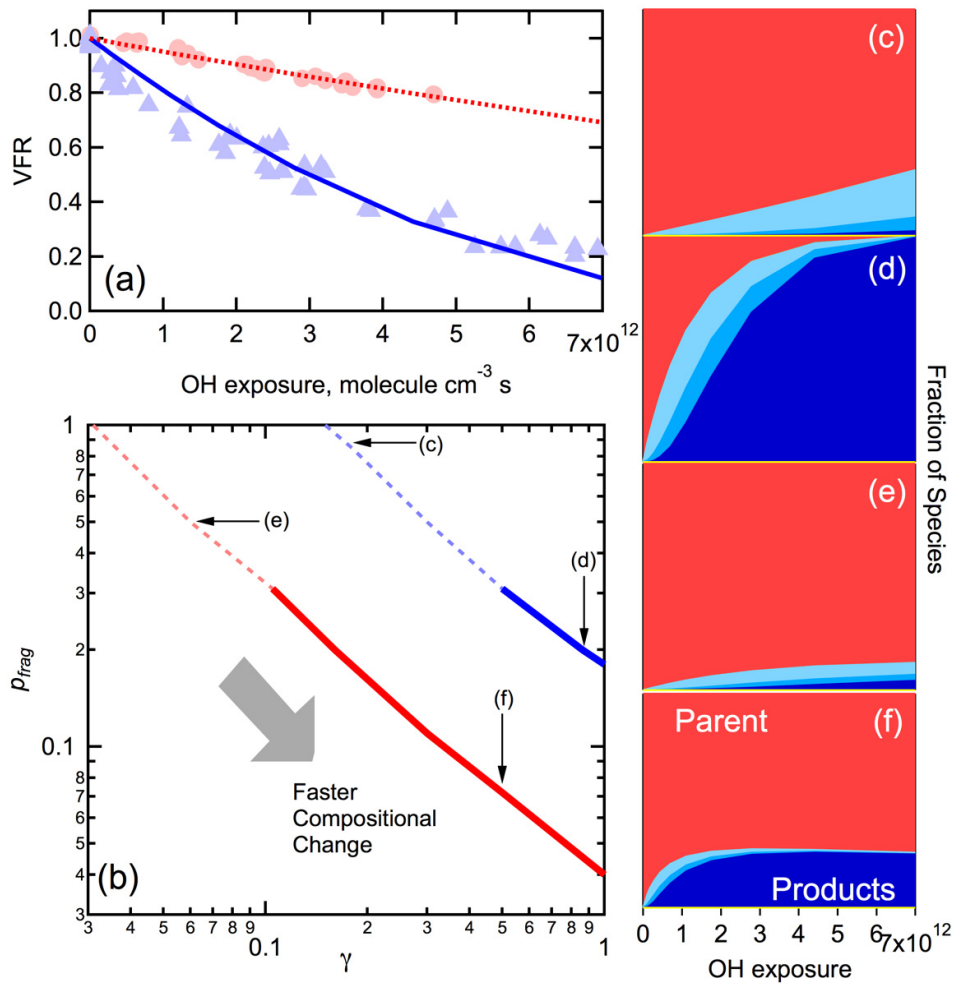

**Figure 8.** Signal fraction remaining of all the individual ions observed above background in the range  $m/z = 15 - 350$  under low RH conditions. Ions are colored according to the groupings determined for the high RH conditions (c.f. **Figure 6**).  
5

5 **Figure 9.** Comparison between observations (points) and simulations (lines) at varying  $D_{\text{org}}$  of the dependence of the volume fraction remaining versus OH exposure for SOA for low RH (red triangles) and high RH (blue circles) conditions. The simulations assumed  $\gamma = 0.6$ ,  $p_{\text{frag}} = 0.5$ ,  $GF = 1.0$  and  $k_{\text{RO2}+\text{RO2}} = 3 \times 10^{-22} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ . The  $D_{\text{org}}$  range from  $10^{-16}$  to  $10^{-11} \text{ cm}^2 \text{ s}^{-1}$ , denoted by colored lines.

**Figure 10.** Simulated effect of variations in the diffusion coefficient on mass loss and compositional change. For these simulations, the  $D_{org}$  is allowed to vary from  $10^{-11}$  to  $10^{-15} \text{ cm}^2 \text{ s}^{-1}$  while all other parameters are held constant and chosen to give good agreement with the high RH observations ( $\gamma = 0.50$ ,  $p_{frag} = 0.31$ ). (a) The simulated volume fraction remaining versus OH exposure. Observations (symbols) are shown for reference for low RH (red triangles) and high RH (blue circles) conditions. The simulation results overlap because diffusivity has no effect on bulk mass loss. (b) The calculated coefficient of determination ( $R^2$ ) between the molecular density of all simulated species as a function of OH exposure, referenced to the no oxidation case. The  $D_{org}$  is indicated by the line color, with the purple solid line denoting the fastest diffusion. (c-g) Simulated fractional concentrations of each species as a function of OH exposure for different  $D_{org}$ . Colors indicate different species and generation (see legend). Only the ROH species are readily visible.

**Figure 11.** (a) Observed (points) and modeled (lines) VFR versus OH exposure for the best-fit models for both low RH (red) and high RH (blue) conditions. (b) Illustration of the relationship between  $\gamma$  and  $\rho_{frag}$  that allow for a good fit to the observed VFR decay for low RH (red) and high RH (blue) conditions. The dashed lines show the full relationship, and the solid lines the best-estimate range. Four specific combinations of  $\gamma$  and  $\rho_{frag}$  are indicated for consideration of the associated composition change. (c-f) Simulated normalized composition change as a function of OH exposure for the  $\gamma$  and  $\rho_{frag}$  combinations indicated in panel (b). The colors correspond to different species with red indicating precursor (parent) species and other colors indicating various oxidation products (c.f. **Figure 10**). Greater compositional changes for a given OH exposure result from combinations with larger  $\gamma$  and smaller  $\rho_{frag}$  for a given RH condition.
