A Point-by-point Response to Review Comments

Dear Dr. Feingold,

We are submitting the revised manuscript (#acp-2018-499) for your consideration of publication in *Atmospheric Chemistry and Physics*. We have carefully studied the reviewer's comments and revised the manuscript accordingly. Please find the point-by-point response (marked as blue) to the review comments. We have provided a copy of track-change manuscript as well as a clean copy of the revised manuscript.

Thank you for your consideration of this submission. We hope you find our response adequately address the review comments and the revision acceptable. We would greatly appreciate it if you could get back to us with your decision at your earliest convenience.

Sincerely,

Peng Wu

Review of Wu et al., "Evaluation of autoconversion and accretion enhancement factors in GCM warm-rain parameterizations using ground-based measurements at the Azores," first revision

I must start by acknowledging the major effort undertaken by the authors to address my comments on the initial submission, especially with respect to obtaining collocated, vertically-resolved cloud and rain liquid water contents. I'm sure this was a significant undertaking, but it puts the premise of their analysis on solid footing and gives me much greater confidence in their conclusions. The addition of Appendix A to demonstrate the rain water content retrieval is also greatly appreciated. I still have a number of minor comments and there remain many language issues that introduce ambiguity in interpreting the authors' statements. I therefore recommend **acceptance pending minor revisions** to address these comments, and I **strongly** recommend the authors use a professional copyediting service to handle the language issues.

Thanks for the insightful comments and suggestions for this and the initial submission, which helped to improve the manuscript a lot.

We have made point-to-point revisions and did a thorough proofreading for the revised manuscript.

Other general comments:

- It's misleading that you call the effective length scale calculated from (wind speed * time elapsed) a "model grid size." It would be more accurate to use language such as "equivalent grid size" or "equivalent model grid size."
- There is a pervasive units issue. Almost everywhere that grid size is given as an area, the units are given in km where they should be km2. Please correct throughout the manuscript or change all instances to "horizontal grid size of X km" such that they do not reference an area. Thanks for the suggestions.

We have changed the terminology to 'horizontal equivalent grid size'. For simplicity and convenience, it is referred to as 'equivalent size' in the text.

- Using a constant value of DSD width is analogous to using a constant LWC distribution width or E_{auto}/E_{accr} width – the spectral width of the DSD is something that varies (increases) with length scale (e.g. Geoffroy et al, 2010, ACP) and is also dependent on the choice of in situ instrumentation (e.g. Witte et al., 2018, GRL; also mentioned but not dealt with in Miles et al., 2000, JAS). While I don't think there's an obvious "better" solution at this point (the math would get considerably hairier if one also considers variable DSD shape), I think it's important to note that by making this assumption, you're essentially just kicking the use of "parameters constant with length scale" down the line from LWC distributions to DSD width. This seems particularly prescient given that your argument for regime-dependence is reflected in the finding of Miles et al. (2000) that the distribution of DSD parameters is different for marine and continental clouds. Thanks for the comment.

The assumed DSD width is used to retrieve LWC within a radar range gate and it is important to note that the LWC within a radar range gate is a bulk property and do not have a distribution. The qc distribution within a specific time interval is used in the Gamma fitting and this distribution do not have a constant width and is little affected by the constant with od DSD. However, we agree with the reviewer that DSD width should vary with different sampling length/time and different instruments. We added the following discussion in Append A to feather this: 'Geoffroy et al. (2010) suggested that σ_x increases with the length scale and Witte et al.

(2018) showed that σ_x also dependent on the choice of instrumentation. The variations of σ_x should be reflected in the retrieval by using different σ_x values with time. However, no aircraft measurements were available during CAP-MBL to provide σ_x over the Azores region. The inclusion of solving σ_x in the retrieval adds another degree of freedom to the equations and complicates the problem considerably. In this study, σ_x is set to a constant value of 0.38 from Miles et al. (2000), which is a statistical value from aircraft measurements of marine low-level clouds.'

Specific content-related comments are given in the remainder of the review in reference to page and line number(s) (format: PX, LY-Z = page X, lines Y-Z). Please see the annotated PDF following these comments for a non-comprehensive list of language issues.

P1, L33: This sentence gives the impression that there is a particular value that the qr-qc ratio should be. Be more explicit here about why this value matters – just throwing out the values without context (e.g. observed vs. typical GCM values) doesn't "prove" that the presently-used constant enhancement factors are wrong.

Thanks for the comment.

This sentence has been revised to 'The ratios of rain to cloud water mixing ratio at E_{accr} =1.07 and E_{accr} =2.0 are 0.063 and 0.142, respectively, from observations, further suggesting that the prescribed value'.

P3, L55: How do aerosol effects being tied to precipitation suppression fit with the rest of your argument? I fail to see the relevance, especially since your results show that precipitation frequency has almost no relationship with E_{auto,Nc}.

Thanks for the comment. This sentence has been deleted.

P4, L60-62: I don't see the point of this sentence. If you're getting at the idea that the "cloud" and "rain" sub-categories are an arbitrary division by drop size, say so.

Thanks for the comment.

This sentence is an elaboration of the parameterized rather than resolved process in GCMs and uses warm rain process as an example. We do not intend to explain the separation of rain and cloud sub-categories here.

P4, L72: Is there not one single study that parameterizes accretion as something other than a power law? You're on firmer ground saying "The vast majority" or something like that because it only takes one counterexample to make your statement false.

Thanks for the comment.

This sentence has been rephrased in the revised manuscript.

P5, L91-93: Cheng and Xu's autoconversion equation is independent of vertical velocity and rain mixing ratio (Text in right column of pg 2319 and their Eq. 6).

Thanks for the comment. This sentence has been revised.

P6, L 109: Why is recognition of spatial scales the important aspect? This seems trivial. Please expand.

Thanks for the comment.

Because the inhomogeneity parameter, similar as the enhancement factor in this study, characterizes cloud field in a grid. An inhomogeneous cloud in a GCM grid can be homogeneous in a WRF grid. Also, in the lon-lat grid setting GCMs the grid size can be dramatically different in tropical and polar regions. The inhomogeneity parameter in Xie and Zhang (2015) can be applied to the globe without manually tuning.

We expanded the following in the revised manuscript: "...found that it can recognize spatial scales without manual tuning and can be applied to the entire globe".

P6, L113-114: Do you mean Zhang et al. derived sub-grid distributions or the actual pixel-scale CLWP and Nc? Please clarify.

Thanks for the comment.

Zhang et al. (2018) derived sub-grid distributions of CLWP and Nc and describe them using lognormal and gamma distributions. This is clarified in the revised manuscript.

P7, L131-132: Enhancement factors are applied at the grid scale by definition, so it seems repetitive to say "grid-mean process enhancement factors."

Thanks for the comment.

This has been rephrased to 'enhancement factors' in the revised manuscript.

P15, L268: You don't show qr in Fig 1. Either reference rain LWC as shown in Fig. A1 or remove "and qr" from the sentence.

Thanks for the comment.

This sentence has been rephrased to "...as seen from WACR reflectivity and q_r in Figure A1." in the revised manuscript.

P17, L305: What does "relative constant" mean? Clarify what the adjective means or remove it. Thanks for the comment. This has been removed.

P18, L317-319: There are a number of other explanations for this result: the dependence of autoconversion parameterizations on number concentration may be flawed, there could be problems with your number concentration retrieval, or perhaps the assumption of constant Nc with height doesn't work. Unless you have evidence that a) there is significant subgrid variability of Nc and b) it matters at the process level, I don't think you can make this statement. Thanks for the comment. We decided to delete this statement in the revised manuscript.

P22, L402-404: The differences from prescribed values only have explanatory power if the simulations used to diagnose it were run at something comparable to 30 km horizontal resolution. Do you have a reference to support this?

Thanks for the comment.

The problem of 'too frequent and too light' is most prominent for the equivalent size of 30-km from the aspect of enhancement factors. We are not aware of any reference that draw similar conclusion.

P22, L410: The language "...the location we choose to collect ground-based observations..." implies that the authors were the primary decision makers regarding the location of the CAP-MBL deployment. If this is the case, this wording is fine. Otherwise, considering alternate

wording, e.g. "...the location of the ground-based observations and retrievals used in this study is..."

Thanks for the comment. This sentence has been re-written in the revised manuscript.

P25, L464: Use the 180² km² value here for consistency. You use 120² km² here while you show a maximum grid size of 180² km² in the figures and use this same maximum grid size in reference to Eacer below.

Thanks for the comment.

This sentence has been changed in the revised to 'The calculated E_{auto} values from observations and retrievals increase from 1.96 at an equivalent size of 30 km to 3.18 at an equivalent size of 150 km. These values are 38% and 0.625% lower than the prescribed value of 3.2. The prescribed value in MG08 represents well in large grid sizes in GCMs (e.g., 180^2 km² grid).' in the revised manuscript.

P28, L519-520: This sentence is confusing. I think you're trying to say "if the vertical gradient of Nw is negative below cloud base" - can you confirm?

Thanks for the comment.

Yes, if the Nw vertical gradient below cloud base is negative, we use constant Nw in cloud. This sentence has been rephrased in the revised manuscript.

P29, L526-527: Italicize all instances in the text of Z (Zc, Zd, etc.). Also, does the subscript "d" indicate drizzle? You use the subscript "r" in Eq. A1 and elsewhere in the main manuscript. Thanks for the comment. These have been changed in the revised manuscript.

P29, L530: Rearrange Eq. A2 for the value you're actually solving for (CLWC(1)_reflectivity). Thanks for the comment. The equation has been rearranged.

P29, L536: Eq. A2 only gives reflectivity at cloud base. How do you integrate up for the profile? Thanks for the comment. The reflectivity is calculated from the updated adiabatic LWC (after multiplying by s). for clarification, the sentence is rephrased as 'Reflectivity profile from cloud is then calculated from Eq. (A2.1) using the updated *CLW C_{adiabatic}*'.

P30, L543-544: What if there is no drizzle at cloud top? How good is the assumption that you can just decrease NW until your criteria is satisfied?

Thanks for the comment. The big assumption in the rain estimation method is that, whenever rain occurs below cloud base, it exists in the whole cloud layer. This assumption may not hold in situations that the top layer is affected by entrainment and no rain drops exist. However, without in situ measurement, we are unable to identify if rain drops exist near cloud in a case by case base.

The minimum value of Nw at the top layer in our estimation is on the order of 10⁻⁴, which is considered a good approximation to the situation that Nw is zero and this approximation has little effect on the reflectivity calculation.

Table 2 (P 42, L819): While visually repetitive, the table is more readable if the upper left corner cell is clear. The entries in the leftmost column should then read (from top to bottom): LTS > 18

K, 13.5 < LTS < 18 K, LTS <13.5 K. You may also consider placing a vertical line between the first and second columns to differentiate between the category column and results/data. Thanks for the comment. Table 2 has been changed in the revised manuscript.

Figure 1, panel c (P44, L825): Why does the histogram look so much different than the fitted gamma distribution? Assuming 5-10 m/s wind speeds there would be something like 60-120 samples for an equivalent 60 km scale, so is this just a consequence of coarse binning? Thanks for catching this. It was a mistake in our plotting code. The figure has been updated in the revised manuscript.

Figure 1 caption (P44, L 832): Replace "mean-qc" with an overbar over qc. Thanks, this is changed.

Figure 2, panels e-f (P45, L 839): The label "cov(qc, qr)" is misleading because you don't actually show the covariance anywhere.

Figure 2, panels e-f (P45, L839): Consider adding minor ticks to the y axes or plot the ratios on a separate right axis. It's very difficult to get a sense for the maximum magnitude of qr/qc because it's all below the 0.2 tick.

Figure 2 (P45, L839): Add labels to the y axes to show that both the PDF and (precip frequency/qr-qc ratio) are shown on the same scale, i.e. label y axes "PDF, precipitation frequency" and "PDF, qr-qc ratio" or similar. This information shouldn't be buried at the bottom of the caption.

Thanks for the comment. We have changed cov(qc, qr) to qc, qr, changed y-axis label and added minor ticks in the revised manuscript.

Figure 5 (P48, L856): How do these adjustments compare with retrieval uncertainty? I ask because you show in Fig. 4 that uncertainty in E decrease with equivalent grid size. For example, if the retrieval uncertainty at 30 km is 20%, then does a qc adjustment tell you something physical or is it just another way of describing uncertainty?

Thanks for the comment.

We do not think the percentages in Figure 5c is a direct result of retrieval uncertainty. Rather, the percentages in Figures 5a and 5b may result from uncertainties of qc retrieval. For example, for the 60-km equivalent size, the broad range from -40% to 40% is the actual adjustment and is greater than the retrieval error.

The averaged adjustment for 180-km equivalent size is zero but the uncertainty in Eaccr is comparable to the 60-km equivalent size.

This figure should be considered as another way of demonstrating the information in Figure 4. If the retrieval uncertainty is to be considered, a similar shaded area as in Figure 4 should be around the solid line in Figure 5c.

1Evaluation of autoconversion and accretion enhancement factors in GCM warm-rain 2parameterizations using ground-based measurements at the Azores

22 Abstract

A great challenge in climate modelling is how to parametrize sub-grid cloud processes, such 23 as autoconversion and accretion in warm rain formation. In this study, we use ground-based 24 observations and retrievals over the Azores to investigate the so-called enhancement factors, 25 E_{auto} and E_{accr} , which are often used in climate models to account for the influences of sub-grid 26 variances of cloud and precipitation water on the autoconversion and accretion processes. E_{auto} 27 and E_{accr} are computed for different equivalent model gridresolution sizes. The calculated E_{auto} 28 values increases from 1.96 (30 km) to 3.245 (1280 km), and the calculated E_{accr} values increase 29 from 1.53 (30 km) to 1.76 (180 km). Comparing the prescribed enhancement factors in 30 Morrison and Gettleman (2008, MG08) to the observed ones, we found that a higher E_{auto} (3.2) 31 at small grids and lower $E_{accr}(1.07)$ are used in MG08, which helps to explain why most of the 32 33 GCMs produce too frequent precipitation events but with too light precipitation intensity. The ratios of rain to cloud water mixing ratio at E_{accr} =1.07 and E_{accr} =2.0 are 0.063 and 0.142, 34 respectively, from observations, further proving suggesting that the prescribed value of 35 E_{accr} =1.07 used in MG08 is too small to simulate correct precipitation intensity. Both E_{auto} and 36 E_{accr} increase when the boundary layer becomes less stable, and the values are larger in 37 precipitating clouds (CLWP>75 gm⁻²) than those in nonprecipiting clouds (CLWP<75 gm⁻²). 38 Therefore, the selection of E_{auto} and E_{accr} values in GCMs should be regime-and resolution-39 dependent. 40

42 1. Introduction

41

Due to their vast areal coverage (Warren et al., 1986, 1988; Hahn and Warren, 2007) and 43 strong radiative cooling effect (Hartmann et al., 1992; Chen et al., 2000), small changes in the coverage or thickness of marine boundary layer (MBL) clouds could change the radiative 45 energy budget significantly (Hartmann and Short, 1980; Randall et al., 1984) or even offset the 46 radiative effects produced by increasing greenhouse gases (Slingo, 1990). The lifetime of MBL 47 clouds remains an issue in climate models (Yoo and Li, 2012; Jiang et al., 2012; Yoo et al., 48 2013; Stanfield et al., 2014) and represents one of the largest uncertainties in predicting future 49 climate (Wielicki et al., 1995; Houghton et al., 2001; Bony and Dufresne, 2005). 50 MBL clouds frequently produce precipitation, mostly in the form of drizzle (Austin et al., 51 1995; Wood, 2005a; Leon et al., 2008; Wood, 2012). A significant amount of drizzle is 52 evaporated before reaching the surface, for example, about ~76\% over the Azores region in 53 Northeast Atlantic (Wu et al., 2015), which provides another water vapour source for MBL 54 55 clouds. Due to their pristine environment and their close vicinity to the surface, MBL clouds are especially sensitive to aerosol perturbations (Quaas et al., 2009; Kooperman et al., 2012). 56 Most aerosol indirect effects are associated with precipitation suppression (Albrecht, 1989; 57 Ackerman et al., 2004; Lohmann and Feichter, 2005; Wood, 2007). Thus, accurate prediction 58

indirect effects in climate projections. 60 Due to the coarse spatial resolutions of the general circulation model (GCM) grid, many 61 cloud processes cannot be adequately resolved and must be parameterized. For example, warm 62 rain parameterizations in most GCMs treat the condensed water as either cloud or rain from the 63 collision-coalescence process, which is partitioned into autoconversion and accretion subprocesses in model parameterizations (Kessler, 1969; Tripoli and Cotton, 1980; Beheng, 1994; 65 Khairoutdinov and Kogan, 2000; Liu and Daum, 2004). Autoconversion represents the process 66 that drizzle drops being formed through the condensation of cloud droplets and accretion 67 represents the process where rain drops grow by the coalescence of drizzle-sized drops with 68 cloud droplets. Autoconversion mainly accounts for precipitation initiation while accretion 69 70 primarily contributes to precipitation intensity. Autoconversion is often parameterized as functions of cloud droplet number concentration (N_c) and cloud water mixing ratio (q_c) , while accretion depends on both cloud and rain water mixing ratios (q_c and q_r) (Kessler, 1969; Tripoli 72 and Cotton, 1980; Beheng, 1994; Khairoutdinov and Kogan, 2000; Liu and Daum, 2004; 73 Wood, 2005b). All-The majority of previous studies suggested that these two processes as 74 power law functions of cloud and precipitation properties (See section 2 for details). 75

of precipitation is essential in simulating the global energy budget and in constraining aerosol

59

76

77

precipitation leads to the unavoidable use of the grid-mean quantities $(\overline{N_c}, \overline{q_c}, \text{ and } \overline{q_r}, \text{ where})$

In conventional GCMs, the lack of information on the sub-grid variances of cloud and

78 overbar denotes grid mean, same below) in calculating autoconversion and accretion rates. MBL cloud liquid water path (CLWP) distributions are often positive skewed (Wood and Hartmann, 2006; Dong et al., 2014a and 2014b), that is, the mean value is greater than mode 80 value. Thus, the mean value only represents a relatively small portion of samples. Also, due to 81 the nonlinear nature of the relationships, the two processes depend significantly on the sub-82 grid variability and co-variability of cloud and precipitation microphysical properties (Weber 83 and Quass, 2012; Boutle et al., 2014). In some GCMs, sub-grid scale variability is often ignored 84 or hard coded using constants to represent the variabilities under all meteorological conditions 85 and across the entire globe (Pincus and Klein, 2000; Morrison and Gettleman, 2008; Lebsock 86 et al., 2013). This could lead to systematic errors in precipitation rate simulations (Wood et al., 87 2002; Larson et al., 2011; Lebsock et al., 2013; Boutle et al., 2014; Song et al., 2018), where 88 GCMs are found to produce too frequent but too light precipitation compared to observations 89 (Zhang et al., 2002; Jess, 2010; Stephens et al., 2010; Nam and Quaas, 2012; Song et al., 2018). The bias is found to be smaller by using a probability density function (PDF) of cloud water to 91 92 represent the sub-grid scale variability in autoconversion parameterization (Beheng, 1994; Zhang et al., 2002; Jess, 2010), or more complexly, by integrating the autoconversion rate over 93 a joint PDF of liquid water potential temperature, and vertical velocity, total water mixing ratio 94 and rain water mixing ratio (Cheng and Xu, 2009).

96 Process rate enhancement factors (E) are introduced when considering sub-grid scale variability in parameterizing grid-mean processes and they should be parameterized as functions of the PDFs of cloud and precipitation properties within a grid box (Morrison and 98 Gettleman, 2008; Lebsock et al., 2013; Boutle et al., 2014). However, these values in some GCM parameterization schemes are prescribed as constants regardless of underlying surface 100 or meteorological conditions (Xie and Zhang, 2015). Boutle et al. (2014) used aircraft in situ 101 measurements and remote sensing techniques to develop a parameterization for cloud and rain, 102 in which not only consider the sub-grid variabilities under different grid scales, but also 103 consider the variation of cloud and rain fractions. The parameterization was found to reduce 104 precipitation estimation bias significantly. Hill et al. (2015) modified this parameterization and 105 developed a regime and cloud type dependent sub-grid parameterization, which was 106 implemented to the Met Office Unified Model by Walters et al. (2017) and found that the 107 radiation bias is reduced using the modified parameterization. Using ground-based observations and retrievals, Xie and Zhang (2015) proposed a scale-aware cloud 109 inhomogeneity parameterization that they applied to the Community Earth System Model 110 (CESM) and found that it can recognize spatial scales without manual tuning and can be applied 111 to the entire globe. The inhomogeneity parameter is essential in calculating enhancement 112 factors and affect the conversion rate from cloud to rain liquid. Xie and Zhang (2015), however, 113 did not evaluate the validity of CESM simulations from their parameterization; the effect of N_c 114

variability or the effect of covariance of cloud and rain on accretion process was not assessed. Most recently, Zhang et al. (2018) derived the sub-grid distribution of CLWP and N_c from the 116 MODIS cloud product. They also studied the implication of the sub-grid cloud property 117 variations for the autoconversion rate simulation, in particular the enhancement factor, in GCMs. For the first time, the enhancement factor due to the sub-grid variation of N_c is derived 119 from satellite observation, and results reveal several regions downwind of biomass burning 120 aerosols (e.g., Gulf of Guinea, East Coast of South Africa), air pollution (i.e., Eastern China 121 Sea), and active volcanos (e.g., Kilauea Hawaii and Ambae Vanuatu), where the enhancement 122 factor due to N_c is comparable, or even larger than that due to CLWP. However, one limitation 123 of Zhang et al. (2018) is the use of passive remote sensing data only, which cannot distinguish 124 cloud and rain water. 125 Dong et al. (2014a and 2014b) and Wu et al. (2015) reported MBL cloud and rain properties 126 over the Azores and provided the possibility of calculating the enhancement factors using 127 128 ground-based observations and retrievals. A joint retrieval method to estimate q_c and q_r profiles is proposed based on existing studies and is presented in Appendix A. Most of the calculations 129 and analyses in this study is based on Morrison and Gettleman (2008, MG08 hereafter) scheme. 130 The enhancement factors in several other schemes are also discussed and compared with the 131 observational results and the approach in this study can be repeated for other microphysics 132 schemes in GCMs. This manuscript is organized as follows: section 2 includes a summary of 133

134 the mathematical formulas from previous studies that can be used to calculate grid-mean

135 process enhancement factors. Ground-based observations and retrievals are introduced in

136 Section 3. Section 4 presents results and discussions, followed by summary and conclusions in

137 Section 5. The retrieval method used in this study is in Appendix A.

2. Mathematical Background

Autoconversion and accretion rates in GCMs are usually parameterized as power law

equations (Tripoli and Cotton, 1980; Beheng, 1994; Khairoutdinov and Kogan, 2000; Liu and

141 Daum, 2004):

138

149

$$142 \quad \left(\frac{\partial q_r}{\partial t}\right)_{auto} = A\bar{q}_c^{a1}\bar{N}_c^{a2},\tag{1}$$

143
$$\left(\frac{\partial q_r}{\partial t}\right)_{accr} = B(\overline{q_c}\overline{q_r})^b,$$
 (2)

where A, a1, a2, B, and b are coefficients in different schemes listed in Table 1. The \overline{q}_c , \overline{q}_r ,

and $\overline{N_c}$ are grid-mean cloud water mixing ratio, rain water mixing ratio, and droplet number

146 concentration, respectively. Because it is widely used in model parameterizations, the detailed

results from Khairoutdinov and Kogan (2000) parameterization that been used in MG08

scheme will be shown in Section 4 while a summary will be given for other schemes.

Ideally, the covariance between physical quantities should be considered in the calculation

of both processes. However, \overline{q}_c and \overline{N}_c in Eq. (1) are arguably not independently retrieved in

our retrieval method which will be introduced in this section and Appendix A. Thus we only

- assess the individual roles of q_c and N_c sub-grid variations in determining autoconversion rate.
- 153 q_c and q_r , on the other hand, are retrieved from two independent algorithms as shown in Dong
- et al. (2014a and 2014b), Wu et al. (2015) and Appendix A, we will assess the effect of cloud
- and rain property covariance on accretion rate calculations.
- In the sub-grid scale, the PDFs of q_c and N_c are assumed to follow a gamma distribution
- based on observational studies of optical depth in MBL clouds (Barker et al., 1996; Pincus et
- 158 al., 1999; Wood and Hartmann, 2006):

159
$$P(x) = \frac{\alpha^{\nu}}{\Gamma(\nu)} x^{\nu-1} e^{-\alpha x}$$
, (3)

- where x represents q_c or N_c with grid-mean quantity \overline{q}_c or \overline{N}_c , represented by μ , $\alpha = \nu/\mu$ is the
- scale parameter, σ^2 is the relative variance of x (= variance divided by μ^2), $\nu = 1/\sigma^2$ is the
- shape parameter. ν is an indicator of cloud field homogeneity, with large values representing
- 163 homogeneous and small values indicating inhomogeneous cloud field.
- By integrating autoconversion rate, Eq. (1), over the grid-mean rate, Eq. (3), with respect
- to sub-grid scale variation of q_c and N_c , the autoconversion rate can be expressed as:

166
$$\left(\frac{\partial q_r}{\partial t}\right)_{auto} = A\mu_{q_c}^{a1}\mu_{N_c}^{a2}\frac{\Gamma(\nu+a)}{\Gamma(\nu)\nu^a},$$
 (4)

- where a = a1 or a2. Comparing Eq. (4) to Eq. (1), the autoconversion enhancement factor
- 168 (E_{auto}) can be given with respect to q_c and N_c :

$$169 \quad E_{auto} = \frac{\Gamma(\nu + a)}{\Gamma(\nu)\nu^a}.$$
 (5)

In addition to fitting the distributions of q_c and N_c , we also tried two other methods to calculate E_{auto} . The first is to integrate Eq. (1) over the actual PDFs from observed or retrieved parameters and the second is to fit a lognormal distribution for sub-grid variability like what has been done in other studies (e.g., Lebsock et al., 2013; Larson and Griffin, 2013). It is found that all three methods get similar results. In this study, we use a gamma distribution that is consistent with MG08. Also note that, in the calculation of E_{auto} from $\overline{N_c}$, the negative exponent (-1.79) may cause singularity problems in Eq. (5). When this situation occurs, we do direct calculations by integrating the PDF of $\overline{N_c}$ rather than using Eq. (5).

To account for the covariance of microphysical quantities in a model grid, it is difficult to apply bivariate gamma distribution due to its complex nature. In this study, the bivariate lognormal distribution of q_c and q_r is used (Lebsock et al., 2013; Boutle et al., 2014) and can be written as:

182
$$P(\overline{q}_c, \overline{q}_r) = \frac{1}{2\pi \overline{q}_c} \frac{1}{\overline{q}_r \sigma_{q_c} \sigma_{q_r} \sqrt{1-\rho^2}} exp \left\{ -\frac{1}{2} \frac{1}{1-\rho^2} \left[\left(\frac{\ln \overline{q}_c - \mu_{q_c}}{\sigma_{q_c}} \right)^2 - 2\rho \left(\frac{\ln \overline{q}_c - \mu_{q_c}}{\sigma_{q_c}} \right) \left(\frac{\ln \overline{q}_r - \mu_{q_r}}{\sigma_{q_r}} \right) + \right] \right\},$$
(6)

where σ is standard deviation and ρ is the correlation coefficient of q_c and q_r .

Similarly, by integrating the accretion rate in Eq. (2) from Eq. (6), we get the accretion enhancement factor (E_{accr}) of:

187
$$E_{accr} = \left(1 + \frac{1}{\nu_{q_c}}\right)^{\frac{1.15^2 - 1.15}{2}} \left(1 + \frac{1}{\nu_{q_r}}\right)^{\frac{1.15^2 - 1.15}{2}} \exp(\rho 1.15^2 \sqrt{\ln\left(1 + \frac{1}{\nu_{q_c}}\right) \ln(1 + \frac{1}{\nu_{q_r}})}).$$
 (7)

3. Ground-based observations and retrievals

189 The datasets used in this study were collected at the Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Mobile Facility (AMF), which was deployed on 190 191 the northern coast of Graciosa Island (39.09°N, 28.03°W) from June 2009 to December 2010 (for more details, please refer to Rémillard et al., 2012; Dong et al., 2014a and Wood et al., 192 193 2015). The detailed operational status of the remote sensing instruments on AMF was summarized in Figure 1 of Rémillard et al. (2012) and discussed in Wood et al. (2015). The 194 ARM Eastern North Atlantic (ENA) site was established on the same island in 2013 and 195 196 provides long-term continuous observations. The cloud-top heights (Z_{top}) were determined from W-band ARM cloud radar (WACR) 197 reflectivity and only single-layered low-level clouds with $Z_{top} \le 3$ km are selected. Cloud-base 198 heights (Zbase) were detected by a laser ceilometer (CEIL) and the cloud thickness was simply 199 200 the difference between cloud top and base heights. The cloud liquid water path (CLWP) was retrieved from microwave radiometer (MWR) brightness temperatures measured at 23.8 and 201 31.4 GHz using a statistical retrieval method with an uncertainty of $20~{\rm g~m^{-2}}$ for CLWP < 200202 g m⁻², and 10% for CLWP > 200 g m⁻² (Liljegren et al., 2001; Dong et al., 2000). Precipitating 203 status is identified through a combination of WACR reflectivity and Z_{base} . As in Wu et al. 204

- (2015), we labelled the status of a specific time as "precipitating" if the WACR reflectivity
 below the cloud base exceeds -37 dBZ.
 The ARM merged sounding data have a 1-min temporal and 20-m vertical resolution below
 3 km (Troyan, 2012). In this study, the merged sounding profiles are averaged to 5-min
- resolution. Pressure and temperature profiles are used to calculate air density (ρ_{air}) profiles
- 210 and to infer adiabatic cloud water content.
- Cloud droplet number concentration (N_c) is retrieved using the methods presented in Dong
- et al. (1998, 2014a and 2014b) and are assumed to be constant in a cloud layer. Vertical profiles
- 213 of cloud and rain water content (CLWC and RLWC) are retrieved by combining WACR
- 214 reflectivity, CEIL attenuated backscatter and by assuming adiabatic growth of cloud parcels.
- $\ \, \text{The detailed description is presented in Appendix A with the results from a selected case. The } \\$
- 216 CLWC and RLWC values are transformed to q_c and q_r by dividing by air density (e.g., $q_c(z) =$
- 217 $CLWC(z)/\rho_{air}(z)$).
- The estimated uncertainties for the retrieved q_c and q_r are 30% and 18%, respectively (see
- Appendix A). We used the estimated uncertainties of q_r and q_c as inputs of Eqs. (4) and (7) to
- assess the uncertainties of E_{auto} and E_{accr} . For instance, $(1 \pm 0.3)q_c$ are used in Eq. (4) and the
- mean differences are then used as the uncertainty of E_{auto} . Same method is used to estimate the
- 222 uncertainty for E_{accr} .

223 The autoconversion and accretion parameterizations partitioned from the collisioncoalescence process dominate at different levels in a cloud layer. Autoconversion dominates 224 around cloud top where cloud droplets reach maximum by condensation and accretion is 225 dominant at middle and lower parts of the cloud where rain drops sediment and continue to 226 grow by collecting cloud droplets. Complying with the physical processes, we estimate 227 autoconversion and accretion rates at different levels of a cloud layer in this study. The 228 averaged q_c within the top five range gates (~215 m thick) are used to calculate E_{auto} . To 229 calculate E_{accr} , we use the averaged q_c and q_r within five range gates around the maximum 230 radar reflectivity. If the maximum radar reflectivity appears at the cloud base, then five range 231 gates above the cloud base are used. 232 The ARM merged sounding data are also used to calculate lower tropospheric stability 233 $(LTS = \theta_{700 hPa} - \theta_{1000 hPa})$, which is used to infer the boundary layer stability. In this study, 234 unstable and stable boundary layers are defined as LTS less than 13.5 K and greater than 18 K. 235 respectively, and environment with an LTS between 13.5 K and 18 K is defined as mid-stable 236 (Wang et al. 2012; Bai et al. 2018). Enhancement factors in different boundary layers are 237 summarized in Section 4.2 and may be used as references for model simulations. Further, two 238 regimes are classified: CLWP greater than 75 g m⁻² as precipitating and CLWP less than 75 g 239 m⁻² as nonprecipitating (Rémillard et al., 2012). 240

241 To evaluate the dependence of autoconversion and accretion rates on sub-grid variabilities for different model spatial resolutions, an averaged wind speed within a cloud layer was 242 extracted from merged sounding and used in sampling observations over certain periods to 243 mimic different grid sizes in GCMs. For example, two hours of observations corresponds to a 244 72-km horizontal equivalent grid box if mean in-cloud wind speed is 10 m s⁻¹ horizontal wind 245 and if the wind speed is 5 m s^{-1} , four hours of observations is needed to mimic the same 246 horizontal equivalent grid. We used six horizontal equivalent grid sizes (30-, 60-, 90-, 120-, 247 150-, and 180-km) and mainly show the results from 60-km and 180-km horizontal equivalent 248 grid sizes in Section 4. For convenience, we refer 'equivalent size' as 'horizontal equivalent 249 grid size' from now on. 250

4. Results and discussions 251

In this section, we first show the data and methods using a selected case, followed by 252 statistical analysis based on 19 months of data and multiple time-intervals. 253

4.1 Case study

254

256

257

258

259

The selected case occurred on July 27, 2010 (Figure 1a) at the Azores. This case was 255 characterized by a long time of non-precipitating or light drizzling cloud development (00:00-14:00 UTC) before intense drizzling occurred (14:00-20:00 UTC). Wu et al. (2017) studied this case in detail to demonstrate the effect of wind shear on drizzle initiation. Here, we choose two periods corresponding to a 180-km equivalent size grid and having similar mean q_c near

cloud top: 0.28 g kg⁻¹ for period c and 0.26 g kg⁻¹ for period d but with different distributions 260 (Figures 1c and 1d). The PDFs of q_c are then fitted using gamma distributions to get shape 261 parameters (v) as shown in Figures 1c and 1d. Smaller v is usually associated with a more 262 inhomogeneous cloud field, which allows more rapid drizzle production and more efficient 263 liquid transformation from cloud to rain (Xie and Zhang, 2015) in regions that satisfy 264 precipitation criteria, which is usually controlled using threshold q_r , droplet size or relative 265 humidity (Kessler, 1969; Liu and Daum, 2004). The period d has a wider q_c distribution than 266 the period c, resulting in a smaller ν and thus larger E_{auto} . Using the fitted ν , the E_{auto} from q_c 267 is calculated from Eq. (5) and the period d is larger than the period c (1.80 vs. 1.33). The E_{auto} 268 values for the periods d and c can also be calculated from N_c using the same procedure as q_c 269 with a similar result (2.1 vs. 1.51). The E_{accr} values for the periods d and c can be calculated 270 from the covariance of q_c and q_r and Eq. (7). Not surprisingly, the period d has larger E_{accr} than 271 the period c. The combination of larger E_{auto} and E_{accr} in the period d contributes to the rapid 272 drizzle production and high rain rate as seen from WACR reflectivity and q_r : in Figure A1. 273 It is important to understand the physical meaning of enhancement factors in precipitation 274 275 parameterization. For example, if we assume two scenarios for q_c with a model grid having the same mean values but different distributions: (1) The distribution is extremely homogeneous, 276 there will be no sub-grid variability because the cloud has the same chance to precipitate and 277 the enhancement factors would be unity (this is true for arbitrary grid-mean q_c amount as well).

279 (2) The cloud field gets more and more inhomogeneous with a broad range of q_c within the model grid box, which results in a greater enhancement factor and increases the possibility of 280 precipitation. That is, a large enhancement factor can make the part of the cloud with higher q_c 281 within the grid box become more efficient in generating precipitation, rather than the entire 282 model grid. 283 Using the LWP retrieved from the Moderate Resolution Imaging Spectroradiometer 284 (MODIS) as an indicator of cloud inhomogeneous, Wood and Hartmann (2006) found that 285 when clouds become more inhomogeneous, cloud fraction decreases, and open cells become 286 dominant with stronger drizzling process (Comstock et al., 2007). The relationship between 287 reduced homogeneity and stronger precipitation intensity is found in this study, which is similar 288 to the findings in other studies (e.g., Wood and Hartmann, 2006, Comstock et., 2007, Barker 289 et al., 1996; Pincus et al., 1999). 290 It is clear that q_c and N_c in Figure 1b are correlated with each other. In addition to their 291 natural relationships, q_c and N_c in our retrieval method are also correlated (Dong et al., 2014a 292 and 2014b). Thus, the effect of q_c and N_c covariance on E_{auto} is not included in this study. In 293 Figures 1c and 1d, the results are calculated using equivalent size model grid of 180-km for the 294 selected case on 27 July 2010. In Section 4.2, we will use these approaches to calculate their 295 statistical results for multiple equivalent-grid sizes using the 19-month ARM ground-based 296 observations and retrievals. 297

4.2 Statistical result

298

For a specific equivalent grid-size, e.g. 60-km, we estimate the shape parameter (ν) and 299 calculate E_{auto} through Eqns. (5) and (7). The PDFs of E_{auto} for both 60-km and 180-km 300 equivalent grids sizes are shown in Figures 2a-2d. The distributions of E_{auto} values calculated 301 from q_c with 60-km and 180-km equivalent grid sizes (Figures 2a and 2b) are different to each 302 other (2.79 vs. 3.3). The calculated E_{auto} values range from 1 to 10, and most are less than 4. 303 The average value for the 60-km equivalent sizegrid (2.79) is smaller than that for the 180-km 304 equivalent sizegrid (3.2), indicating a possible dependence of E_{auto} on model grid size. Because 305 drizzle-sized drops are primarily resulted from the autoconversion, we investigate the 306 relationship between E_{auto} and precipitation frequency, which is defined as the average 307 percentage of drizzling occurrence based on radar reflectivity below the cloud base. Given the 308 average LWP at Azores from Dong et al. (2014b, 109-140 g m⁻²), the precipitation frequency 309 (black lines in Figures 2a and 2b) agrees well with those from Kubar et al. (2009, 0.1-0.7 from 310 their Figure 11). The precipitation frequency within each bin shows an increasing trend for 311 E_{auto} from 0 to 4-6, then oscillates around a relative constant-when $E_{auto} > 6$, indicating that in 312 precipitation initiation process, E_{auto} keeps increasing to a certain value (\sim 6) until the 313 precipitation frequency reaches a near-steady state. Larger E_{auto} values do not necessarily result 314 in higher precipitation frequency but instead may produce more drizzle-sized drops from 315 316 autoconversion process when the cloud is precipitating.

317 The PDFs of E_{auto} calculated from N_c also share similar patterns of positive skewness and 318 peaks at ~1.5-2.0 for the 60-km and 180-km equivalent grid sizes (Figures 2c and 2d). Although the average values are close to their q_c counterparts (2.54 vs. 2.79 for 60-km and 3.45 vs. 3.2 319 for 180-km), the difference in E_{auto} between 60-km and 180-km equivalent grid-sizes becomes 320 large. The precipitation frequencies within each bin are nearly constant or slightly decrease, 321 which are different to their q_c counterparts shown in Figures 2a and 2b. This suggests 322 323 complicated effects of droplet number concentration on precipitation initiation and warrants more explorations of aerosol-cloud-precipitation interactions. This is very intriguing result, 324 which suggests the existence of significant sub-grid variation of N_e and this variation can 325 significantly influence the warm rain process. As mentioned in Section 2, q_c and N_c are also 326 fitted using lognormal distributions to calculate E_{auto} , those are close to the results in Figure 2 327 328 (not shown here) with average values of 3.28 and 3.84, respectively, for 60-km and 180-km 329 equivalent grid sizes. Because the E_{auto} values calculated from q_c and N_c are close to each other, we will focus on analyzing the results from q_c only for simplicity and clarity. The effect 330 of q_c and N_c covariance, as stated in Section 4.1, is not presented in this study due to the intrinsic 331 correlation in the retrieval (Dong et al., 2014a and 2014b and Appendix A of this study). 332 The covariance of q_c and q_r is included in calculating E_{accr} and the results are shown in 333 Figures 2e and 2f. The calculated E_{accr} values range from 1 to 4 with mean values of 1.62 and 334 1.76 for 60-km and 180-km equivalent grid-sizes, respectively. These two mean values are 335

much greater than the prescribed value used in MG08 (1.07). Since accretion is dominant at 336 middle and lower parts of the cloud where rain drops sediment and continue to grow by 337 collecting cloud droplets, we superimpose the ratio of q_r to q_c within each bin (black lines in 338 Figures 2e and 2f) to represent the portion of rain water in the cloud layer. In both panels, the 339 ratios are less than 15%, which means that q_r can be one order of magnitude smaller than q_c . 340 The differences in magnitude are consistent with previous CloudSat and aircraft results (e.g., 341 Boutle et al., 2014). This ratio increases from $E_{accr}=0$ to ~ 2 , and then decreases, suggesting a 342 possible optimal state for the collision-coalescence process to achieve maximum efficiency for 343 converting cloud water into rain water at E_{accr} =2. In other words, the conversion efficiency 344 cannot be infinitely increased with E_{accr} under available cloud water. The ratio of q_r to q_c 345 increases from $E_{accr}=1.07$ (0.063) to $E_{accr}=2.0$ (0.142), indicating that the fraction of rain water 346 in total water using the prescribed E_{accr} is too low. This ratio could be increased significantly 347 using a large E_{accr} value, therefore increasing precipitation intensity in the models. This further 348 proves that the prescribed value of E_{accr} =1.07 used in MG08 is too small to correctly simulate 349 precipitation intensity in the models. Therefore, similar to the conclusions in Lebsock et al. 350 (2013) and Boutle et al. (2014), we suggest increasing E_{accr} from 1.07 to 1.5-2.0 in GCMs. 351 To illustrate the impact of using prescribed enhancement factors, autoconversion and 352 accretion rates are calculated using the prescribed values (e.g., 3.2 for E_{auto} and 1.07 for E_{accr} , 353 MG08; Xie and Zhang, 2015) and the newly calculated ones in Figure 2 that use observations 354

accretion rates (Figures 3c and 3d) from observations (x-axis) and model parameterizations (y-356 axis) for 60-km and 180-km equivalent grid-sizes. Despite the spread, the peaks of the joint 357 density of autoconversion rate appear slightly above the one-to-one line especially for the 60-358 km equivalent size, suggesting that cloud droplets in the model are more easily to be converted 359 into drizzle/rain drops than observations. On the other hand, the peaks of accretion rate appear 360 slightly below the one-to-one line which indicates that simulated precipitation intensities are 361 lower than observed ones. The magnitudes of the two rates are consistent with Khairoutdinov 362 and Kogan (2000), Liu and Daum (2004), and Wood (2005b). 363 Compared to the observations, the precipitation in GCMs occurs at higher frequencies with 364 lower intensities, which might explain why the total precipitation amounts are close to surface 365 measurements over an entire grid box. This 'promising' result, however, fails to simulate 366 precipitation on the right scale and cannot capture the correct rain water amount, thus providing 367 limited information in estimating rain water evaporation and air-sea energy exchange. 368 Clouds in an unstable boundary layer have a better chance of getting moisture supply from 369 the surface by upward motion than clouds in a stable boundary layer. Precipitation frequencies 370 are thus different in these two boundary layer regimes. For example, clouds in a relatively 371 unstable boundary layer more easily produce drizzle than those in a stable boundary layer (Wu 372 et al., 2017). Provided the same boundary layer condition, CLWP is an important factor in 373

and retrievals. Figure 3 shows the joint density of autoconversion (Figures 3a and 3b) and

355

374 determining the precipitation status of clouds. At the Azores, precipitating clouds are more likely to have CLWP greater than 75 g m⁻² than their nonprecipitating counterparts (Rémillard 375 et al., 2012). To further investigate what conditions and parameters can significantly influence 376 the enhancement factors, we classify low-level clouds according to their boundary layer 377 conditions and CLWPs. 378 The averaged E_{auto} and E_{accr} values for each category are listed in Table 2. Both E_{auto} and 379 E_{accr} increase when the boundary layer becomes less stable, and these values become larger in 380 precipitating clouds (CLWP>75 gm⁻²) than those in nonprecipiting clouds (CLWP<75 gm⁻²). 381 In real applications, autoconversion process only occurs when q_c or cloud droplet size reaches 382 a certain threshold (e.g., Kessler, 1969 and Liu and Daum, 2004). Thus, it will not affect model 383 simulations if a valid E_{auto} is assigned to Eq. (1) in a nonprecipitating cloud. The E_{auto} values 384 in both stable and mid-stable boundary layer conditions are smaller than the prescribed value 385 386 of 3.2, while the values in unstable boundary layers are significantly larger than 3.2 regardless of if they are precipitating or not. All E_{accr} values are greater than the constant of 1.07. The 387 E_{auto} values in Table 2 range from 2.32 to 6.94 and the E_{accr} values vary from 1.42 to 1.86, 388 depending on different boundary layer conditions and CLWPs. Therefore, as suggested by Hill 389 et al. (2015), the selection of E_{auto} and E_{accr} values in GCMs should be regime-dependent. 390 To properly parameterize sub-grid variabilities, the approaches by Hill et al. (2015) and 391 Walters et al. (2017) can be adopted. To use MG08 and other parameterizations in GCMs as 392

listed in Table 1, proper adjustments can be made according to the model grid size, boundary 393 layer conditions, and precipitating status. As stated in the methodology, we used a variety of 394 equivalent model grid sizes. Figure 4 demonstrates the dependence of both enhancement 395 factors on different model grid sizes. The E_{auto} values (red line) increase from 1.97 at an 396 equivalent grid boxsize of 30×30 km to 3.15 at an equivalent grid boxsize of 120×120 km, 397 which are 38.4% and 2% percent lower than the prescribed value (3.2, upper dashed line). After 398 that, the E_{auto} values remain relatively constant of ~3.18 when the equivalent model grid-size 399 is 180 km, which is close to the prescribed value of 3.2 used in MG08. This result indicates 400 that the prescribed value in MG08 represents well in large grid sizes in GCMs. The E_{accr} values 401 (blue line) increase from 1.53 at an equivalent grid boxsize of 30×30 km to 1.76 at an equivalent 402 grid boxsize of 180×180 km, those are 43% and 64%, respectively, larger than the prescribed 403 404 value (1.07, lower dashed line). The shaded areas represent the uncertainties of E_{auto} and E_{accr} 405 associated with the uncertainties of the retrieved q_c and q_r . When modelequivalent -grid size 406 increases, the uncertainties slightly decrease. The prescribed E_{auto} is close to the upper boundary of uncertainties except for the 30-km equivalent grid size, while the prescribed E_{accr} 407 is significantly lower than the lower boundary. 408 It is noted that E_{auto} and E_{accr} depart from their prescribed values at opposite directions as 409 the equivalent model grid size increases. For models with finer resolutions (e.g., 30-km), both 410 411 E_{auto} and E_{accr} are significantly different from the prescribed values, which can partially explain

the issue of 'too frequent' and 'too light' precipitation. Under both conditions, the accuracy of 412 precipitation estimation is degraded. For models with coarser resolutions (e.g., 180-km), 413 average E_{auto} is exactly 3.2 while E_{accr} is much larger than 1.07 when compared to finer 414 resolution simulations. In such situations, the simulated precipitation will be dominated by the 'too light' problem, in addition to regime-dependent (Table 2) and as in Xie and Zhang (2015), 416 E_{auto} and E_{accr} should be also scale-dependent. 417 Also note that the location we choose to collectof ground-based observations and retrievals 418 used in this study is on the remote ocean where the MBL clouds mainly form in a relatively 419 stable boundary layer and are characterized by high precipitation frequency. Even in such 420 environments, however, the GCMs overestimate the precipitation frequency (Ahlgrimm and 421 Forbes, 2014). 422 To further investigate how enhancement factors affect precipitation simulations, we use 423 E_{auto} as a fixed value of 3.2 in Eq. (4), and then calculate the q_c needed for models to reach the 424 same autoconversion rate as observations. The q_c differences between models and observations 425 are then calculated, which represent the q_c adjustment in models to get a realistic 426 autoconversion rate in the simulations. Similar to Figure 1, the PDFs of q_c differences (model 427 observation) are plotted in Figures 5a and 5b for 60-km and 180-km equivalent grid-sizes. 428 Figure 5c shows the average percentages of model q_c adjustments for different equivalent 429 model grid sizes. The mode and average values for 30-km equivalent grid size is negative, 430

suggesting that models need to simulate lower q_c in general to get reasonable autoconversion 431 rates. Lower q_c values are usually associated with smaller E_{auto} values that induce lower 432 simulated precipitation frequency. On average, the percentage of q_c adjustments decrease with 433 increasing equivalentmodel grid size. For example, the adjustments for finer resolutions (e.g., 434 30-60 km) can be \sim 20% of the q_c , whereas adjustments in coarse resolution models (e.g., 120 435 -180 km) are relatively small because the prescribed E_{auto} (=3.2) is close to the observed ones 436 (Figure 4) and when equivalent model grid size is 180-km, no adjustment is needed. The 437 adjustment method presented in Figure 5, however, may change cloud water substantially and 438 may cause a variety of subsequent issues, such as altering cloud radiative effects and disrupting 439 the hydrological cycle. The assessment in Figure 5 only provides a reference to the equivalent 440 effect on cloud water by using the prescribed E_{auto} value as compared to those from 441 observations. 442 All above discussions are based on the prescribed E_{auto} and E_{accr} values (3.2 and 1.07) in 443 MG08. Whereas there are quite a few parameterizations that have been published so far. In this 444 study, we list E_{auto} and E_{accr} for three other widely used parameterization schemes in Table 3, 445 which are given only for 60-km and 180-km equivalent grid sizes. The values of the exponent 446 in each scheme directly affect the values of the enhancement factors. For example, the scheme 447 in Beheng (1994) has highest degree of nonlinearity and hence has the largest enhancement 448 factors. The scheme in Liu and Daum (2004) is very similar to the scheme in Khairoutdinov 449

and Kogan (2000) because both schemes have a physically realistic dependence on cloud water content and number concentration (Wood, 2005b). For a detailed overview and discussion of various existing parameterizations, please refer to Liu and Daum (2004), Liu et al. (2006a), Liu et al. (2004b), Wood (2005b) and Michibata and Takemura (2015). A physical based autoconversion parameterization was developed by Lee and Baik (2017) in which the scheme was derived by solving stochastic collection equation with an approximated collection kernel that is constructed using the terminal velocity of cloud droplets and the collision efficiency obtained from a particle trajectory model. Due to the greatly increased complexity of their equation, we do not attempt to calculate E_{auto} here but should be examined in future studies due to the physics feasibility of the Lee and Baik (2017) scheme.

5. Summary

To better understand the influence of sub-grid cloud variations on the warm-rain process simulations in GCMs, we investigated the warm-rain parameterizations of autoconversion (E_{auto}) and accretion (E_{accr}) enhancement factors in MG08. These two factors represent the effects of sub-grid cloud and precipitation variabilities when parameterizing autoconversion and accretion rates as functions of grid-mean quantities. E_{auto} and E_{accr} are prescribed as 3.2 and 1.07, respectively, in the widely used MG08 scheme. To assess the dependence of the two parameters on sub-grid scale variabilities, we used ground-based observations and retrievals

From the retrieved q_c and q_r profiles, the averaged q_c within the top five range gates are 471 used to calculate E_{auto} and the averaged q_c and q_r within five range gates around maximum 472 reflectivity are used to calculate E_{accr} . The calculated E_{auto} values from observations and 473 retrievals increase from 1.96 at an equivalent sizegrid box of 30×30 km to 3.185 at an 474 equivalent sizegrid box of 1520×120 km. These values are 38% and 20.625% lower than the 475 prescribed value of 3.2. The prescribed value in MG08 represents well in large grid sizes in 476 GCMs (e.g., 180^2 km² grid). On the other hand, the E_{accr} values increase from 1.53 at an equivalent sizegrid box of 30×30 km to 1.76 at an equivalent sizegrid box of 180×180 km, 478 which are 43% and 64% higher than the prescribed value (1.07). The higher E_{auto} and lower 479 480 E_{accr} prescribed in GCMs help to explain the issue of too frequent precipitation events with too 481 light precipitation intensity. The ratios of rain to cloud liquid water increase with increasing E_{accr} from 0 to 2, and then decrease after that, suggesting a possible optimal state for the 482

collected at the DOE ARM Azores site to reconstruct the two enhancement factors in different

469

Formatted: Superscript

collision-coalescence process to achieve maximum efficiency for converting cloud water into

rain water at E_{accr} =2. The ratios of q_r to q_c at E_{accr} =1.07 and E_{accr} =2.0 are 0.063 and 0.142,

further proving that the prescribed value of E_{accr} =1.07 is too small to simulate correct

487 To further investigate what conditions and parameters can significantly influence the enhancement factors, we classified low-level clouds according to their boundary layer 488 conditions and CLWPs. Both E_{auto} and E_{accr} increase when the boundary layer conditions 489 become less stable, and the values are larger in precipitating clouds (CLWP>75 gm⁻²) than 490 those in nonprecipiting clouds (CLWP<75 gm $^{-2}$). The E_{auto} values in both stable and mid-stable 491 boundary layer conditions are smaller than the prescribed value of 3.2, while those in unstable 492 boundary layers conditions are significantly larger than 3.2 regardless of whether or not the 493 cloud is precipitating (Table 2). All E_{accr} values are greater than the prescribed value of 1.07. 494 Therefore, the selection of E_{auto} and E_{accr} values in GCMs should be regime-dependent, which 495 also has been suggested by Hill et al. (2015) and Walters et al. (2017). 496 This study, however, did not include the effect of uncertainties in GCM simulated cloud 497 498 and precipitation properties on sub-grid scale variations. For example, we did not consider the behavior of the two enhancement factors under different aerosol regimes, a condition which 499 may affect precipitation formation process. The effect of aerosol-cloud-precipitation-500 interactions on cloud and precipitation sub-grid variabilities may be of comparable importance 501 to meteorological regimes and precipitation status and deserves a further study. Other than the 502 large-scale dynamics, e.g., LTS in this study, upward/downward motion in sub-grid scale may 503 also modify cloud and precipitation development and affect the calculations of enhancement 504 factors. The investigation of the dependence of E_{auto} and E_{accr} on aerosol type and concentration 505

506 as well as on vertical velocity would be a natural extension and complement of current study. In addition, other factors may also affect precipitation frequency and intensity even under the 507 same aerosol regimes and even if the clouds have similar cloud water contents. Wind shear, for 508 example as presented in Wu et al. (2017), is an external variable that can affect precipitation 509 formation. Further studies are needed to evaluate the role of the covariance of q_c and N_c in sub-510 grid scales on E_{auto} determinations, which is beyond the scope of this study and requires 511 independent retrieval techniques. 512

513

521

Appendix A: Joint cloud and rain LWC profile estimation 514

If a time step is identified as non-precipitating, the cloud liquid water content (CLWC) 515 profile is retrieved using Frisch et al. (1995) and Dong et al. (1998, 2014a and 2014b). The 516 retrieved CLWC is proportional to radar reflectivity. 517

If a time step is identified as precipitatinging (maximum reflectivity below cloud base 518 exceeds -37 dBZ), CLWC profile is first inferred from temperature and pressure in merged 519 520 sounding by assuming adiabatic growth. Marine stratocumulus is close to adiabatic (Albrecht et a. 1990) and was used in cloud property retrievals in literature (e.g., Rémillard et al., 2013). In this study, we use the information from rain properties near cloud base to further constrain 523 the adiabatic CLWC (CLWC_{adiabatic}).

Adopting the method of O'Connor et al. (2005), Wu et al. (2015) retrieved rain properties below cloud base (CB) for the same period as in this study. In Wu et al. (2015), rain drop size (median diameter, D_0), shape parameter (μ), and normalized rain droplet number concentration (N_W) are retrieved for the assumed rain particle size distribution (PSD):

528
$$n_r(D) = N_W f(\mu) \left(\frac{D}{D_0}\right)^{\mu} \exp\left[-\frac{(3.67 + \mu)D}{D_0}\right]$$
 (A1)

To infer rain properties above cloud base, we adopt the assumption in Fielding et al. (2015) 529 that N_W increases from below CB to within the cloud. This assumption is consistent with the *in* 530 situ measurement in Wood (2005a). Similar as Fielding et al. (2015), we use constant N_W within 531 cloud if the vertical gradient of N_W is negative decrease with height below CB. The μ within 532 cloud is treated as constant and is taken as the averaged value from four range gates below CB. 533 Another assumption in the retrieval is that the evaporation of rain drops is negligible from one 534 range gate above CB to one range gate below CB thus we assume rain drop size is the same at 535 the range gate below and above CB. 536 With the above information, we can calculate the reflectivity contributed by rain at the first 537

range gate above CB ($Z_{dr}(1)$) and the cloud reflectivity ($Z_c(1)$) is then $Z_c(1) = Z(1) - Z_{dr}(1)$,

where Z(1) is WACR measured reflectivity at first range gate above CB. Using cloud droplet

number concentration (N_c) from Dong et al. (2014a and 2014b), CLWC at the first range gate

above CB can be calculated through

539

540

541

Formatted: Font: Italic

542
$$Z_c(1) = 2^6 \int_0^\infty n_c(r) r^6 dr = \frac{36}{\pi^2 \rho_w^2} \frac{cLWC(1)_{reflectivity}^2}{N_c} \exp(9\sigma_x^2)$$

543 $(A2.1)$

544 $CLWC(1)_{reflectivity} = \sqrt{\frac{Z_c(1)\pi^2 \rho_w^2 N_c}{36 \exp(9\sigma_x^2)}}$ (A2.2)

545 Where ρ_w is liquid water density $n_c(r)$ is lognormal distribution of cloud PSD with logarithmic width σ_x which is set to a constant value of 0.38 (Miles et al., 2000), Geoffroy et al. (2010) suggested that σ_x increases with the length scale and Witte et al. (2018) showed that σ_x also dependent on the choice instrumentation. The variations of σ_x should be reflected in the retrieval by using different σ_x values with time. However, no aircraft measurements were available during CAP-MBL to provide σ_x over the Azores region. The inclusion of solving σ_x in the retrieval adds another degree of freedom to the equations and complicates the problem considerably. In this study, σ_x is set to a constant value of 0.38 from Miles et al. (2000), which is a statistical value from aircraft measurements of marine low-level clouds. ρ_w is liquid water density:

554 We then compare the $CLWC_{adiabatic}$ and the one calculated from $CLWC_{reflectivity}$ at the first range gate above CB. A scale parameter (s) is defined as $s = \frac{cLWC_{reflectivity}(1)}{cLWC_{adiabatic}}$ and the remaining reflectivity profile from Eq. (A2.1) using the specified s adiabaticity. Reflectivity profile from cloud is then calculated from WACR observation is

regarded as rain contribution. Rain particle size can then be calculated given that N_W and μ are 560 known and rain liquid water content (RLWC) can be estimated. 561 There are two constrains used in the retrieval. One is that the summation of cloud and rain 562 liquid water path (CLWP and RLWP) must be equal to the LWP from microwave radiometer 563 observation. Another is that rain drop size (D₀) near cloud top myst be equal or greater than 50 564 μm and if D_0 is less than 50 μm , we decrease N_W for the entire rain profile within cloud and 565 repeat the calculation until the 50 µm criteria is satisfied. 566 It is difficult to quantitatively estimate the retrieval uncertainties without aircraft in situ 567 measurements. For the proposed retrieval method, 18% should be used as uncertainty for 568 RLWC from rain properties in Wu et al. (2015) and 30% for CLWC from cloud properties in 569 Dong et al. (2014a and 2014b). The actual uncertainty depends on the accuracy of merged 570 sounding data, the detectability of WACR near cloud base and the effect of entrainment on 571 cloud adiabaticity during precipitating. In the recent aircraft field campaign, the Aerosol and 572 Cloud Experiments in Eastern North Atlantic (ACE-ENA) was conducted during 2017-2018 573 with a total of 39 flights over the Azores, near the ARM ENA site on Graciosa Island. These 574 aircraft in situ measurements will be used to validate the ground-based retrievals and 575 quantitatively estimate their uncertainties in the future. 576 Figure A1 shows an example of the retrieval results. The merged sounding, ceilometer, 577 microwave radiometer, WACR and ceilometer are used in the retrieval. Whenever one or more

instruments are not reliable, that time step is skipped, and this results in the gaps in the CLWC and RLWC as shown in Figures A1(b) and A1(c). When the cloud is classified as nonprecipitating, no RLWC will be retrieved as well. Using air density (ρ_{air}) profiles calculated from temperature and pressure in merged sounding, mixing ratio (q) can be calculated from LWC using $q(z) = LWC(z)/\rho_{air}(z)$.

 $\label{thm:conversion} \textbf{Table 1. The parameters of autoconversion and accretion formulations for four parameterizations.}$

	A	a1	a2	В	b
Khairoutdinov and Kogan (2000)	1350	2.47	-1.79	67	1.15
Liu and Daum (2004)	$1.3 \times 10\beta_6^6$, where $\beta_6^6 = [(r_v + 3)/r_v]^2$, r_v is mean volume radius. modification was made by Wood (2005b)	3	-1	N/A	N/A
Tripoli and Cotton (1980)	3268	7/3	-1/3	1	1
Beheng (1994)	3×10^{34} for $N_c < 200$ cm ⁻³ 9.9 for $N_c > 200$ cm ⁻³	4.7	-3.3	1	1

Table 2. Autoconversion (left) and accretion (right) enhancement factors in different boundary layer conditions (LTS > 18 K for stable, LTS < 13.5 K for unstable and LTS within 13.5 and 18 K for mid-stable) and in different LWP regimes (LWP \leq 75 g m⁻² for non-precipitating and LWP > 75 g m⁻² for precipitating).

848

LTS (K)	LWP \leq 75 g m ⁻²	LWP > 75 g m ⁻²
> 18 <u>K</u>	2.32/1.42	2.75/1.52
(13.5 <u>, ≤ LTS ≤</u>	2.61/1.47	2 07/1 69
18 <u>K</u>)	2.01/1.4/	3.07/1.68
	4 (2/1 72	6.04/1.06
<u>LTS</u> < 13.5 <u>K</u>	4.62/1.72	6.94/1.86

Formatted Table

Table 3. Autoconversion and accretion enhancement factors (E_{auto} and E_{accr}) for the parameterizations in Table 1 except the Khairoutdinov and Kogan (2000) scheme. The values are averaged for 60-km and 180-km equivalent size model grids.

Formatted: Font: Bold

	Eauto		E_{c}	accr
	60-km	180-km	60-km	180-km
Liu and Daum (2004)	3.82	4.23	N/A	N/A
Tripoli and Cotton (1980)	2.46	2.69	1.47	1.56
Beheng (1994)	6.94	5.88	1.47	1.56

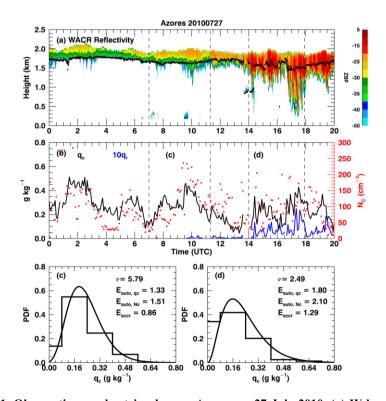

Figure 1. Observations and retrievals over Azores on 27 July 2010. (a) W-band ARM cloud radar (WACR) reflectivity (contour) superimposed with cloud-base height (black dots). (b) Black line represents averaged cloud water mixing ratio (q_c) within the top five range gates, blue line represents averaged rain (×10) water mixing ratio within five range gates around maximum reflectivity, red dots are the retrieved cloud droplet number concentration (N_c) . Dashed lines represent two periods that have 60 km equivalent model gridsizes with similar $\overline{q_c}$ mean- q_c but different distributions as shown by step lines in (c) and (d). Curved lines in (c) and (d) are fitted gamma distributions with the corresponding shape parameter (ν) shown on the upper right. N_c distributions are not shown. The calculated autoconversion (Eauto, qc from q_c and Eauto, Nc from N_c) and accretion (Eaccr) enhancement factors are also shown.

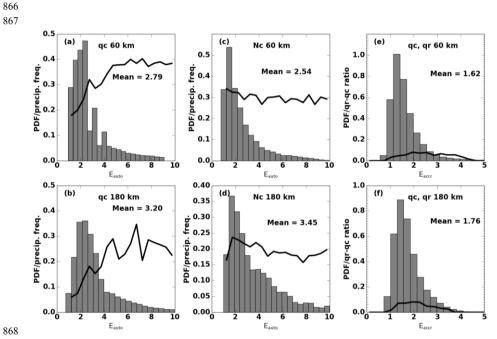

Figure 2. Probability density functions (PDFs) of autoconversion (a - d) and accretion (e - f) enhancement factors calculated from q_c (a-b), N_c (c-d), and the covariance of q_c and q_r (e-f). The two rows show the results from 60-km and 180-km equivalent model gridsizes, respectively, with their average values. Black lines represent precipitation frequency in each bin in (a)-(d) and the ratio of layer-mean q_r to q_c in (e)-(f).

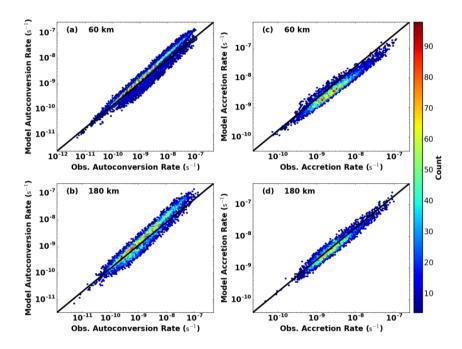

Figure 3. Comparison of autoconversion (a-b) and accretion (c-d) rates derived from observations (x-axis) and from model (y-axis). Results are for 60-km (a and c) and 180-km model equivalent gridssizes. Colored dots represent joint number densities.

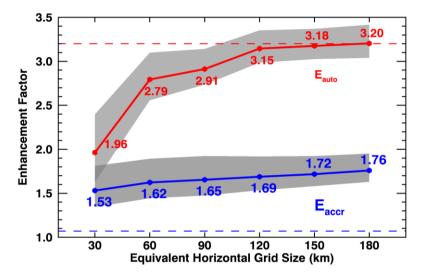

Figure 4. Autoconversion (red line) and accretion (blue line) enhancement factors as a function of <u>equivalent model grid</u> sizes. The shaded areas are calculated by varying q_c and q_r within their retrieval uncertainties. The two dashed lines show the constant values of autoconversion (3.2) and accretion (1.07) enhancement factors prescribed in MG08.

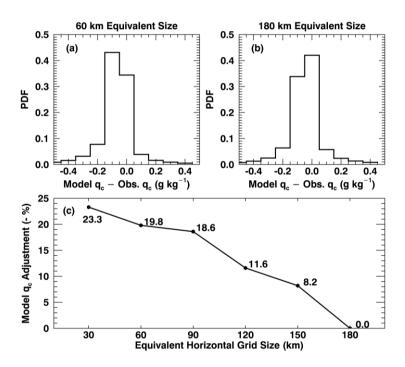

Figure 5. q_c needed for models to adjust to reach the same autoconversion rate as observations for (a) 60-km and (b) 180-km model <u>equivalent gridssizes</u>. Positive biases represent increased q_c are required in models and negative biases mean decreased q_c . The average percentages of adjustments for different <u>equivalent model grid-sizes</u> are shown in panel (c) and note that the percentages in the vertical axis are negative.

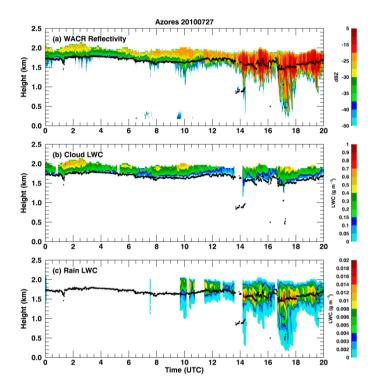

Figure A1. Joint retrieval of cloud and rain liquid water content (CLWC and RLWC) for the same case as in Figure 1. (a) WACR reflectivity, (b) CLWC, and (c) RLWC. The black dots represent cloud base height. Blank gaps are due to the data from one or more observations are not available or reliable. For example, the gap before 14 UTC is due to multiple cloud layers are detected whereas we only focus on single layer cloud.
