6

7 **Abstract**

8 Long-term trends of the parameters related to convection and instability obtained from 27 radiosonde
9 stations across 6 sub-divisions over Indian region during the period 1980-2016 is presented. A total of 16 parcel
10 and instability parameters along with moisture content, wind shear, and thunderstorm and rainfall frequencies
11 have been utilized for this purpose. Robust fit regression analysis is employed on the regional average time
12 series to calculate the long-term trends on both seasonal and yearly basis. The Level of Free Convection (LFC)
13 and Equilibrium Level (EL) height is found to ascend significantly in all Indian sub-divisions. Consequently, the
14 coastal regions (particularly the western coasts) experience strengthening in Severe Thunderstorm (TSS) and
15 Severe Rainfall Frequencies (SRF) in the pre-monsoon while the inland regions (especially central India)
16 experience an increase in Ordinary Thunderstorm (TSO) and Weak Rain Frequency (WRF) during the monsoon
17 and post-monsoon. The 16-20 year periodicity is found to dominate the long-term trends significantly compared
18 to other periodicities and the increase in TSS, SRF and CAPE is found more severe after the year 1999. The
19 enhancement in moisture transport and associated cooling at 100 hPa along with dispersion of boundary layer
20 pollutants is found to be the main cause for the increase in Convective Available Potential Energy (CAPE)
21 which leads to more convective severity in the coastal regions. However, in inland regions moisture-laden winds
22 are absent and the presence of strong capping effect of pollutants on instability in the lower troposphere has
23 resulted in more Convective Inhibition Energy (CINE). Hence, TSO and weak rainfall occurrences have
24 increased particularly in these regions.

25 *Key words:* Instability, Convection, Long-term trends, Radiosonde

26

27 **1. Introduction**

28 Intense convective phenomena are a common climatic feature in the Indian tropical region which occurs
29 during the pre-monsoon to post-monsoon seasons (April–October) (Annanthakrishnan, 1977) and they are
30 generally accompanied by intense thunderstorms, lightning, wind gusts with heavy rainfall. Hence, they are
31 known to induce immense socio-economic hazards including loss of life and property. Several reports have
32 showed an increase in the climatic extreme occurrence and intensity of these phenomena throughout the world
33 (Emanuel, 2006; Webster et al., 2005). In this connection, the traditional surface-based parcel theory has been
34 utilized to understand convective processes using atmospheric soundings as it calculates the atmospheric
35 instabilities and other parameters at various heights (Huntrieser, 1997; Shanti et al., 2014, Nelli et al., 2018a).

36 Considering the importance of studying the long-term trends in climatic extremes, a series of research
37 attempts have been orchestrated world-wide in the last two decades. Using multiple tropical stations and re-

38 analysis data, Gettleman et al. (2002) and Reimann-Campe et al. (2009) has shown that Convective Available
39 Potential Energy (CAPE) has been increasing during the period 1958-1997 due to surface heating and moisture.
40 Gensini and Mote (2015) projected a 236 % increase in severe thunderstorm frequency over the eastern United
41 States (US). Further, Brooks (2013) used various combinations of CAPE and Vertical Wind Shear (VWSH)
42 products and results hinted towards a probable increase in the severe thunderstorms over the US. It was also
43 observed that the effect of increasing CAPE is more dominant on convective severity than in case of decreasing
44 shear. On the other hand, studies by Kharin et al. (2013), Trenbreth et al. (2003) and Prein et al. (2017) showed
45 that a recent increase of temperature has led to a rise of moisture ingress and consequently the frequency and
46 severity of extreme precipitations associated with intense convections have shown a steep rise everywhere in the
47 world. At the same time, an increase in thunderstorm severity and instability has also been reported by many
48 attempts over the Asian region (Wang et al., 2011; Saha et al., 2016).

49 Over Indian region, Manohar et al. (1999) studied the latitudinal variation and distribution of
50 thunderstorm frequency and CAPE and postulated that the temperature at 100 hPa has a strong relationship with
51 it. Dhaka et al. (2010) utilized radiosonde observations to support this hypothesis and arrived at similar
52 conclusions. Later, Murugavel et al. (2012) added to this hypothesis, stating that low-level moisture and solar
53 cycle also have additional impact on these phenomena. Recently, Chakraborty et al. (2017a) and Saha et al.
54 (2017) reported that lower instability is reducing at certain Indian stations due to pollution and global warming.
55 Apart from that, some studies have also attempted to correlate convective severity with boundary layer
56 phenomena, surface fluxes, solar effect and precipitation; (Murthy and Shivaramakrishnan, 2006; Allapattu and
57 Kunnikrishnan, 2009; Xie et al., 2011, Nelli et al. 2018b).

58 Previous studies over India has shown the distribution of CAPE only whereas other parameters like
59 Convective Inhibition Energy (CINE), Mixed Layer CAPE (MLC), Lifted Index (LI), Total Totals Index (TTI),
60 and Precipitable Water Vapor (PWV) are also important as they explain how the atmospheric instability and
61 moisture changes at various levels of the atmosphere. In addition, the influence of climatic oscillation (Quasi-
62 Biennial Oscillation (QBO), El-Nino Southern Oscillation (ENSO) and Solar Cycle) on the seasonal and annual
63 variation of convective parameters is also not studied in detail. Therefore in the present study, long-term
64 variation of parcel parameters (Lifted Condensation Level (LCL), Level of Free Convection (LFC), Equilibrium
65 Level (EL), CAPE and CINE), with instability (LI, Vertical Totals Index (VT)), moisture (PWV, and PWV at
66 low levels (PWL)), thunderstorm and rainfall severity frequencies (Thunder Storm-Severe (TSS), Thunder
67 Storm-Ordinary (TSO), Weak Rain Fall (WRF) and Strong Rain Fall (SRF)) followed by Temperature at
68 100hPa (T100) and Wind Shear (WSH) is investigated using 27 radiosonde stations along with gridded rainfall
69 data over India. This article is structured as follows: Section 2 describes the datasets and methodology adopted
70 for the present study. Section 3 presents the long-term analysis of parcel and instability parameter over Chennai
71 (13.08°N, 80.27°E) and 6 sub-divisions of the Indian subcontinent on both annual and seasonal basis, followed
72 by the periodicity and split trend analysis. Finally, a discussion on the results and conclusions is appended in
73 Section 4 and 5, respectively.

74

75 2. Dataset and Methodology

76 Radiosonde observations from 27 stations over Indian region from 1980-2016 are obtained from
77 Integrated Global Radiosonde Archives (Durre et al., 2006). These datasets provide daily temperature and

78 humidity profiles from 1538 stations around the world in fixed pressure levels after doing quality checks (Durre
79 et al., 2006; Zhe et al., 2013). These studies have concluded that the radiosonde data quality from IGRA has
80 faced certain problems from time to time, but such cases are not so prominent over the Indian region, especially
81 after the year 1980. It is mainly because of the higher accuracy and reliability of this in-situ measurement
82 technique that these datasets are widely used worldwide nowadays for calibrating other continuous profiler
83 instruments (Chakraborty et al., 2016). In accordance with the above, we have considered only 27 stations out of
84 37 IGRA Indian radiosonde stations which provide a data availability of at least 8000 profiles in order to obtain
85 statistically significant results. Note that the volume of usable radiosonde profiles for analysis at 00Z is found to
86 be ~60-70% of the total number of days between (1980-2016) for all the IGRA stations. When an in depth
87 investigation is done on the data continuity by plotting the temperature and humidity profiles for all days, a set
88 of monthly gaps were discovered in the data. Most of the stations had 2-7 months gap but, leaving only two to
89 three cases, the duration of these individual data gaps were mostly within 1 month. Since seasonal or annual
90 average is used, hence in long term those small gaps were not found to be significant with respect to the total
91 span of (37 years X 12 months).the data.

92 These 27 stations have been divided into six homogenous regions as defined by the India
93 Meteorological Department (IMD) (Rao, 1976) which are: Central India (CI), East Coast (EC), North East (NE),
94 North West (NW), Peninsula India (PI) and the West Coasts (WC) as shown in Fig. 1. Further, for simplicity,
95 these regions have again been combined into three major categories namely: coastal regions (EC and WC),
96 Inland (CI and PI) and others (NE and NW). Atmospheric profiles at 00Z have only been used in this analysis to
97 preserve the maximum availability of data and to negate issues related to the diurnal variability of convection.
98 Again, out of the available radiosonde profiles, some profiles have displayed absurd variations of temperature
99 and humidity at various heights and hence they are discarded. A complete detail about the final dataset used for
100 every station is indicated in Table A1. It may be noted here that the volume of observations are found to
101 distributed almost homogeneously throughout the measurement period and a detailed year wise breakup of
102 radiosonde launches utilized are not shown to maintain the focus of the work. For calculation of the instability
103 parameters, the temperature and humidity profiles were transformed from the standard pressure levels using
104 cubic spline interpolation at every 100 m height bins. After this, a similar surface-based parcel method is
105 utilized for estimating the parcel and instability parameters (LCL, LFC, EL, CAPE, MLC, CINE) as already
106 described by Chakraborty et al. (2018). A small detail about the physical significance of these parameters is now
107 given in Supplementary Section. For thunderstorm genesis, moisture growth and wind shear are extremely
108 important, therefore we calculated the total amount of water vapor (PWV) and that upto 700 hPa level (PWL)
109 along with the horizontal wind shear between surface and 6 km altitude. In addition to these, we have used
110 temperature at the 100 hPa pressure level as it is found to strongly influence the convective strengths over the
111 Indian region (Manohar et al., 1999; Dhaka et al., 2010).

112 Along with these parameters, the long-term impact of instability on the convection has also been
113 studied from thunderstorm and rain frequencies. Daily measurements of surface wind speeds is obtained for all
114 the radiosonde observations at 00Z using the Wyoming Website. The thunderstorm frequencies are calculated
115 on yearly basis based on the criterion given by IMD. According to this criterion, if the maximum surfaces wind
116 speed is greater than 62 km/h then it is considered as a severe thunderstorm event otherwise if wind speeds are
117 between 31 and 62 km/h then it is considered as an ordinary thunderstorm case (also used by Saha et al. (2014)).

118 Hereafter, the total number of thunderstorm occurrences per year in both severe and ordinary category is
119 counted and represented by thunderstorm frequencies as TSS and TSO. In the same way, IMD provides daily
120 rainfall accumulations in 0.25 degree spatial resolution over the Indian region since the year 1900 (Rajeevan et
121 al., 2006, 2008; Pai et al., 2014). This daily precipitation data at the closest grid point is used to define the
122 frequency of severe and weak rainfall days. The severe rainfall frequencies constitute those days where the daily
123 accumulation is greater than 124.5 mm/day while for the weak rainfall cases it is less than 7.5 mm/day
124 according to IMD glossary as given in <http://imd.gov.in/section/nhac/termglossary.pdf>

125 From the previous section, it follows that a set of 14 parcel parameters with thunderstorm and rainfall
126 frequencies are essential to understand the convective climatology over India. But other than these, we also
127 require some important instability parameters. Hence, principle component analysis test is performed on the
128 total set of 8 well known instability parameters (LI, KI, TTI, CT and VT with CAPE, CINE, and MLC), as
129 already elaborated in previous attempts by Chakraborty et al. (2018) to identify the parameters that effectively
130 represents the variance of all the instability parameters. To do this analysis, daily datasets of all instability
131 parameters are averaged to yearly for every regions and then the principal components on the datasets are
132 obtained. The variance distribution plot (not shown) for each region showed that only the first two components
133 contribute to more than 70% of the total variance; hence the covariance scores of these two strongest orthogonal
134 components are plotted in Fig. 2 which depict that the LI is completely unrelated to rest of the parameters. Since
135 VT is found to lie exactly in the middle of the rest of the parameters, thus these two parameters can represent the
136 population in a convenient way.

137 Thus, a set of 16 parameters are finally taken for the analysis: LCL, LFC, EL, LI, VT, CAPE, CINE,
138 MLC, PWV, PWL, WSH, T100, TSO, TSS, WRF and SRF. However, apart from the IGRA radiosonde and the
139 IMD rainfall database, it was believed that some other parameters may also be externally responsible for the
140 changing trends in atmospheric instability and hence they are also included. They comprise the monthly mean
141 aerosol absorption index (AAI) data taken from the Tropospheric Emission Monitoring Internet Service
142 (TEMIS) Air Pollution Archive (De Graaf et al., 2005). In addition, the monthly average gridded data of ozone
143 mixing ratio (OMR) and Specific Humidity (SHUM) along with Downward Long Wave Radiation Flux
144 (DLWRF) are also utilized from ERA-Interim Re-analysis datasets.

145 We have estimated all parameters from daily radiosonde data and averaged over a season and annually
146 for obtaining trend at 95% confidence interval using robust regression analysis (Shepard, 1968). Further, the
147 parameters from radiosonde were averaged region wise and then the robust fit algorithm is employed on the
148 normalized time series to get the long-term trends (Anderson, 2008; Raj et al., 2018). These yearly trend values
149 are multiplied by 37 to get the total climatological trend in one parameter over the complete data span of 1980-
150 2016. For seasonal trend analysis, the same approach has been utilized for different seasons. The seasonal
151 distribution has been adopted from IMD reports which are as follows: Pre-monsoon (March-May), Monsoon
152 (June-September), Post-monsoon (October-November) and Winter (December-February). Further, for studying
153 the periodicities associated with each of these time series, an Empirical Mode Decomposition (EMD) technique
154 is used (Wu and Huang, 2009). Finally, the robust fit analysis is done on each of these components to compare
155 the trends from each periodicity to determine which of the periodicities dominates in each parameter.

156

157

158 3. Results

159 3.1. Climatic trends over Chennai

160 In the previous study by Chakraborty et al. (2018), long term trends of instability were investigated over
161 Gadanki. To see whether, the observed trends of these parameters are behaving similarly in case of IGRA
162 profiles also, in Fig.3 the climatic trends of instability are now described over Chennai (13.08°N, 80.27°E)
163 which is the closest radiosonde station from Gadanki. A decreasing trend in VT, PWL and a strengthening of
164 CINE with LI is noticed which indicates a reduction in the lower atmospheric instability (Fig.3d,e,h,i).
165 However, CAPE (Fig.3f) shows significant increasing trends throughout the period. LFC has a slightly
166 increasing trend (~18 hPa) which leads to increasing CINE and decreasing VT over Chennai, while the EL is
167 found to get lifted up drastically (Fig.3c) resulting in an increase in the total instability and CAPE. The
168 intensification in EL can be caused by a reduction in temperatures in the upper tropospheric heights (Manohar et
169 al, 1999). Hence, it can be inferred that the reduction in temperatures near 100 hPa (Fig.3i) plays an important
170 role in modulating the total atmospheric instability and CAPE.

171 The enhancement in CINE and reduction VT leads to the reduction in the frequency of weaker
172 convective systems with medium or lower CAPE values. Again, as CAPE is one of most important parameters
173 that modulate convective severity, hence the frequency of severe thunderstorms and heavy rainfall occurrences
174 is expected to rise (Fig.3n,p). Thus, it is inferred that lower level instability has reduced due to elevated CINE
175 and LFC; while the upper-level atmospheric instability has intensified significantly due to a cooling at 100 hPa
176 and ascension in EL over Chennai. Hence, CAPE value increases drastically leading to more severe
177 thunderstorm and heavy rainfall frequency events during the mentioned period.

178 Before proceeding to the investigation on the climatological trends of convection and instability over
179 the Indian region, it is necessary to validate whether the obtained hypothetical trends from Chennai are free
180 from any data quality issues. Hence a region wise climatology of the most important parameter CAPE is
181 obtained from all the Indian regions using ERA-Interim Reanalysis data and the trends are shown in Fig. S1.
182 This figure clarifies that all the Indian regions (especially the coastal regions) have experienced a common
183 strengthening in CAPE especially after 1996-2000. Thus, the stated hypothesis looks clear and hence this can be
184 progressed over a much broader way.

185 3.2. Climatological average of parameters

186 The climatological mean values of all instability parameters over six different Indian sub-divisions are
187 shown with boxplot analysis in Fig. 4. The utility of using this approach is that, it will reveal which regions of
188 India shows normal expected variation (if it lies within the box limits signifying 25-75% percentage of the
189 distribution), while on the other hand it will also identify those regions having the extreme outlier values (lying
190 outside the whiskers signifying the outermost 5% of the distribution). The LCL (Fig.4a) and LFC (Fig.4b) are
191 found to be at the lowest altitudes in the coastal regions. As these stations receive most of the moisture from
192 Sea, the EL (Fig.4c) is also expected to be higher in the coasts and lower elsewhere. However, due to low
193 moisture availability, the inland regions experience weaker instability which results in lower CAPE (~900 J/kg)
194 (Fig.4f) with higher CINE (Fig.4h) and WSH (Fig.4k). During strong convection, values of LI (Fig.4d) (which
195 represents that the mid-tropospheric instability) are also higher in the coastal regions. Similarly, height integrals
196 of instability such as CAPE (Fig.4f) and MLC (Fig.4g) are significantly higher (~1500 J/kg) in the coastal
197 regions while the magnitude of MLC (Fig.4g) is found to be almost half of CAPE. As the trends in total

198 convective strengths below 300 hPa are quite low compared to that over the total atmospheric column, hence it
199 follows that the portion of buoyant column above 300 hPa must have contributed significantly to the total
200 convective developments over the Indian region. Again, being opposite of CAPE, CINE values are minimum in
201 the coastal regions compared to inland and continental regions thereby serving as a potential cause for the
202 reduced instability in these regions.

203 Similar to CAPE and MLC combination, the PWV (Fig.4i) and PWL (Fig.4j) pair shows the highest
204 averages in the coastal regions due to their closest proximity to the adjoining seas. Also, PWL (moisture integral
205 up to 700 hPa) is found to be almost half of PWV, hence the mid and upper tropospheric humidity is found to
206 play a strong role in modulating the convective systems over India. The instability and moisture are highest in
207 the coastal regions hence the frequency of severe thunderstorms and rainfall occurrences are comparatively
208 higher (Fig.4n,p). The North Western region shows the large values of thunderstorm frequency which is not
209 supported by other parameters. Hence, it may be inferred that this is due to frequent dry storms called “Andhi”
210 which have no relation with convective instability and rainfall (Rajpal and Deka, 1980). Thus, it can be
211 concluded that the effect of convection is large in the coastal regions compared to other regions which resulted
212 in high CAPE with more thunderstorms and intense rain occurrences.

213 3.3. Long-term trends in the instability parameters

214 The long-term trends are calculated for each parameter during the entire study period of 1980-2016 for all
215 regions using the robust regression analysis at 95% confidence interval as depicted in Fig. 5. For simplicity, the
216 average trends along with their standard deviation values are depicted in Table 1. Also to investigate about the
217 significance of trend values calculated from these time series datasets, a ttest analysis is done on all parameter
218 and locations. The p values are calculated at 95% confidence limits and they are depicted in Table 1. It is very
219 interesting to note that the p values are always lesser than 0.05; hence the time series variations to be presented
220 in subsequent sections will always be statistically significant in nature. The LCL (Fig.5a) height is found to
221 decrease which may lead to an overall increase in the number of rain occurrences throughout the country
222 (provided that the amount of atmospheric instability is adequate). On contrary, LFC (Fig.5b) is found to ascend
223 in all the regions resulting in the reduction of lower level instability and a strengthening of CINE (Fig.5h).
224 However, the extent of change in LFC (Fig.5b) and LCL (Fig.5a) is minimum in the coastal regions (~10 hPa).
225 In case of EL (Fig.5a), a drastic increase is depicted in all regions (highest in coastal regions) which increase the
226 height of the buoyant column; hence the net effect on total instability and CAPE (Fig.5f) is expected to increase
227 prominently. Similarly, LI (Fig.5d) values also show an enhancement in all the regions with slightly higher
228 magnitudes in the coastal regions. VT represents the lower level atmospheric instability and hence is expected to
229 be affected by the elevation in LFC. Thus, a reduction in VT (Fig.5e) is seen with minimum values in the coastal
230 regions (~0.3), medium in the NE and NW regions (~0.5) and highest in deep inland regions such as CI and PI
231 (~0.8). An intensification in CAPE (Fig.5f) is seen in all regions (~1100 J/kg) as expected from EL (Fig.5c) and
232 LI. However, the increase is the highest (~100%) at the coastal regions whereas in MLC (Fig.5g), which is
233 measured only up to 300 hPa level, the increment is only 20% of that in CAPE. Hence, it follows that the
234 maximum contribution towards the strengthening of CAPE comes above 300 hPa. In case of CINE, an overall
235 enhancement is observed as expected (~60 J/kg). In addition, the trend values suggest a two-fold increase of
236 CINE in inland regions while the values are much lesser (50%) in the coastal regions due to balancing effect
237 from strong convections and CAPE in those regions.

238 The PWV (Fig.5i) and PWL (Fig.5j) values are increasing similar to CAPE and MLC. The long-term
239 trends in PWV are about 10% of its climatological average with highest in the coastal regions. Further, the
240 lower level moisture content of PWL (up to 700 hPa) showed an increase but the trend values are comparatively
241 smaller (~6%). Hence, the mid and upper tropospheric moisture plays a crucial role in modulating the Indian
242 climate. The WSH (Fig.5k) parameter increases in all regions of the country, and hence it produces an inhibiting
243 effect on the lower level instability. An upper tropospheric cooling is found in all other regions (Fig. 5l) with
244 minimum values in the inland regions and maximum in the coastal regions. Consequently, the increase in CAPE
245 values is maximum in the coastal regions and lesser elsewhere. The ordinary thunderstorm frequency is also
246 found to increase (Fig. 5m) which may be due to the partial damping effect of an elevated LFC and CINE on
247 lower level instabilities. However, the TSS (Fig.5n) is found to increase drastically with a doubling effect in the
248 coastal regions. On the other hand, an increase in CINE and decrease of VT lead to an increase in the number of
249 WRF (Fig.5o). However, due to rise in CAPE and TSS (Fig.5n), the SRF (Fig.5p) is also found to rise
250 significantly by about 20% particularly in the coastal regions. It may be noted that, as EL has more dominant
251 effect on CAPE hence the rise in SRF is much larger than that WRF (5%). Finally, the long-term trends have
252 been compared between the east and west coastal regions and it is observed that the rate of increase in total
253 instability is the most prominent in the western coasts while factors related to ascending LFC, CINE and
254 reducing VT are more significant in the central India which is the farthest from both the sea coasts. Thus, the
255 long-term analysis infers that lower atmospheric instability has reduced while the upper tropospheric instability
256 and moisture increased drastically over the Indian region. As a result, convective severity as expressed in terms
257 of CAPE, TSS and SRF is increasing more strongly in the coastal regions while in the continental areas this
258 effect is dampened due to the contribution of increasing CINE and WSH.

259 3.4. Seasonal effect on long-term trends in the instability parameters

260 The seasonal variation of atmospheric instability is shown in Fig. 6. LCL shows a uniform descent by
261 10 hPa in all seasons (Fig.6a) whereas LFC ascends in most of the regions and seasons (Fig.6b). However, this
262 ascent is more prominent in the monsoon and post-monsoon due to the occurrence of more convective rain. The
263 seasonal variation is absent in EL and LI (Fig.6c,d) which are mainly associated with an upper layer
264 phenomenon. VT shows the most prominent weakening in monsoon and post-monsoon seasons (Fig.6e). MLC
265 and CAPE show a lot of regional disparities with a uniform increase in its value in all the seasons (Fig.6f,g). In
266 monsoon and post-monsoon, the increase in CAPE is slightly lesser due to the effect of decreasing VT and
267 elevated LFC. CINE is closely related to VT and LFC, hence it shows slight strengthening in the monsoon and
268 post-monsoon seasons with maximum values in inland regions as expected (Fig.6h).

269 PWV, PWL and WSH represent a prominent increase in the monsoon followed by the post-monsoon
270 (Fig.6i-k). T100 is related to an upper atmospheric phenomenon hence no seasonal or spatial variation is
271 displayed, except for a small strengthening in pre-monsoon (Fig.6l) due to the prevalence of intense convections
272 events which is supported by the strongest increase in CAPE. A decrease in lower atmospheric instability and
273 increase in CINE is observed; hence TSO and WRF are expected to increase. However, this increase is found
274 more dominant only in the monsoon and post-monsoon (Fig.6m,o). Another interesting result is that TSS and
275 SRF donot behave similarly. TSS increases almost uniformly in all seasons with the highest in the pre-monsoon.
276 However, SRF increases mainly in the monsoon followed by the post-monsoon season (Fig.6n,p). The observed

277 disparity between them is due to the profuse moisture availability during monsoon and post-monsoon compared
278 to the pre-monsoon.

279 Further, in seasonal trends, east and west coasts show equivalent trends in all instability parameters
280 while the Central India still remains as the region which is most affected by the ascension of LFC and CINE.
281 Thus, the seasonal analysis reveals that the yearly long-term trends are almost uniformly distributed in all the
282 seasons. The ordinary and weak thunderstorm frequencies show the strongest increase during monsoon and
283 post-monsoon while the upper atmospheric instability shows a weak influence in the pre-monsoonal trends on
284 the yearly climatology.

285 3.5. Effect of specific periodicities on long-term trends

286 In case of both annual and seasonal trend analysis, all Indian sub-divisions are found to follow similar
287 behavior. Hence, to find out the periodicities in the average long-term trends, the time series of all regions are
288 averaged and then subjected to EMD technique which reveals the existence of four main periodicities namely:
289 1.5 - 2.5 years corresponding to QBO, 4-6 years corresponding to ENSO, 10-12 years corresponding to the solar
290 cycle and the fourth one is of 16-20 years. A similar multi-decadal climatic oscillation was also reported by
291 Dhaka et al. (2010). Hence for simplicity, this periodicity has been renamed as a Multi-decadal Climatic
292 Oscillation (MCO).

293 The climatic trends of these periodicities for each parameter are calculated from robust regression
294 analysis. An illustration of the obtained MCO periodicities for CAPE along all the Indian regions is shown in
295 Fig. S2. Further for comparison, the trend values from each periodicity is normalized to percentage with respect
296 to the total trend values for each parameters and the net contribution of these individual periodicities are
297 depicted in Fig. 7. Fig. 7 suggests that ENSO, QBO and solar cycle have no effect on LCL (Fig.7a) while MCO
298 is quite strong. LFC shows minimal effects to all periodicities except solar cycle period which may be due to
299 solar-terrestrial heating (Fig.7b). EL and LI are significantly affected by both solar and MCO periodicities
300 (Fig.7c-d). But in LI, the contribution from MCO is much more than solar effect. In case of VT (Fig. 7e) the
301 effect of both ENSO and MCO are found prominent. CAPE is found to be strongly influenced by MCO
302 followed by solar effect (Fig.7f) and this is also discernible from the most strong increasing trends in CAPE
303 especially in the coastal regions after the years 1996-2000 in Fig. S2. However, in case of MLC, contribution of
304 MCO is comparatively lesser (Fig.7g) hence some separate phenomena above 300 hPa may have prominent
305 influence on increasing CAPE. Apart from CAPE, effect of MCO is also found very strong in case of CINE
306 (Fig.7h).

307 The moisture parameters like PWV and PWL show similar variability as in CAPE and MLC which
308 indicates significant moisture transport changes only above 300 hPa in the past 18 years (Fig.7i-j). WSH does
309 not show the dominance of any periodicity (Fig.7k) while T100 shows the most prominent contribution from the
310 MCO (Fig.7l) thereby showing its connection with the long-term variability in EL and CAPE with associated
311 thunderstorm severity in the recent years. TSO and TSS are both affected by solar and MCO (Fig.7m-n) but TSS
312 shows that the effect of MCO is higher compared to TSO. Finally, the effect of MCO is also found more
313 prominent in case of SRF and WRF (Fig.7o-p). In nutshell, the MCO acts as the most dominant periodicity
314 which has influenced the convective severity over India.

315

316

317 3.6. Investigation of two-part trends

318 In the previous section, the annual averaged time series of instability parameters showed a drastic change
319 with respect to MCO. It has also been indicated from Fig. S2 that the climatic trends before and after the period
320 1996-2000 are significantly different from each other. Therefore, we have estimated the trends with respect to
321 two segments before and after the year 1998. The time series for both MCO are produced and their trend values
322 are represented in Fig. 8. For simplicity, the MCO are referred as C1 (1980 to 1998) and C2 (1999 to 2016),
323 respectively. Starting with LCL, in C1 there is almost no change, but in C2 there is a strong descent which
324 influences the overall change in the time series (Fig.8a). In case of LFC, C1 shows a decreasing trend, but in C2,
325 a significant increasing pattern is seen hence an overall increase is observed in LFC (Fig.8b). An increase in EL
326 is noticed in both the periods however during C2 the trends show significant enhancement (Fig.8c). LI is
327 expected to strengthen from 37 years trend, however it shows a slight weakening in C1 followed by a prominent
328 strengthening in C2 resulting in a net increasing trend (Fig.8d). VT shows an overall decreasing pattern in both
329 the periods (Fig.8e). CAPE (Fig.8f) shows an enhancement in both the cycles but the trends become more
330 prominent in C2 (1500 J/Kg). Similar to CAPE, MLC (Fig.8g) also shows an increasing trend in both the cycles
331 but the trend values are also much smaller than in CAPE. Hence, the rise in EL height can be considered as a
332 primary factor for the increase in CAPE above 300 hPa during C2. CINE shows increasing trend in both C1 and
333 C2 but again the trend values are much stronger (~80 J/kg) during C2 especially in the inland regions (Fig.8h).

334 The moisture trends in both PWV and PWL have shown a constant increase in both the MCO
335 throughout India (Fig.8i-j). The WSH (Fig.8k) also increases uniformly in both MCO with strongest trends in
336 the inland regions. A prominent cooling of ~1.5 degrees is seen in 100 hPa levels everywhere in C1, but in C2
337 the trend increases to ~2.5 degrees (Fig.8l) which can be considered responsible for the abrupt elevation in EL
338 and strengthening in CAPE values during the recent years. TSO increases slightly in C2 compared to C1
339 (Fig.8m). But in case of TSS, the positive trend gets doubled in C2 mainly in the coastal regions (Fig.8n).
340 Finally, in case of SRF the trend values in C2 are slightly higher with the maximum magnitudes in the coastal
341 regions as expected (Fig.8p). A further comparison between the six regions reveals that the west coast shows the
342 maximum enhancement in all the instability and convective severity parameters in the past 18 years due to
343 strong growth in moisture content and associated cooling at 100 hPa.

344 On the contrary, during C2 central India suffers from the maximum reduction in lower level instability
345 as seen in CINE and LFC due to the dearth of moisture content. Similar results are also found in other coastal
346 and inland regions. Hence it follows that mainly during C2, the upper tropospheric instability has enhanced
347 everywhere while the lower tropospheric instability has weakened which has led to the development in both
348 CAPE and CINE. As a result both TSS-TSO and WRF -SRF combination increases.

349

350 4. Discussion

351 From the previous section, it is inferred that a cooling trend at 100 hPa levels has led to the ascent in EL
352 which results in an increase in CAPE, TSS and SRF. To explain the reason behind this, we consider the ozone to
353 be a primary heating agent by absorbing the incoming solar ultraviolet radiation near 100 hPa level
354 (Mohankumar, 2008). OH hydroxyl radicals are formed by oxidation of water vapor molecules by a reactive
355 oxygen atom at the same height. On the other hand, it has been reported by Forster et al. (2007) that in the recent
356 years there has been a cooling in upper troposphere due to ozone breakup near 70 hPa. Hence, it is hypothesized

357 that the OH radicals formed from the oxidation of water vapour can take an active role in the breakup of ozone
358 molecules at 100 hPa levels which may lead to this cooling effect. The preceding sections have shown a
359 significant increase in moisture content especially in the coastal areas hinting towards more moisture transport
360 from the adjoining seas. Again, an increase in LI and CAPE values have also been reported in most of the
361 regions which can lift the available moisture to upper atmospheric levels (Das et al., 2016; Guha et al., 2017).
362 To add to this increasing CAPE and LI, many recent researchers' have reported a net increase in the Hadley cell
363 and Brewer-Dobson circulation strength (Liu et al., 2012; Lu et al., 2007; Fu et al., 2015; Shepherd and
364 McLandress, 2011) which also assists in the up-liftment of moisture to upper atmospheric levels. Thus, it is
365 inferred that low-level moisture is transported to the upper troposphere and above where it is responsible for
366 ozone depletion and cooling thereby elevating the EL and increasing the thunderstorm severity.

367 To test this hypothesis, yearly averaged time series of specific humidity and ozone mixing ratio data are
368 collected for all stations and the two-part trend values are depicted in Fig. 9. This figure shows a rise in specific
369 humidity levels by 7% in C2 over entire India (Fig.9a). On the other hand, trends of specific humidity have
370 almost trebled in C2 phase with the maximum values in the coastal regions (Fig.9e). As water vapor
371 concentration increases, ozone concentration is expected to decrease. The ozone trends support this hypothesis
372 by showing a sharp transition from low positive to high negative values during C2 (Fig.9b,f). It may be
373 additionally noted that the specific humidity increase and reduction in ozone content are strongest in the coastal
374 regions leading to a higher increase in CAPE and severe thunderstorms in those regions.

375 In the recent decades, Indian region has experienced a surface warming trend which is mainly caused
376 by a dominant increase in greenhouse gas concentrations as pointed out by Basha et al. (2017). These
377 greenhouse gases are heat absorbing in nature and these particles reside within the lower troposphere (generally
378 below 700 hPa) due to surface heating and boundary layer dynamics as reported by Chakraborty et al. (2017b).
379 Further, these gases has a tendency to absorb and then re-emit the outgoing longwave radiation as emitted by the
380 earth resulting more downward longwave radiation flux and atmospheric heating which elevates the LFC.
381 Additionally, this near surface heating reduces the vertical temperature lapse rate leading to weakening the
382 lower instability (VT). To prove this hypothesis, yearly averaged DLWRF time series is depicted over Indian
383 region in Fig. 9(c,g) which also suggests that DLWRF values are increasing prominently in C2. To show that
384 the increase in DLWRF is due to the heat absorbing particles only, the trends in Absorbing Aerosol Index (AAI)
385 are shown for all the regions. The figure suggests that the mean of AAI is increasing sharply in C2 with a
386 positive trend (Fig.9d,h). Due to this heating of lower atmosphere and capping of lapse rates by greenhouse
387 gases and absorptive aerosols, the LFC starts ascending, so WSH and CINE get stronger while VT reduces. As a
388 result the ordinary to weak convective occurrences start increasing.

389 Finally, it has to be explained why the upper air instability and CAPE are increasing mainly in the
390 coastal regions. The coastal regions have high moisture content (Saha et al., 2017). Because of the strong land-
391 ocean contrast, low-level winds close to 850 hPa flow into the coastal regions and disperse the pollutants and
392 greenhouse gases to other locations leading to a weaker convective inhibition in those areas. This hypothesis is
393 supported by the lowest AAI values in the coasts despite having high increasing trends in those areas. In
394 addition, the ample moisture supply in the coastal regions is lifted up to the upper troposphere and lower
395 stratosphere (UTLS) where it undergoes strong cooling due to ozone decomposition. Hence, the EL ascends
396 more resulting in higher CAPE which finally led to an abrupt rise in TSS and SRF in the coastal regions.

397 However, in the inland regions the layer of absorptive aerosols and greenhouse gases cannot be dispersed amply
398 due to the dearth of transported moisture at the lower levels. As a result, the lower atmospheric instability gets
399 limited in inland regions. Further, due to less moisture availability, UTLS cooling and EL ascent are much lower
400 hence there is a less rise in CAPE which ultimately leads to an increase in TSO and WRF in those sub-divisions.
401 It may be noted that the trend in AAI are not significantly different in the two halves of the analysis. Again, it is
402 the EL and not the LFC or LCL which influences CAPE strongly; hence the strong trends of humidity increase
403 and ozone reduction overpowers the weaker inhibitory effect from the atmospheric aerosols and this acts as a
404 major driving force behind the increase in convective severity compared to in most of the cases.

405

406 5. Summary and conclusions

407 In recent decades, global warming has become a threat to human life and society in terms of its various
408 implications. Increase in surface temperature leads to stronger atmospheric instabilities which in term may
409 increase the CAPE resulting in more severe thunderstorm and precipitation activity. Hence, the long term
410 variations of instability parameters will help to better understand the changes in the weather extremes with
411 respect to climate change. In light of the above, the main objective of the present study is to check whether
412 convective instability is changing over the Indian region during the last 37 years, and then to find its possible
413 effects on thunderstorm and rainfall severity. Radiosonde measurements from Integrated Global Radiosonde
414 Archives (IGRA) pertaining to 27 stations across 6 Indian sub-divisions are utilized to depict the spatial
415 distribution of these long-term trends. The selection of instability parameters is done based on Principle
416 Component Test (PCT) which showed the importance of taking LI and VT for further investigations. A total of
417 16 parameters (including parcel and instability data with moisture content, wind shear, and thunderstorm and
418 rainfall frequencies) have been utilized. Robust fit approach is employed on the regional average time series to
419 calculate the long-term trends on both yearly and seasonal basis. The main highlights obtained from the present
420 study are listed below:

- 421 1. The coastal regions experience a significant increase in Convective Available Potential Energy (CAPE)
422 and Equilibrium Level (EL) leading to more occurrences of Severe Thunderstorms (TSS) and severe
423 rainfall events (SRF) while the inland regions suffer from a decrease in lower atmospheric instability due
424 to elevated Convective Inhibition Energy (CINE) and Level of Free Convection resulting in more Ordinary
425 thunderstorm (TSO) and Weak Rainfall occurrences (WRF).
- 426 2. Seasonal variation of LFC, CINE, Wind Shear (WSH), TSO and WRF shows drastic increase during
427 monsoon and post-monsoon seasons while strengthening in CAPE, EL, Lifted Index (LI) and TSS are
428 found more prominent during the pre-monsoon.
- 429 3. The Empirical Mode Decomposition (EMD) analysis on the instability parameters reveals that the 16-20
430 year multi-decadal oscillation (MCO) as the most dominant component in all six Indian sub-divisions.
- 431 4. The two-part analysis reveals that many parameters like EL, CAPE, CINE, Temperature at 100 hPa
432 (T100), TSO and TSS show significant rise during C2 (1999-2016) which dominates 37-year trend.
- 433 5. The annual and two-part trends support that the increase in thunderstorm severity and associated
434 convection is strongest along western coasts due to maximum moisture ingress while the greatest reduction
435 in lower atmospheric instability is experienced in central India owing to its largest distance from the seas.

- 436 6. In the coastal regions, ample amount of water vapor is advected into the mid-troposphere from the
437 surrounding seas which in presence of strong lifting goes up to upper troposphere and lower stratosphere
438 (UTLS) where it decomposes to OH radical and further breaks down the ozone particles leading to a
439 strong cooling effect. This cooling effect will ascend the EL resulting in much stronger LI and CAPE,
440 hence more TSS and SRF.
- 441 7. In the inland regions, the dispersing effect by sea winds is absent hence the capping effect of lower
442 instability is more leading to stronger CINE values. Again, due to the dearth of moisture transport from the
443 seas, the UTLS cooling is lesser; leading to a weaker rise in CAPE consequently the TSO and WRF
444 frequencies increase significantly.
- 445 8. However, as EL has a stronger contribution over increasing CAPE than the inhibitory effect of LFC, hence
446 the long term trends are expected to be more strongly influenced by the ozone decomposition and cooling
447 at 100 hPa levels than the capping effect of low level inversions from absorptive aerosols; hence the
448 convective severity over the Indian regions is found to increase.

449 Thus, it may be inferred that in the near future also, convective severity will increase strongly in the
450 coastal regions while weak and ordinary thunderstorms will be more common in the inland regions. It may also
451 be noted that this study supports and explains the hypothesis brought forward by early research attempts that
452 UTLS cooling at 100 hPa and greenhouse gases concentration rise can regulate the climatic trends of convective
453 severity and frequency. However, this set of explanations is based on isolated information from selected in-situ
454 observations and hence it needs to be studied in more detail spatially in future using model-based observations.
455 In the recent years, certain studies have utilized multiple GCM outputs over the US to infer the robust increase
456 in thunderstorm frequency (Diffenbaugh et al., 2013; Seeley and Romps, 2015). However, these types of studies
457 have not yet been done over the Indian region. Hence, a combination of multi-station radiosonde data with
458 model data will be utilized to provide a generalized picture about convective severity over Indian region.

579 **Table 1: Statistical Information related to the 37-year trend of all instability parameters over the six sub-divisions of India.**

Figures

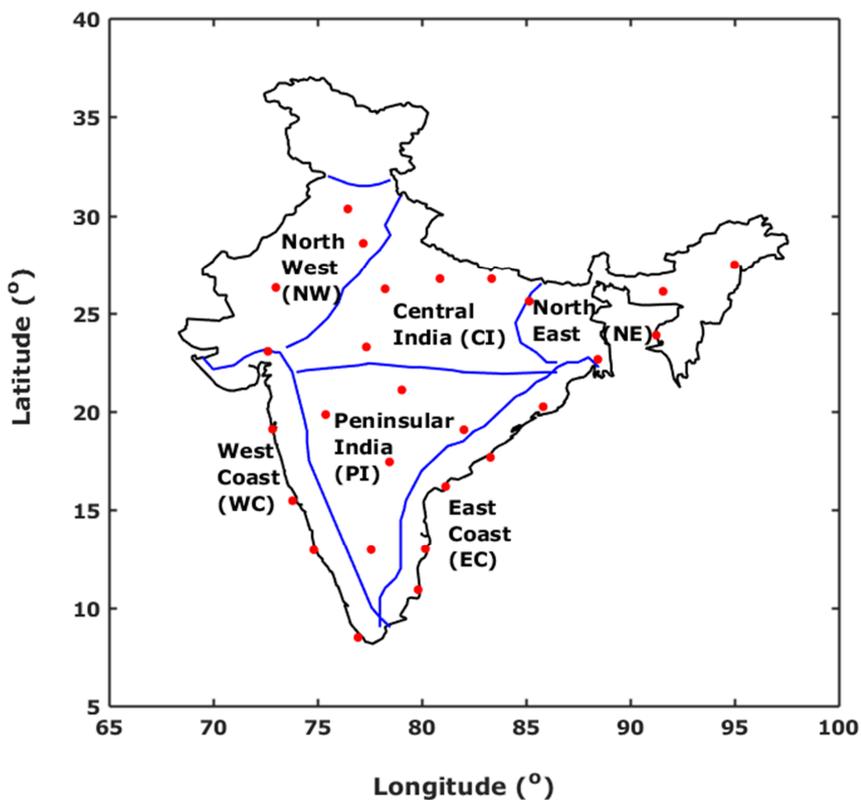

Figure 1: The locations of the 27 IGRA stations used for the present study. The distribution of the 27 stations over Indian regions is as follows: 4 stations in the NC, 6 stations in EC, 4 stations in NE, 4 stations in the NW, 5 stations in the PI and finally 4 stations in WC.

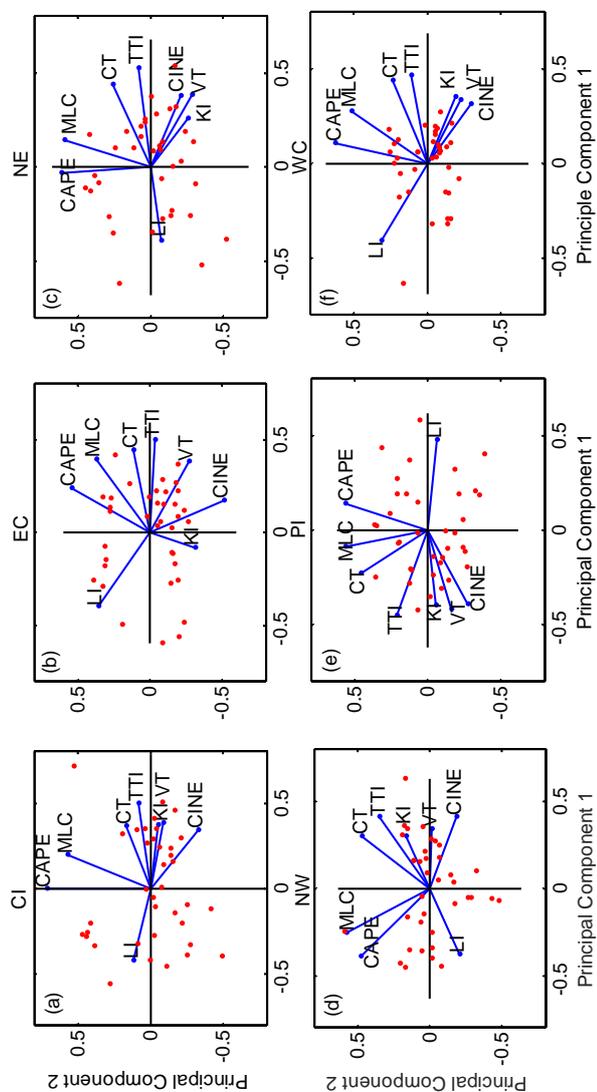

Figure 2: Principle Component Analysis for selection of instability parameters for the long-term trend study in (a) Central India, (b) East Coast, (c), North East, (d) North West, (e) Peninsular India and (f) West Coasts obtained using IGRA observations.

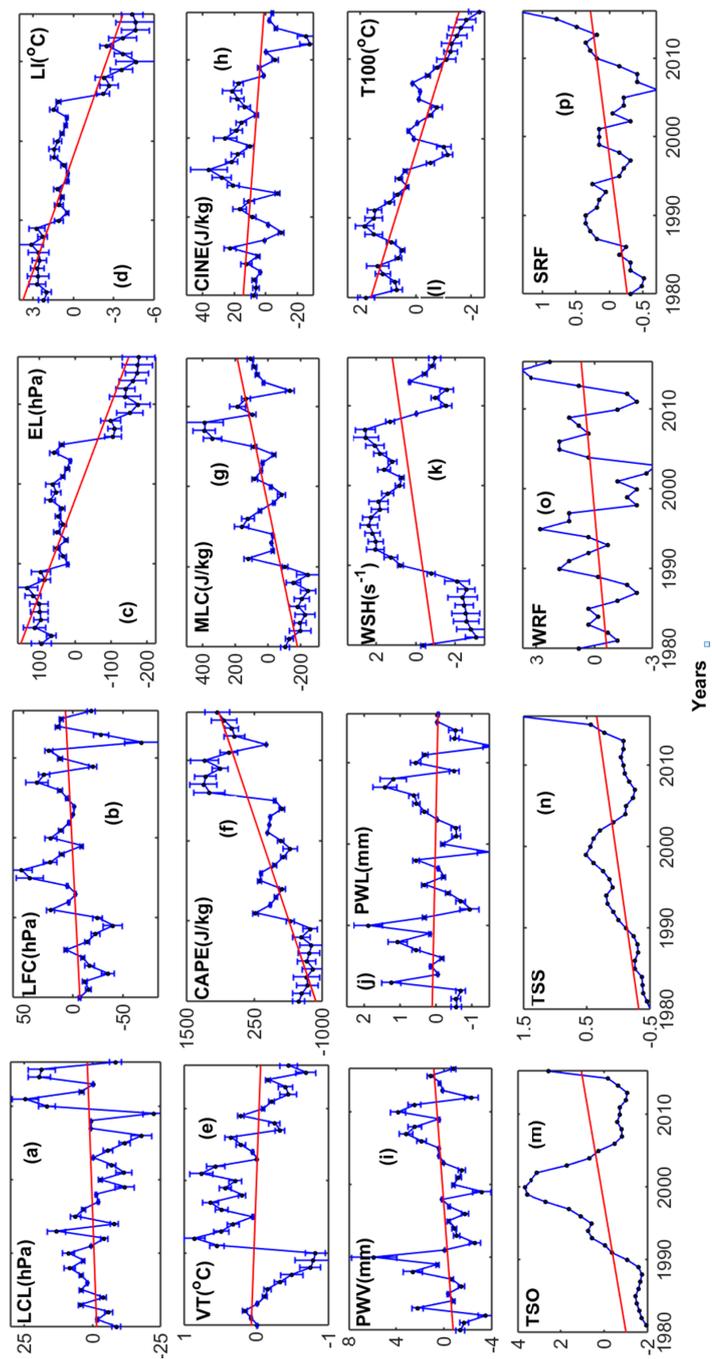

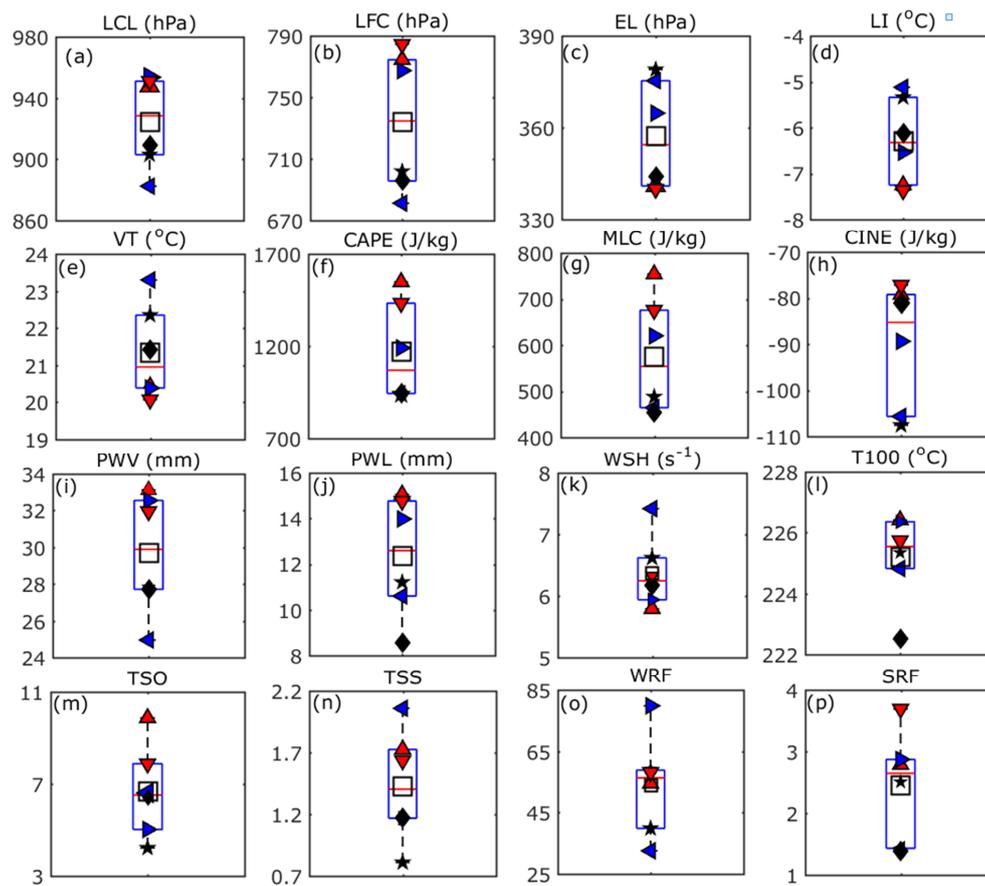

Figure 3: Long-term variation of (a) LCL, (b) LFC, (c) EL, (d) LI, (e) VT, (f) CAPE, (g) MLC, (h) CINE, (i) PWV, (j) PWL, (k) WSH, (l) T100, (m) TSO, (n) TSS, (o) WRF and (p) SRF observed over Chennai.

1
 2 **Figure 4:** Climatological mean values of (a) LCL, (b) LFC, (c) EL, (d) LI, (e) VT, (f) CAPE, (g) MLC, (h)
 3 CINE, (i) PWV, (j) PWL, (k) WSH, (l) T100, (m) TSO, (n) TSS, (o) WRF and (p) SRF over the six sub-
 4 subdivisions of India. Coastal Regions are represented by red cones, the north eastern and western regions are
 5 denoted by black stars and diamonds while the blue cones represent the inland regions. Here the box limits
 6 refer to the upper and lower quartiles (25% and 75%) while the whiskers refer to the outlier limit of the data
 7 (5% and 95% limit of the population)
 8

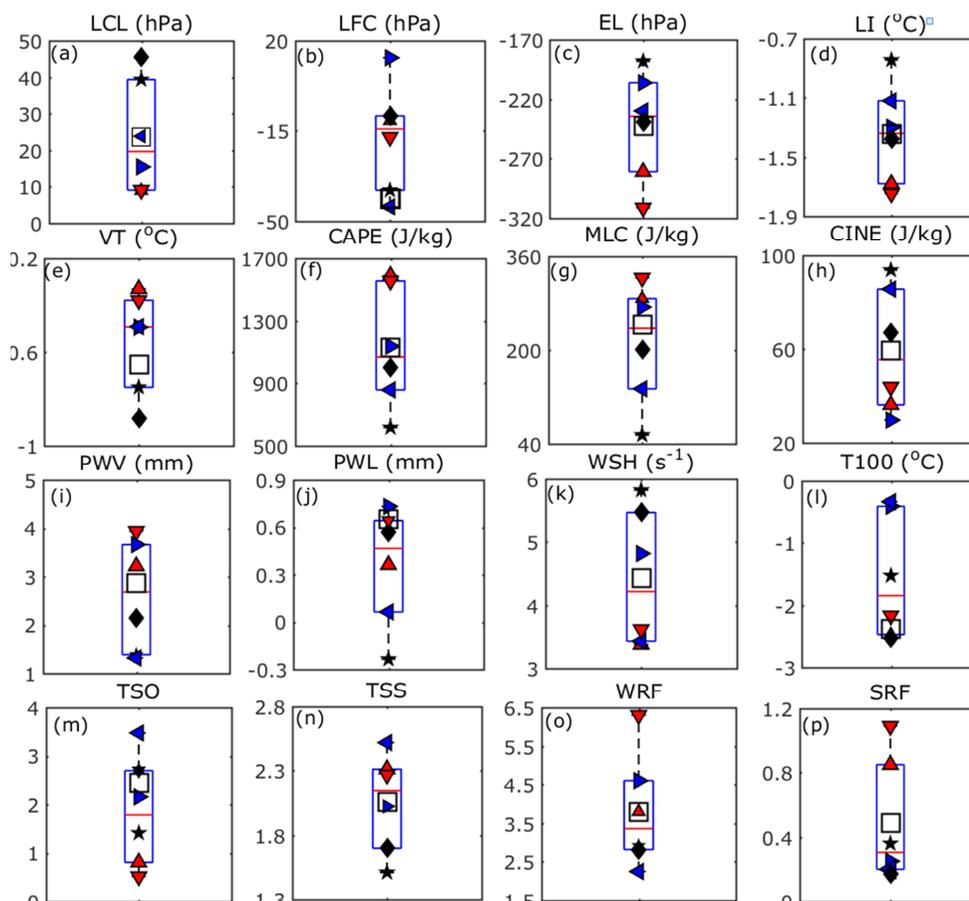

Figure 5: Long-term variation of (a) LCL, (b) LFC, (c) EL, (d) LI, (e) VT, (f) CAPE, (g) MLC, (h) CINE, (i) PWV, (j) PWL, (k) WSH, (l) T100, (m) TSO, (n) TSS, (o) WRF and (p) SRF over the six sub-divisions of India during the period 1980-2016. Legends are same as in Figure 4.

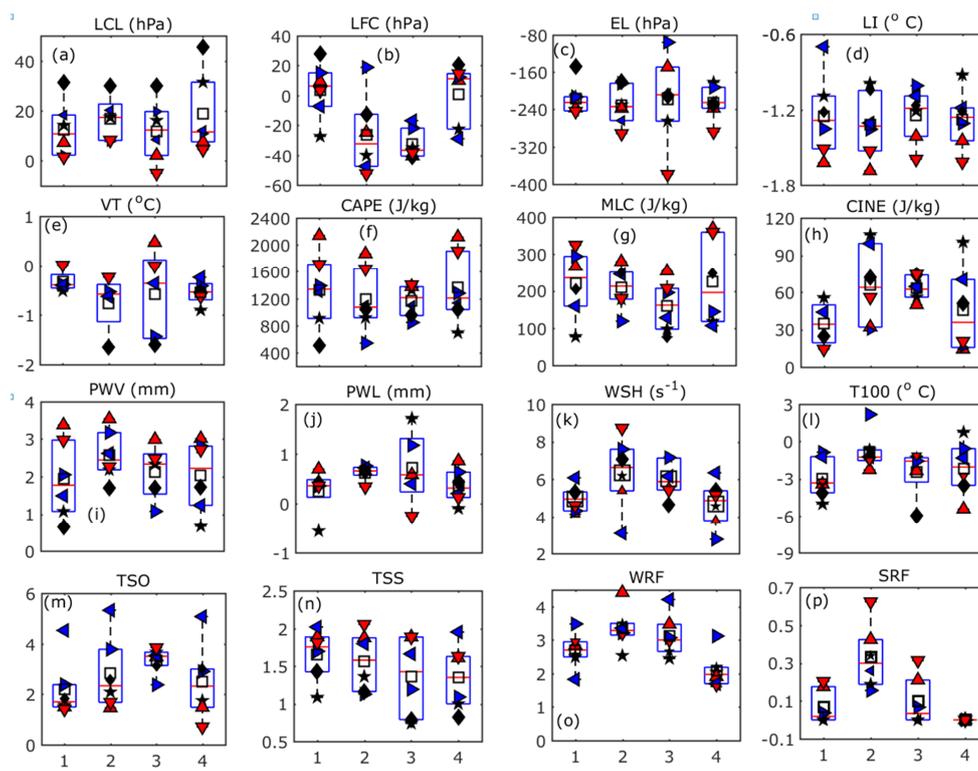

Figure 6: Seasonal trend of (a) LCL, (b) LFC, (c) EL, (d) LI, (e) VT, (f) CAPE, (g) MLC, (h) CINE, (i) PWV, (j) PWL, (k) WSH, (l) T100, (m) TSO, (n) TSS, (o) WRF and (p) SRF over India during all seasons. Here 1 refers to pre-monsoon (March-May), 2 refers to Monsoon (June-September), 3 for Post-monsoon (October-November) and 4 for Winter (December-February) Legends are same as in Figure 4.

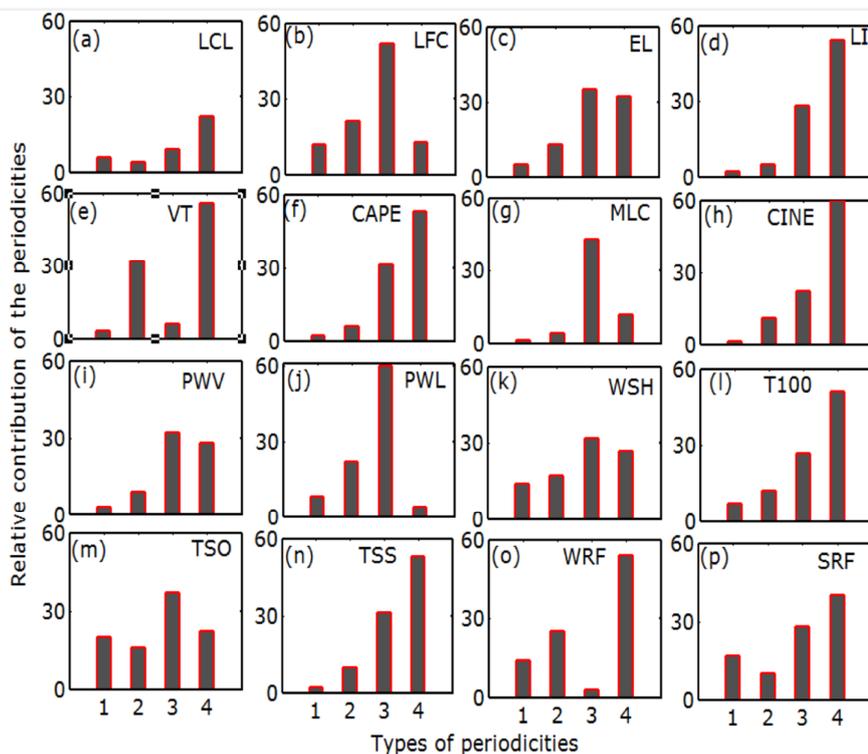

Figure 7: Percentage contribution of various periodicities on long-term trend of all instability parameters over India namely: 1.5 -2.5 years periodicity denoted as 1, 4 -6 years periodicity denoted as 2, 10-12 years periodicity displayed as 3 and 16 – 20 years periodicity represented as 4.

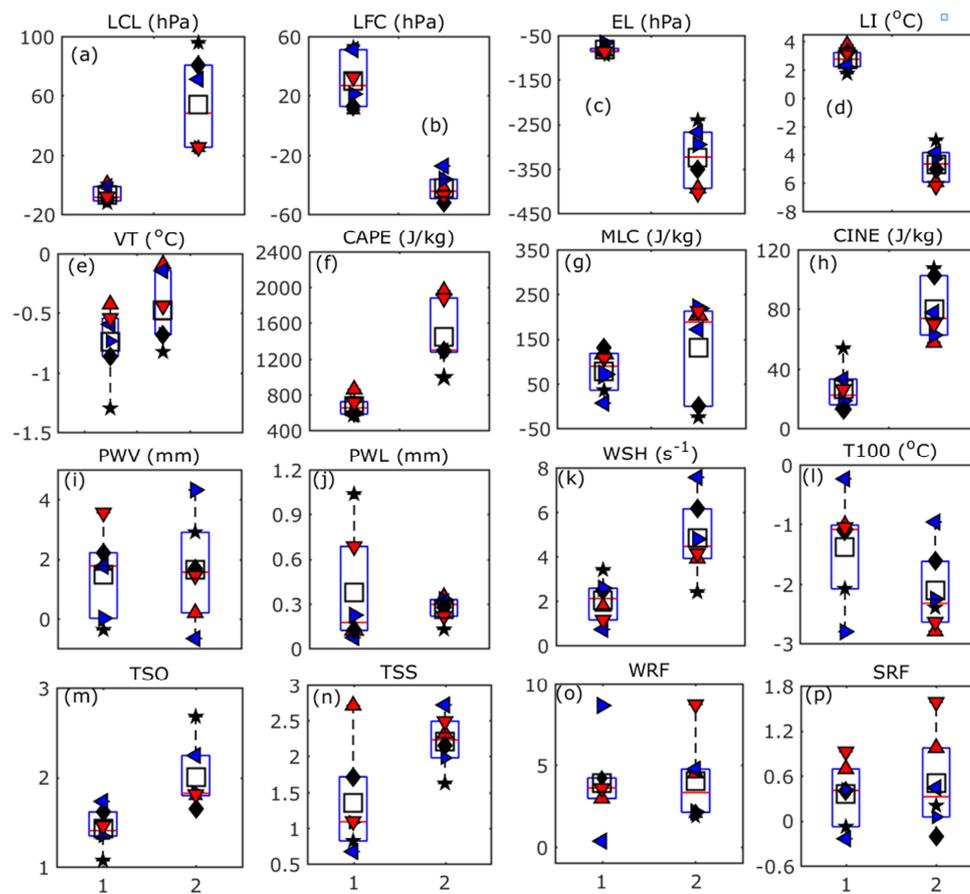

Figure 8: Average long-term trends of various instability parameters over the six sub-divisions of India in two half periods of 18 years each (1 represents first half period C1 during 1980-1997 and 2 showing second half period C2) during 1999-2016. Legends are same as in Figure 4.

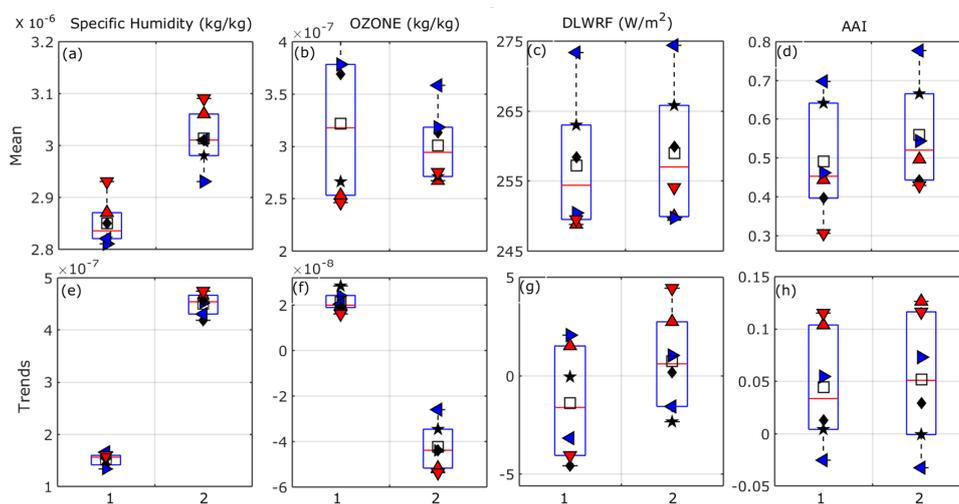

Figure 9: Average and climatological trends of specific humidity, ozone mixing ratio at 100 hPa and Downward Longwave radiation flux with Absorptive Aerosol Index over the six sub-divisions of India over two half periods of 18 years each (1980-1997 and 1999-2016). Legends are same as in Figure 4.

Appendix

Table A1: Details of the dataset used.

Serial no.	Station no.	Latitude	Longitude	Station Name	No. of profiles available	No. of profiles utilized	Region

**Table A2:** List of Abbreviations

<i>Sln.</i>	<i>Abbreviation</i>	<i>Full Form</i>
1	LCL (hPa)	Lifted Condensation Level
2	LFC (hPa)	Level of Free Condensation
3	EL (hPa)	Equilibrium Level
3	LI (°C)	Lifted Index
4	VT (°C)	Vertical Totals Index
5	CAPE (J/kg)	Convective Available Potential Energy
6	MLC (J/kg)	Mixed Layer CAPE
7	CINE (J/kg)	Convective Inhibition
8	PWV (mm)	Precipitable Water Vapour
9	PWL (mm)	Lower Level PWV
10	WSH (s ⁻¹)	Wind Shear
11	T100 (°C)	Temperature at 100 hPa
12	TSO	Ordinary Thunderstorm Frequency
13	TSS	Severe Thunderstorm Frequency
14	WRF	Weak Rainfall Frequency
15	SRF	Severe Rainfall Frequency
16	SHUM (kg/kg)	Specific humidity
17	AAI	Absorptive Aerosol Index
18	IMD	India Meteorological Department
19	IGRA	Integrated Global Radiosonde Archive
20	GHG	Green House Gas
21	DLWRF (W/m ²)	Downward Long Wave Radiation Flux
22	EMD	Empirical Mode Decomposition
23	UTLS	Upper Troposphere Lower Stratosphere
24	QBO	Quasi-biennial oscillation
25	ENSO	El Niño–Southern Oscillation
