14

15 **Abstract.**

16 Black carbon (BC) aerosols in the atmosphere strongly affect radiative forcing. They
17 are mainly removed from the air by wet deposition, and their lifetime is controlled by
18 their water uptake ability or hygroscopicity, which is a function of the aerosol mixing
19 states. It is well known that atmospheric aging processes coat various materials on BC
20 aerosols and affect their mixing states and hygroscopicity. However, detailed relations
21 between the aging processes, the hygroscopicity and mixing state of BC aerosol
22 particles in polluted city areas are not well understood. Here, we studied the temporal
23 variation of the hygroscopicity and its correlation with the mixing state of ambient BC
24 particles during 2017 summer in Shanghai, China using a hygroscopicity tandem
25 differential mobility analyzer in-line with a single particle soot photometer
26 (HTDMA-SP2 system) as well as a single particle aerosol mass spectrometer
27 (SPAMS). BC particles with 120 nm, 240 nm and 360 nm dry diameter were

28 humidified at RH=85%. After humidification, particles with growth factors (GFs) of
29 1.0, 1.2 and 1.4, representing the BC particles with different hygroscopicities
30 (hydrophobic, transition and hydrophilic modes, respectively), were analyzed by a
31 SP2 to obtain their BC mixing states. The diurnal trends of coating thickness and
32 chemical mixing state show that coating materials of BC particles were distinct
33 between daytime and nighttime. The differences were associated with the
34 hygroscopicity of BC particles. Single particle mass spectrometry and other chemical
35 characterization techniques revealed that during nighttime with lower temperature and
36 higher relative humidity (RH), formation or condensation of nitrates resulted in an
37 enhanced hygroscopicity of BC particles. During daytime, secondary organic carbon
38 formation was mainly responsible for the change of hygroscopicity of BC particles.
39 Due to the high hygroscopicity of inorganic nitrate, a thinner nitrate coating on BC
40 particles could convert fresh BC particles to aged hygroscopic ones during nighttime
41 while a thicker coating layer of secondary materials was required to reach the same
42 overall hygroscopicity during daytime since the participation of secondary organic
43 carbon. Different atmospheric aging processes between daytime and nighttime led to
44 the change of BC particles' mixing states, which play a fundamental role in
45 determining their hygroscopicity. To our knowledge, this is the first report of links
46 between temporal variations of the hygroscopic growth of BC particles and
47 atmospheric aging processes in polluted environment. These findings have significant
48 ramification of understanding the aging process, wet removal as well as climate
49 effects of BC particles.

50 **1 Introduction**

51 Black carbon (BC) aerosols are a strong light absorbing component in the
52 atmosphere and a major contributor to the positive radiative forcing (Bond et al., 2013)
53 (Change, 2015; Kondo, 2015). They are mainly generated from incomplete
54 combustion of fossil fuels and biomass. Freshly emitted BC particles are hydrophobic.
55 However, their hygroscopicity can be enhanced by internally mixing with secondary
56 materials through atmospheric aging processes (Schneider et al., 2005; Shiraiwa et al.,
57 2007; Matsui et al., 2013; Pratt et al., 2011). Hygroscopicity of BC aerosol
58 significantly affects their removal rate through wet deposition, absorption in human's
59 respiratory tract (Löndahl et al., 2007), optical properties (Chen et al., 2012), and their
60 surface reactivity (Mogili et al., 2006). Therefore, it is critical to understand the
61 relations between atmospheric aging processes and hygroscopicity of BC aerosols. In
62 the atmosphere, an aerosol population typically consists of aerosol particles with
63 various sizes and chemical compositions, which is usually described as "mixing state".
64 The mixing state of atmospheric BC particles is closely linked to their sources and
65 aging processes (Chirico et al., 2010; Heringa et al., 2011). Aerosol hygroscopicity
66 are determined by the chemical compositions of each individual particle (McMeeking
67 et al., 2011; Liu et al., 2013). Thus, aerosol mixing states play a critical role in
68 determining the hygroscopicity of BC particles.

69 The relations between the hygroscopicity and mixing state of BC aerosols had
70 been studied with many novel measurement techniques. Herich et al. (2008)
71 combined an aerosol time of flight mass spectrometer (ATOFMS) with a
72 hygroscopicity tandem differential mobility analyzer (HTDMA) to investigate the
73 mixing state and hygroscopicity of BC-containing particles at an urban site in Zurich,
74 Switzerland. It shows that most of BC-containing particles internally mixed with
75 organics and combustion species (m/z $^{-26}\text{CN}^-$ and $^{-42}\text{CNO}^-$) have lower
76 hygroscopicity compared with sulfate and nitrate mixed (Herich et al., 2008). A single
77 particle soot photometer (SP2) was installed in downstream of HTDMA by Laborde

78 et al., which shows that the majority of urban aerosol particles with high
79 hygroscopicity ($GF \approx 1.6$) do not contain a detectable refractory BC core while
80 hydrophobic or less hygroscopic particles ($1.1 \leq GF \leq 1.2$) have a BC core with no or
81 little coating of soluble species (Laborde et al., 2013). Similarly, by coupling a SP2
82 with a HTDMA, McMeeking et al. (2011) measured the hygroscopicity of ambient
83 BC particles externally and internally mixed BC particles using uncoated and coated
84 laboratory generated model BC particles. The obtained information is compared to the
85 hygroscopicity distribution of ambient BC aerosols. Their results suggest that the
86 dominant fraction of the BC particles is not readily act as cloud condensation nuclei
87 (CCN) at 0.2% super saturation in an urban area (McMeeking et al., 2011). By
88 coupling a HTDMA and an ATOFMS, our previous study finds that condensation of
89 amine and secondary inorganic species would enhance the hygroscopicity of
90 submicron particles, including BC particles (Wang et al., 2014). In addition, Liu et al.
91 (2013) deployed a similar instrument setup and investigated the relation between the
92 hygroscopic properties and mixing state of BC particles (Liu et al., 2013). It shows
93 that the GF of BC particles was influenced by the composition of soluble materials.

94 These previous studies have relied on real time hygroscopicity measurements, but
95 usually without detailed temporal information on changes of mixing state of BC
96 particles. Time resolved information on aerosol mixing state would be very useful to
97 identify their sources and aging processes. During summer time in heavily polluted
98 areas, the atmospheric aging processes could be much more complex due to higher
99 temperature, higher pollutants concentrations and stronger sunlight radiation.
100 However, according to our knowledge, few studies have reported time resolved
101 analysis on the mixing state and hygroscopicity of BC particles of particular GFs
102 during summer time. Therefore, with high time resolution single particle analysis, this
103 field study has aimed to determine the relations between BC particle hygroscopicity
104 and real time mixing state measurement in Shanghai, a heavily polluted megacity area.
105 It would provide more insights on the effects of atmospheric processes on

106 hygroscopicity of BC particles.

107 **2 Experimental section**

108 **2.1 HTDMA-SP2 system**

109 Temporal variation of BC aerosols mixing state and hygroscopic property were
110 measured using a custom-built HTDMA-SP2 system (Fig. 1). The HTDMA used in
111 this study is described in detail in our previous publications (Ye et al., 2009; Wang et
112 al., 2014). Brief descriptions about the instruments and their operations can be found
113 in the supplementary material. More details of SP2 data analysis are available in our
114 group's previous work (Gong et al., 2016).

115 Similar to those employed by Herich et al. (2008), Zelenyuk et al. (2008) and
116 Wang et al (2014), our HTDMA-SP2 system used a SP2 (DMT, Boulder, CO, USA)
117 in the downstream of a HTDMA to probe BC content as a function of hygroscopicity.
118 The first DMA in the HTDMA system selects monodisperse particles with a dry
119 particle diameter. Then the selected aerosols are humidified at a specified relative
120 humidity (RH=85% in this study). The size distribution of humidified (wet) particles
121 are measured by a scanning mobility particle sizer (SMPS), which includes another
122 DMA and a condensation particle counter (CPC, model 3771, TSI Inc.). GF is the
123 ratio between particle wet size and dry size. The SP2 identifies BC-containing
124 particles at each selected GF. The water uptake properties of BC particles can be
125 linked directly to the mixing state measured by SP2.

126 In this study, aerosol particles with three electrical mobility sizes (120 nm, 240
127 nm and 360 nm in dry diameter) are selected. After humidification, particles with
128 growth factors (GFs) of 1.0, 1.2 and 1.4, representing particles with different
129 hygroscopicities, which are defined as (1) hydrophobic, (2) transition and (3)
130 hydrophilic mode, respectively.

131 2.2 Single particle aerosol mass spectrometer (SPAMS)

132 A single particle aerosol mass spectrometer (SPAMS Hexin Analytical
133 Instrument Co., Ltd., China) was used in parallel to the HTDMA-SP2 system. The
134 SPAMS first measures the size of a single aerosol particle. Then, it uses a 266 nm
135 laser to disintegrate the particle and ionize its chemical compounds, of which
136 mass-to-charge ratios (m/z) and concentration are determined by a bipolar
137 time-of-flight mass spectrometer. Detailed information on the SPAMS has been
138 described elsewhere (Li et al., 2011).

139 In this work, a total of 158,410 individual particle mass spectra were collected,
140 accounting for about 56% of all the particles that were sized in the SPAMS. Element
141 carbon ion clusters has been considered an important marker for BC aerosols (Gong et
142 al., 2016). Using $C_n^{+/-}$ ($n=1, 2, 3, \dots$) as the BC marker, a total of 64,368 BC-containing
143 particles were identified, accounting for about 40.1% of sampled particles. The mass
144 spectra of BC-containing particles were classified into several types based on their
145 similarities using a clustering algorithm called adaptive resonance theory (ART-2a)
146 (Song et al., 1999). Similar to previous studies (Huang et al., 2013; Zhai et al., 2017)
147 (Gong et al., 2016; Spencer et al., 2007), the vigilance factor, learning rate, and
148 iterations for ART-2a algorithm were set to 0.85, 0.05, and 20, respectively. Finally,
149 five particle types were manually combined based on the similarity of their chemical
150 nature.

151 Noticeably, the particles with mobility size at 120 nm cannot be detected by the
152 SPAMS, as they were smaller than the lower limit (200 nm) of size range of the
153 SPAMS. According to Slowik's study, the vacuum aerodynamic diameter (d_{va}) of
154 compact aggregated BC particles was linearly proportional to mobility diameter (d_m),
155 specifically, $d_{va} = 1.3 * d_m$ (Slowik et al., 2004). Here we assume that most detected BC
156 particles follows this relation ($d_{va} = 1.3 * d_m$). In this study, only particles with $D_0 =$
157 120 nm, 240 nm and 360 nm were studied with the HTDMA-SP2 system. These

158 mobility sizes correspond to $d_{va} = 150$ nm, 312 nm and 468 nm, respectively. Thus,
159 the SPAMS cannot provide mixing state information for particles with $d_{va} = 150$ nm
160 ($d_m = 120$ nm), which was out of the SPAMS detection range (200 to 2000 nm).

161 **2.3 Other instruments**

162 **2.3.1 OC/EC analyzer**

163 Hourly mass concentrations of elemental carbon (EC) and organic carbon (OC)
164 were measured by a semi-continuous OC/EC analyzer (Model 4, Sunset Laboratory
165 Inc., Portland, USA.) based on the National Institute of Occupational Safety and
166 Health thermal/optical transmittance measurement protocol (NIOSH 5040), with a
167 PM_{2.5} impactor inlet. Detailed information can be found in the previous publication
168 (Wang et al., 2016a). Concentration of secondary organic carbon (SOC) was
169 estimated using the method of minimum ratio of OC/EC (Chou et al., 2010), which is
170 calculated by the following equation.

$$171 \quad \text{SOC} = \text{OC}_{\text{total}} - \text{EC} \times (\text{OC/EC})_{\text{pri}} \quad (1)$$

172 where OC and EC are the measured hourly mass concentrations of organic
173 carbon and elemental carbon. $(\text{OC/EC})_{\text{pri}}$ is the OC/EC ratio for primary aerosol
174 emission. At urban locations, the $(\text{OC/EC})_{\text{pri}}$ was assumed to be the minimum value of
175 OC/EC ratio throughout the whole study sampling period (Cao et al., 2013). The OC
176 vs EC plot is displayed in Fig. S1. We use the minimum value 2.2 as the $(\text{OC/EC})_{\text{pri}}$,
177 in this work.

178 **2.3.2 Monitor for Aerosols and Gases in Air (MARGA)**

179 A Monitor for Aerosols and Gases in Air (MARGA, Applikon Analytical B. B.
180 Corp., ADI 2080, Netherlands), with a PM_{2.5} cyclone impactor, was deployed to
181 measure the concentrations of inorganic ionic species (i.e. SO_4^{2-} , NO_3^- and NH_4^+) in

182 PM_{2.5}. Detailed description about the MARGA is available in the previous publication
183 (Du et al., 2010).

184 **2.4 Sampling period and site**

185 The measurements of the relationship between mixing state and hygroscopicity
186 of BC particles various with time were carried out from 4 to 16 July 2017 using a
187 SPAMS and a HTDMA-SP2 system. The sampling site is located at the Department
188 of Environmental Science and Engineering in the main campus of Fudan University
189 (31.30°N, 121.5°E), and it is surrounded by residential and commercial areas. An
190 elevated road (the Middle Ring Line) with heavy traffic is ~ 400 m away from the
191 sampling location.

192 **2.5 Meteorology**

193 The meteorology and air quality information were obtained at a nearby air
194 quality monitoring station, which is operated by Shanghai Environmental Monitoring
195 Center (Yangpu Site). (<http://www.semc.com.cn/aqi/home/Index.aspx>). The station
196 was 3.3 km from the sampling site. Temporal profiles of measured gaseous pollutants
197 (O₃, SO₂, CO, and NO₂), temperature, relative humidity (RH), PM_{2.5}, and hourly PM₁₀
198 mass concentrations from July 4 to 16, 2017 are shown in Fig. 2. The temperature and
199 RH varied between 24.1°C and 38.0 °C, and 46% and 100%, with an average of 30.4
200 °C, 74.1%, respectively, during the sampling period. Figure 2 shows that the
201 temperature was negatively correlated with RH, but positively correlated with O₃
202 mass concentration. Hourly O₃ concentration usually peaked in the afternoon during
203 this period. Its maximum value reached 316 µg/m³ at 14:00 on July 12, showing
204 extremely active photochemical activities in this afternoon. The maximum value of
205 PM_{2.5} reached 72 µg/m³ at 18:00 on July 13, with an average of 29.2 µg/m³.
206 Meanwhile, PM₁₀ varied from 15 to 141 µg/m³, with an average of 57.9 µg/m³.

207

208 3 Results and discussion

209 The focus of this paper is temporal variation of hygroscopicity and mixing states
210 of ambient BC particles. Due to the slow scanning rate of DMA voltage and sampling
211 time requirement of SP2, obtaining temporal information of BC concentrations
212 requires the DMA size selection to be fixed for a certain amount of time. Therefore,
213 for HTDMA-SP2 system, only one size (D_0) was studied for each sampling period.
214 Specifically, $D_0 = 120, 240$ and 360 nm was measured during 2017/07/04 06:00:00~
215 2017/07/07 05:00:00, 2017/07/07 06:00:00~2017/07/10 05:00:00 and 2017/07/10
216 06:00:00~2017/07/16 05:00:00, respectively.

217 We studied three GFs (GF=1.0, 1.2 and 1.4) for each D_0 . The GF selection was
218 based on the GF size distribution of BC particles. A general picture of hygroscopicity
219 of total sampled ambient particles is shown in Fig. 3(a), which illustrates averaged
220 hygroscopic growth factor distributions at three selected sizes ($D_0 = 120, 240$ and 360
221 nm). All three GF curves featured a bimodal distribution, which contained a
222 hydrophobic mode peaks at GF = ~ 1.0 and a hydrophilic mode peaks at larger GFs
223 ($1.3 \sim 1.6$). Clearly, the hygroscopic particles were typically more abundant than the
224 hydrophobic ones. The hygroscopic growth distributions featured a size dependent
225 hygroscopic growth, significantly reducing of the particle number and shifting to
226 larger growth with increasing particle size, which were conventionally attributed to a
227 size dependent chemical composition (Swietlicki et al., 2008). In contrast,
228 hygroscopic growth factor distributions of BC particles only show one mode (Fig.
229 3(b)). The GF curve of BC particles peaked at GF = ~ 1.0 . The BC-containing number
230 fraction decreased sharply for larger GFs. When GF was greater than 1.4, few BC
231 particles were detected by SP2.

232 GF=1.0, 1.2 and 1.4 was selected to represent hydrophobic, transition, and
233 hydrophilic mode for BC particles, respectively. Higher GFs (GF>1.4) were not
234 selected due to the low BC-containing number fractions at these GFs. For each day,

235 the sampling was divided to eight 3-hour sampling periods. Three GFs (GF=1.0, 1.2
236 and 1.4) were set sequentially for one hour during each sampling period.

237 Here, the diurnal trend (in Section 3.1) and classification (in Section 3.2) of BC
238 particles are described and discussed in detail. Then, the relations between mixing
239 state and hygroscopicity of BC particles are elucidated (in Section 3.3).

240 **3.1 Diurnal variations of BC particles with different hygroscopicities**

241 **3.1.1 Diurnal variation of hydrophobic mode BC particles**

242 The averaged diurnal patterns of the number concentration and number fraction
243 of BC particles are shown in Fig. 4(a) and 4(b), respectively. The number fraction of
244 BC particles is defined as the ratio of the number concentration of BC particles to that
245 of total ambient aerosol particles at a certain D_0 and GF. The majority of hydrophobic
246 mode (GF=1.0) BC particles typically exhibited two peaks for all three D_0 s (Fig. 4(a)).
247 They were likely to be freshly emitted from combustion sources (McMeeking et al.,
248 2011). The number concentrations of hydrophobic BC particles reached their first
249 peak in the morning around 6:00 to 9:00 local time (LT), and then followed by a dip
250 in the afternoon around 12:00 to 17:00. The hydrophobic BC particles reached the
251 second peak in the evening and then slowly decreased during the night. This trend is
252 similar to some field studies in other city areas, such as Shenzhen and Xiamen in
253 China (Huang et al., 2012; Wang et al., 2016b). The elevated BC particle number
254 concentration in the morning and early evening can be explained by increases in local
255 anthropogenic emissions, especially those from rush hour traffic. This trend
256 presumably was also intensified by lower boundary layer heights at those times.

257 As shown in Fig. 4(b), hydrophobic BC particles accounted for the largest
258 percentage among three GFs for all D_0 s. However, number fractions of hydrophobic
259 BC particles decreased with the increased D_0 . For $D_0 = 120$ nm, 240 nm, 360 nm, the
260 maximum number fractions of hydrophobic BC particles were ~80%, 70% and 60%,

261 respectively. It is known that most of the fresh BC particles diameter are smaller than
262 200 nm (Kondo et al., 2006), which is consistent to our finding that relatively lower
263 fractions of BC particles were detected at larger sizes.

264 3.1.2 Diurnal variations of transition and hydrophilic mode BC particles

265 The transition and hydrophilic mode BC particles likely originated from aged
266 particles. Condensation of hydrophilic secondary materials (e.g. sulfate, nitrate and
267 secondary organic compounds) would significantly enhance the water uptake ability
268 of BC particles. As shown in Fig. 4(a), the number concentrations of some transition
269 and hydrophilic mode BC particles (like transition mode for 120 and 240nm BC
270 particles) showed a clear daily maximum during 12:00 ~ 15:00 (Fig. 4(a)). This trend
271 could be explained by the intense aging processes during this time when sunlight
272 intensity and atmospheric oxidants' concentration reach their peak values. However,
273 the number concentration of transition and hydrophilic mode BC particles could be
274 affected by other atmospheric aging processes. For example, nitrate formation could
275 be significantly enhanced during nighttime due to the hydrolysis of N_2O_5 (Wang et al.,
276 2009; Wang et al., 2016a). This process would make more transition and hydrophilic
277 mode BC particles during nighttime. To understand their diurnal trends, the
278 measurement of their chemical compositions and mixing states is essential, which will
279 be discussed in Section 3.3.

280 Fig. 4(b) also shows the diurnal variations of number fractions of transition and
281 hydrophilic mode BC particles. Contrast to the hydrophobic mode BC particles, the
282 transition and hydrophilic mode (GF = 1.2 and 1.4) BC particles with larger sizes
283 tended to contribute higher number fractions of total particles. It is known that BC
284 particles originated from traffic emissions are small (median diameter < 200 nm) (Xue
285 et al., 2015). Thus, the increased fraction of BC particles in $D_0 = 360$ nm hydrophilic
286 mode particles suggest these particles were from a different source. A candidate is
287 biomass burning (BB) aerosols, which have slightly higher hygroscopicity than those

288 from traffic emissions (Laborde et al., 2013). Detail discussion of BB aerosol will be
289 shown in Section 3.2.

290 In addition, the diurnal variations of BC particle number fraction showed that
291 during nighttime much larger proportion of BC particles were in hygroscopic mode
292 compared to daytime, indicating that hygroscopicity of BC at night was much
293 stronger than that in the daytime. The main reason will be discussed in Section 3.3.

294 3.1.3 Diurnal variations of BC core diameter and coating thickness

295 BC core diameter (D_c) can be obtained if knowing single particle BC mass and
296 assuming that core is spherical and BC density is 1.8 g/cm^3 . The corresponding
297 coating thickness is $(D_p - D_c)/2$ (Gong et al., 2016). Diurnal variations in average BC
298 core diameter and coating thickness at different GFs are displayed in Fig. 5(a) and Fig.
299 5(b), respectively. For a certain BC particle size, a larger core size and a thinner
300 coating thickness corresponded to BC particles with lower hygroscopicity (e.g.
301 $\text{GF}=1.0$). When BC particles became more hygroscopic (i.e. GF increases), the
302 coating thickness increased.

303 It's interesting to note that the core sizes for the hygroscopic mode BC particles
304 increased during nighttime (21:00 to 6:00) while coating thickness decreased (since
305 the entire electron mobility diameter was fixed). This observation suggests that the
306 coating material on BC particle might be different between daytime and nighttime. To
307 achieve the same GF, a thicker coating thickness is required for the less hygroscopic
308 coating materials, as the hygroscopicity of BC core is always constant ($\text{GF} = 1.0$).

309 3.2 BC-containing particle types identified by SPAMS

310 The mixing state and aging degree of BC-containing particles have been studied
311 using a SPAMS. Noticeably, the particles size range for the SPAMS is from 200 to
312 2000 nm. The detection efficiency drops rapidly below 400 nm and above 1200 nm

313 (Li et al., 2011). However, most pure BC particles are smaller than 200 nm (Kondo et
314 al., 2006), which is close to the lower size limit for the SPAMS and can only be
315 detected at a low efficiency. Based on SPAMS mass spectra patterns, BC particles
316 were classified into five types: EC, NaKEC, ECOC, KEC and Others. Their relative
317 contributions are shown in Table 1. The average mass spectra for each particle type
318 are shown in Fig. S2.

319 Pure EC particles only presented BC fragment ions (C_n^+ and C_n^-) in both positive
320 and negative ion mass spectra. There were low signals of secondary species, such as
321 sulfate or nitrate, indicating that pure EC had not gone through significant aging in the
322 atmosphere, thus EC type were freshly emitted BC particles.

323 NaKEC particles exhibited strong signals for BC fragment ions in both positive
324 and negative mass spectra, in addition, potassium ($^{+39}K^+$) and sodium ($^{+23}Na^+$) in
325 positive ion mass spectra and nitrate ($^{-46}NO_2^-$ and $^{-62}NO_3^-$) and sulfate ($^{-97}HSO_4^-$) in the
326 negative ion mass spectra also exhibited. Hydrocarbon-like organic aerosol (HOA) is
327 dominated by alkyl fragment signatures, the $C_nH_{2n+1}^+$ ($m/z= 29, 43, 57$) and $C_nH_{2n-1}^+$
328 ($m/z= 27, 41, 55$) ions. The time series of HOA correlated well with those of NO_2 and
329 CO , two tracers of vehicle emissions (Fig. S3(a)). The diurnal pattern of HOA ion
330 intensity further suggests the association of HOA with traffic activities, as it showed
331 two obvious peaks during the morning and evening rush hours (Li et al., 2017). HOA
332 as a tracer of traffic emission correlated reasonably well with the NaKEC particles
333 number ($R^2=0.560$), as shown in Fig. S3(b).

334 The ECOC type particles internally mixed with many organic carbon (OC)
335 signals, including $^{+37}C_3H$, $^{+43}CH_3CO^+$, $^{+50}C_4H_2^+$, $^{+51}C_4H^+$, $^{+61}CH_3C(OH)=OH^+$,
336 $^{+62}(CH_3)_2NHOH^+$, as well as $^{+23}Na^+$ and BC fragment ions (C_n^+). The presence of a
337 high signal intensity for sulfate ($^{-97}HSO_4^-$) and a relatively low signal intensity for
338 nitrate ($^{-46}NO_3^-$, $^{-62}NO_3^-$) suggests that they were aged BC particles. BC particles with
339 various intensities of OC, nitrate and sulfate were commonly detected in ambient

340 measurements by ATOFMS (Moffet et al., 2008; Ault et al., 2009) (Dall’Osto and
341 Harrison, 2006) and were also assigned to aged traffic emissions (Healy et al., 2012).

342 KEC particles were characterized by an intense $^{39}\text{K}^+$ signal in the positive ion
343 mass spectra and strong signals for $^{-26}\text{CN}^-$ and $^{-42}\text{CNO}^-$ in the negative ion mass
344 spectra. Significant intensities of ion fragments of levoglucosan, such as $^{-71}\text{C}_3\text{H}_3\text{O}_2^-$
345 and $^{-73}\text{C}_3\text{H}_5\text{O}_2^-$, were also observed. Typical BC fragments C_n^- appeared in the negative
346 ion mass spectra. Similar to ECOC type, the presence of a high signal intensity of
347 $^{-97}\text{HSO}_4^-$, $^{-46}\text{NO}_2^-$ and $^{-62}\text{NO}_3^-$ signals indicates significant particle aging in the
348 atmosphere (Leskinen et al., 2007; Reid et al., 2005). These characteristics suggest
349 that their sources are either biomass burning or coal combustion or both (Andreae,
350 1983; Soto-Garcia et al., 2011; Wang et al., 2013; Gong et al., 2016). Particles with
351 similar mass spectral patterns were previously observed in several urban field studies
352 are also assigned to the sources of combustion of biomass or coal (Moffet et al., 2008;
353 Healy et al., 2012; Bi et al., 2011; Wang et al., 2013; Gong et al., 2016).

354 “Others” particle type was not grouped to any of the previous four types; and it
355 accounts for only 8.5% in total BC particle number concentration. The average mass
356 spectra of this particle type are displayed in Fig. S2 (e). However, it is not the focus of
357 this study.

358 The relative fractions of aerosol types as a function of particle size were plotted
359 in Fig. S4. Generally, the number fraction for each particle type is highly dependent
360 on particle size. Sharp changes in BC particle mixing states has been found between
361 the size ranges of 200 nm ~ 400 nm and 400nm ~ 800nm. EC and NaKEC types are
362 the major fraction types in the 200 nm ~ 400 nm size range. In contrast, the larger size
363 range (400 nm ~ 800 nm) was dominated by ECOC and KEC types. For the sake of
364 the convenience for discussion, we separate particles to two groups based on their d_{va} ,
365 namely $G_{200-400}$ ($200\text{ nm} < d_{va} < 400\text{ nm}$) and $G_{400-800}$ ($400\text{ nm} < d_{va} < 800\text{ nm}$). In this
366 work, $d_{va} = 150\text{ nm}$ ($d_m = 120\text{ nm}$) was out of the SPAMS detection range, while $d_{va} =$

367 312 nm ($d_m = 240$ nm) and $d_{va} = 468$ nm ($d_m = 360$ nm) was falling in the range of
368 $G_{200-400}$ and $G_{400-800}$, respectively.

369 The diurnal variations of number fraction of each particle type in $G_{200-400}$ were
370 calculated and shown in Fig. 6(a). It is found that number fraction of the EC and
371 NaKEC types displayed pronounced diurnal patterns with two major peaks in the
372 early morning (6:00 ~ 9:00) and in the evening (18:00 ~ 21:00), which possibly
373 related to traffic. From the hygroscopicity measurement ($D_0 = 240$ and 360 nm in Fig.
374 4(a)), the elevated BC particle number concentration at $GF=1.0$ during these two
375 time-frames suggests that the elevated concentrations of hydrophobic BC particles
376 aerosol were probably associated with EC and NaKEC types, which are produced
377 from traffic sources.

378 A different pattern has been observed for $G_{400-800}$ (shown in Fig. 6(b)). The
379 ECOC and KEC types accounted for the major number fractions in the 400 nm ~ 800
380 nm range. The diurnal variations of these two particle types share a similar trend,
381 while other two types (EC and NaKEC) showed no significant variation. The EC and
382 NaKEC types only attributed to small proportions of $G_{400-800}$ particles. Interestingly,
383 the number fraction of ECOC in $G_{400-800}$ also showed two major peaks in the morning
384 and evening, suggesting that ECOC was aged BC particles from traffic emissions. The
385 KEC peak in the evening was much more pronounced than that in the morning, and
386 this might be due to biomass burning which is still widely used by domestic cooking
387 (in the evening) in the countryside around Shanghai city. These BB aerosols were
388 then transport to the sampling site.

389 3.3 The relations between the mixing state and hygroscopicity of BC particles

390 To elucidate the relation between mixing state and hygroscopicity of BC
391 particles, the detailed chemical composition and mixing state information from the
392 EC/OC, MARGA and SPAMS was compared to the HTDMA-SP2 hygroscopicity

393 measurements. As discussed in Section 3.1, we found that the BC core sizes for the
394 hygroscopic mode particles increased during nighttime (21:00 ~ 6:00) while coating
395 thickness decreased, indicating the BC particle coating compositions were different
396 between daytime and nighttime. The major secondary aerosol coating materials in
397 polluted boundary layer could be secondary organic carbon (SOC), sulfate and nitrate.
398 Therefore, the diurnal trends of these species have been investigated and compared to
399 BC particles' hygroscopicity.

400 3.3.1 Major secondary ionic species

401 The dominant ionic species in urban aerosols in Shanghai are sulfate, nitrate and
402 ammonium (Ye et al., 2013). To study the chemical composition dependence on
403 hygroscopicity, mass concentrations of SO_4^{2-} , NO_3^- and NH_4^+ were measured by a
404 MARGA during this field study. As shown in Fig. 7(c), the average sulfate
405 concentration varied in a small range from ~ 4.8 to 6.1 $\mu\text{g}/\text{m}^3$. Its concentration in the
406 daytime was only slightly higher than that of nighttime. The average mass
407 concentration of NO_3^- varied between 1.1 $\mu\text{g}/\text{m}^3$ and 4.4 $\mu\text{g}/\text{m}^3$ with an average of 2.3
408 $\mu\text{g}/\text{m}^3$. Similar to our previous study (Wang et al., 2016a), the nitrate concentrations
409 at night were clearly elevated (Fig. 7(d)). The relative peak area (RPA) of NO_3^- in
410 BC particles measured by SPAMS is also consistent with the MARGA measurement
411 (Fig. 7(d)). During the nighttime in summer, lower temperature, higher relative
412 humidity and high concentration of NO_3 (N_2O_5) favor the formation of nitrate in
413 particle phase (Wang et al., 2009; Wang et al., 2016a).

414 3.3.2 Elevated SOC concentrations in the daytime

415 Photochemical reactions are a major formation pathway of SOC (Kroll and
416 Seinfeld, 2008; Zhang et al., 2018). Odd oxygen ($\text{O}_x = \text{O}_3 + \text{NO}_2$) was often used as
417 an indicator of photochemical oxidant concentration in the atmosphere (Herndon et al.,
418 2008; Hu et al., 2016; Wood et al., 2010). The diurnal variations of SOC and O_x mass

419 concentrations in one-hour resolution were plotted in Fig. 7. In this work, average
420 SOC and O_x varied between $1.8 \mu\text{gC}/\text{m}^3$ and $8.8 \mu\text{gC}/\text{m}^3$, and $58 \mu\text{g}/\text{m}^3$ and 214
421 $\mu\text{g}/\text{m}^3$, respectively. The correlation coefficient (R) between SOC and O_x was 0.772
422 (shown in Fig. S5), indicating that the SOC formation was associated with the
423 photochemical oxidant concentration during this study.

424 Single particle mass spectrometry was also used to further investigate the mixing
425 state and possible formation pathways of SOC. The relative peak area of
426 $+43[\text{CH}_3\text{CO}^+/\text{CHNO}^+]$ during the daytime is a tracer of SOC formation (Qin et al.,
427 2012; Zhang et al., 2014; Zhang et al., 2018). Time-series of hourly-averaged relative
428 peak areas of $m/z +43$ in ECOC type was shown in Fig. 8. Overall, the $m/z +43$ curve
429 peaked in the afternoon, which was consistent with the trend of O_x . This result
430 indicates that SOC ($m/z=+43$) produced by photochemical reactions condensed on BC
431 particles. The average ECOC particle size verse time is also shown in Fig. 8. It peaked
432 between 13:00 to 15:00 in the afternoon. Since the concentration of sulfate in the
433 daytime was only slightly higher than that of nighttime (Fig. 7(c)), the increase of
434 ECOC particle size was mainly caused by the condensation of SOC rather than
435 secondary inorganic species. Therefore, in the afternoon, the intense photochemical
436 processes resulted in BC particles coated with more organic materials, leading to a
437 thicker coating thickness.

438 3.3.3 Hygroscopicity and mixing state (coating material)

439 As discussed above, the chemical composition measurement clearly shows BC
440 particles were coated more SOC in the daytime and more nitrate in the nighttime.
441 Sulfate concentration did not change much between daytime and nighttime.
442 Meanwhile, at a given GF, the coating for hygroscopic mode BC particles was thicker
443 in the daytime and thinner in the nighttime. The water uptake ability of nitrate is much
444 stronger than secondary organics. Thus, compared to SOC, less nitrate coating is
445 needed for a given hygroscopicity or GF.

446 To better understand this finding, we estimated volumes of different coating
 447 materials required for a BC particle with a given hygroscopicity using the
 448 Zdanovskii-Stokes-Robinson (ZSR) mixing rule (Stokes and Robinson, 1966),

$$449 \quad GF_{ZSR}(RH, D_p) = \left(\sum_i GF_i(RH, D_p)^3 \varepsilon_i \right)^{1/3} \quad (2)$$

450 The ε_i is the volume fractions of rBC, nitrate, sulfate or organic coating in BC
 451 particles. For simplicity, we assume BC is covered by mixture containing either
 452 SOC/(NH₄)₂SO₄ or (NH₄)₂SO₄/NH₄NO₃, representing the mixing state of BC in
 453 daytime and nighttime respectively. The GF for SOC is set to be 1.2, since Sjögren et
 454 al. reported a uniform growth factor GF_{SOA}=1.2 (RH=90%) according to the ZSR
 455 modelling results and field measurements (Sjögren et al., 2008). This value is at the
 456 high end of previous measured SOA hygroscopicity range, thereby representing
 457 highly aged and oxidized of SOA (Varutbangkul et al., 2006; Baltensperger et al.,
 458 2005). The GFs of pure black carbon, (NH₄)₂SO₄ and NH₄NO₃ aerosol with a dry size
 459 of 163 nm at RH=90% are calculated using the Aerosol Diameter-Dependent
 460 Equilibrium Model (ADDEM) model. Their values are 1.0, 1.7 and 1.8 respectively
 461 (Topping et al., 2005a, b).

462 For a coated BC particle with a dry diameter of 163 nm and a GF of 1.4, the
 463 following relations would hold for SOC/(NH₄)₂SO₄ coating (eq. 3) and
 464 (NH₄)₂SO₄/NH₄NO₃ coating (eq. 4):

$$465 \quad 1.4 = \sqrt[3]{\varepsilon_{BC} \times GF_{BC}^3 + \varepsilon_{SOC} \times GF_{SOC}^3 + \varepsilon_{(NH_4)_2SO_4} \times GF_{(NH_4)_2SO_4}^3} \quad (3)$$

$$466 \quad 1.4 = \sqrt[3]{\varepsilon_{BC} \times GF_{BC}^3 + \varepsilon_{NH_4NO_3} \times GF_{NH_4NO_3}^3 + \varepsilon_{(NH_4)_2SO_4} \times GF_{(NH_4)_2SO_4}^3} \quad (4)$$

467 ε_{BC} and ε'_{BC} , representing the volume fractions of BC core in two mixing states,

468 are given by $\varepsilon_{\text{BC}} = 1 - \varepsilon_{\text{SOC}} - \varepsilon_{(\text{NH}_4)_2\text{SO}_4}$ and $\varepsilon'_{\text{BC}} = 1 - \varepsilon_{\text{NH}_4\text{NO}_3} - \varepsilon_{(\text{NH}_4)_2\text{SO}_4}$, respectively.

469 Here, we assume $\varepsilon_{(\text{NH}_4)_2\text{SO}_4}$ is constant in both mixing states.

470 Combining equations above, the ratio of volume fraction of SOC to NH_4NO_3 is

$$471 \quad \frac{\varepsilon_{\text{SOC}}}{\varepsilon_{\text{NH}_4\text{NO}_3}} = 6.6 \quad (5)$$

472 This calculation shows that higher volume fraction of $\text{SOC}/(\text{NH}_4)_2\text{SO}_4$ is needed for a
473 BC particle to achieve the same GF as the one covered by $(\text{NH}_4)_2\text{SO}_4/\text{NH}_4\text{NO}_3$.

474 This result confirms that different atmospheric aging pathways lead to changes in
475 aerosol mixing state with distinct hygroscopicities: During nighttime with low
476 temperature and high RH, formation or condensation of nitrates on BC particles
477 enhanced the hygroscopicity of BC particles and resulted in the thinner coating BC
478 particles in the hygroscopic mode for each selected size. During daytime,
479 condensation of photo-chemically generated SOC on BC particles was associated to
480 the thicker coating BC particles with less enhancement of hygroscopicity. The sulfate
481 coating could enhance hygroscopicity of BC particles. However, unlike nitrate and
482 SOC, its formation did not show a significant difference between day and night.

483 **4 Conclusions**

484 In this study, a HTDMA+SP2 system along with SPAMS were used to measure
485 BC particles' hygroscopic properties in Shanghai during 2017 summer. Three
486 hygroscopic modes, namely the hydrophobic mode, transition mode and hydrophilic
487 mode with GF at 1.0, 1.2 and 1.4, respectively, were selected to study the diurnal
488 variations in BC core and coating thickness as a function of time.

489 Our results reveal that the hygroscopicity of BC particle is determined by the
490 coating layer thickness and materials, both of which are affected by atmospheric

491 aging processes. For a specific BC particle size, a thin coating layer corresponded to
492 freshly emitted BC particles with low hygroscopicity (e.g. $GF=1.0$). When BC
493 particles became more hygroscopic (i.e. GF increases), the coating thickness
494 increased. High yielding of particulate nitrate during nighttime was observed, and
495 nitrate coating greatly enhanced the hygroscopicity of BC particles. During daytime,
496 strong SOC formation from photochemical oxidation played an important role in the
497 evolution of the BC mixing state. A thinner layer of nitrate coating could convert
498 fresh BC particles to aged hygroscopic ones while a thicker coating layer of SOC and
499 sulfate was required to reach the same overall hygroscopicity.

500 This study shows that atmospheric aging processes in a polluted city area play
501 critical roles in the fast changing of aerosol mixing state during summer time. Time
502 resolved information on particle hygroscopicity is necessary to evaluate the aging
503 process, wet removal as well as climate effects of BC aerosols.
