17 **Abstract.** The effectiveness of transport of short-lived halocarbons to the upper troposphere and
18 lower stratosphere remains an important uncertainty in quantifying the supply of ozone-depleting
19 substances to the stratosphere. In early 2014, a major field campaign in Guam in the West Pacific,
20 involving UK and US research aircraft, sampled the tropical troposphere and lower stratosphere. The
21 resulting measurements of CH₃I, CHBr₃ and CH₂Br₂ are compared here with calculations from a
22 Lagrangian model. This methodology benefits from an updated convection scheme which improves
23 simulation of the effect of deep convective motions on particle distribution within the tropical
24 troposphere. We find that the observed CH₃I, CHBr₃ and CH₂Br₂ mixing ratios in the Tropical
25 Tropopause Layer (TTL) are consistent with those in the boundary layer when the new convection
26 scheme is used to account for convective transport. More specifically, comparisons between
27 modelled estimates and observations of short-lived CH₃I indicate that the updated convection scheme
28 is realistic up to the lower TTL but is less good at reproducing the small number of extreme
29 convective events in the upper TTL. This study consolidates our understanding of the transport of
30 short-lived halocarbons to the upper troposphere and lower stratosphere by using improved model
31 calculations to confirm consistency between observations in the boundary layer, observations in the
32 TTL, and atmospheric transport processes. Our results support recent estimates of the contribution of
33 short-lived bromocarbons to the stratospheric bromine budget.

34 35 1 Introduction

36 The successful implementation of the Montreal Protocol with its adjustments and amendments has
37 led to reductions in stratospheric chlorine and bromine amounts since the late 1990s (Carpenter et al.,
38 2014). These reductions have halted the ozone decrease (Harris et al., 2015; Chipperfield et al., 2017;
39 Steinbrecht et al., 2017) with the exception of the possible reduction in the lower stratosphere (Ball
40 et al., 2017; Chipperfield et al., 2018; Ball et al., 2019). Recently, the importance of very short-lived
41 (VSL) chlorine- and bromine containing compounds has received a great deal of attention (e.g.
42 Hossaini et al., 2017; Oram et al., 2017). VSLS are not controlled under the Montreal Protocol, but

*Deceased: 19.12.2017

43 are required in order to reconcile observed stratospheric measurements of inorganic or ‘active’
44 bromine with reported anthropogenic bromine emission sources. However VSLs input into the
45 stratosphere has remained a poorly constrained quantity (Carpenter et al., 2014), which hinders our
46 understanding of the on-going decline in lower stratospheric ozone and our ability to make
47 predictions of stratospheric ozone recovery.

48 Three of the most important VSL halocarbons are: methyl iodide, CH₃I; bromoform, CHBr₃; and
49 dibromomethane, CH₂Br₂. They have typical lower tropospheric lifetimes (4, 15 and 94 days,
50 respectively (Carpenter et al., 2014)) which are shorter than tropospheric transport timescales and so
51 they have non-uniform tropospheric abundances. They are emitted predominantly from the oceans
52 and result principally from natural sources (e.g. Lovelock, 1975; Moore et al., 1995; Oram and
53 Penkett, 1994; Vogt et al., 1999; Pyle et al., 2011; Carpenter et al., 1999, 2012, 2014; Tegtmeier et
54 al., 2013; Saiz-Lopez et al., 2014). The short-lived bromocarbons, chiefly CHBr₃ and CH₂Br₂, have
55 been identified as the missing source for stratospheric bromine (the sum of bromine atoms in long-
56 lived brominated organic and inorganic substances; Pfeilsticker et al., 2000; Feng et al., 2007;
57 Dessens et al., 2009). The current estimate of the contribution of the short-lived bromocarbons to the
58 active bromine (Br_v) in the stratosphere is ~5 (3-7) ppt (Engel et al., 2018), which is slightly
59 narrower than the previous range of 3-8 ppt (Liang et al., 2010, 2014; Carpenter et al., 2014;
60 Fernandez et al., 2014; Sala et al., 2014; Tegtmeier et al., 2015; Navarro et al., 2015, 2017; Hossaini
61 et al., 2016; Butler et al., 2017; Fiehn et al., 2017). Much of the uncertainty is linked to the
62 contribution of CHBr₃ which has both the shortest lifetime and the largest emissions of the
63 commonly observed bromocarbons.

64 The transport of VSL halocarbons into the lower stratosphere is by ascent through the tropical
65 tropopause layer (TTL) (Fueglistaler et al., 2009). An important factor influencing the loading of the
66 VSL bromocarbons in the TTL is the strength of the convective transport from the boundary layer
67 where the bromocarbons are emitted (Hosking et al., 2010; Yang et al., 2014; Russo et al., 2015;
68 Hepach et al., 2015; Fuhlbrügge et al., 2016; Krzysztofiak et al., 2018). This is poorly quantified and,
69 when taken together with the large variations in boundary layer concentrations and the uncertainties
70 associated with the model representation of convection, limits our ability to model the bromine
71 budget in the current and future atmosphere (Liang et al., 2010, 2014; Hoyle et al., 2011; Russo et
72 al., 2011, 2015; Schofield et al., 2011; Aschmann et al., 2013; Fernandez et al., 2014; Hossaini et al.,
73 2016; Krzysztofiak et al., 2018).

74 To address this and other challenges, the Natural Environment Research Council Coordinated
75 Airborne Studies in the Tropics (NERC CAST), National Centre for Atmospheric Research
76 Convective Transport of Active Species in the Tropics (NCAR CONTRAST) and National
77 Aeronautics and Space Administration Airborne Tropical Tropopause Experiment (NASA
78 ATTREX) projects were organised (Harris et al., 2017; Jensen et al., 2017; Pan et al., 2017). These
79 projects joined forces in January-March 2014 in the American territory of Guam, in the West Pacific.
80 Three aircraft were deployed to sample air masses at different altitudes to investigate the
81 characteristics of air masses influenced by deep convection. This campaign produced a unique
82 dataset of coordinated measurements for interpretative studies of transport and distribution of the
83 chemical species, including the VSL bromocarbons (Sect. 2.1 and 2.2). The NASA ATTREX project
84 also measured over the less convectively active east Pacific in January - February 2013.

85 The objective of this paper is to model the transport and distribution of CH₃I, CHBr₃ and CH₂Br₂ in
86 the TTL by quantifying their boundary layer and background contribution components using a
87 Lagrangian methodology building on the approach of Ashfold et al (2012). A new parameterisation
88 scheme of convection for the NAME trajectory model is used with the short-lived CH₃I serving as an
89 excellent way to assess the performance of the new scheme. Briefly, the approach uses clusters of
90 back trajectories starting at measurement points to quantify how much of CH₃I, CHBr₃ and CH₂Br₂
91 in the TTL come from the boundary layer, thereby assessing the role of convection in transporting
92 these compounds to the TTL. The calculation is completed by estimating the background component
93 (i.e. how much of CH₃I, CHBr₃ and CH₂Br₂ originate from outside the immediate boundary layer
94 source). Section 2 presents an overview of the field campaigns, the CH₃I, CHBr₃ and CH₂Br₂
95 measurements, and how the NAME calculations are used. In Section 3, the approach is illustrated by
96 comparing model estimates and measurements from one ATTREX 2014 flight. This analysis is then
97 expanded to cover measurements from all ATTREX 2014 and 2013 flights. The role of convection in
98 transporting VSL halocarbons to the TTL is further examined in Section 4. Based on the modelled
99 calculations of CHBr₃ and CH₂Br₂, Section 5 discusses how much these VSL bromocarbons
100 contribute to the bromine budget in the TTL.

101 **2 Methodology**

102 **2.1 Overview of the CAST, CONTRAST and ATTREX campaigns**

103 The joint CAST, CONTRAST and the third stage of the ATTREX campaign took place in January-
104 March 2014, in the West Pacific. Guam (144.5° E, 13.5° N) was used as a research mission centre for
105 these three campaigns. Three aircraft were deployed to measure physical characteristics and
106 chemical composition of tropical air masses from the earth's surface up to the stratosphere. In CAST,
107 the Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 surveyed the boundary
108 layer and lower troposphere (0-8 km) to sample the convection air mass inflow, while in
109 CONTRAST the National Science Foundation - National Center for Atmospheric Research (NSF-
110 NCAR) Gulfstream V (GV) principally targeted the region of maximum convective outflow in the
111 mid- and upper troposphere, and sampled down to the boundary layer on occasion (1-14 km).
112 Finally, in ATTREX, the NASA Global Hawk (GH) sampled the TTL (13-20 km) to cover air
113 masses likely to be detrained from the higher convective outflow. For more details on these
114 campaigns and the objectives, meteorological conditions and descriptions of individual flights,
115 please refer to the campaign summary papers: Harris et al., 2017 (CAST), Pan et al., 2017
116 (CONTRAST) and Jensen et al., 2017 (ATTREX). ATTREX had four active measurement
117 campaigns, and we also consider the second campaign which was based in Los Angeles in January-
118 March 2013 and which extensively sampled the East and Central Pacific TTL in six research flights.

119 **2.2 Measurements of the VSL halocarbons**

120 Whole Air Samplers (WAS) were deployed on all three aircraft to measure VSL halocarbons. The
121 FAAM BAe-146 and NSF-NCAR GV also used on-board gas chromatography-mass spectrometry
122 (GC-MS) system for real-time analysis (Wang et al., 2015; Andrews et al., 2016; Pan et al., 2017),
123 though these measurements are not used in our analysis. WAS instrumentation is well established
124 and has been used routinely in previous deployments. The sampling and analytical procedures are
125 capable of accessing a wide range of mixing ratios at sufficient precision and the measurements from
126 the three aircraft have been shown to be consistent and comparable (Schauffler et al., 1998; Park et
127 al., 2010; Andrews et al., 2016).

128 The CAST VSL halocarbon measurements were made using the standard FAAM WAS canisters
129 with 30 second filling time. Up to 64 samples could be collected on each flight and these were
130 analysed in the aircraft hangar, usually within 72 hours after collection. Two litres of sample air were
131 pre-concentrated using a thermal desorption unit (Markes) and analysed with GC-MS (Agilent 7890
132 GC, 5977 Xtr MSD). Halocarbons were quantified using a NOAA calibration gas standard. The
133 measurement and calibration technique is further described and assessed in Andrews et al. (2013;
134 2016).

135 The ATTREX AWAS sampler consisted of 90 canisters, being fully automated and controlled from
136 the ground. Sample collection for the AWAS samples was determined on a real-time basis depending
137 on the flight plan altitude, geographic location, or other relevant real-time measurements. The filling
138 time for each canister ranged from about 25 seconds at 14 km to 90 seconds at 18 km. Canisters were
139 immediately analysed in the field using a high performance GC-MS coupled with a highly sensitive
140 electron capture detector. The limits of detection are compound-dependent and vary from ppt to sub-
141 ppt scale, set at 0.01 ppt for CHBr_3 , CH_2Br_2 and CH_3I (Navarro et al., 2015). A small artefact of
142 $\sim 0.01\text{-}0.02$ ppt for CH_3I cannot be excluded. AWAS samples collected on the GV were analysed
143 with the same equipment. Detailed comparison of measurements from the three systems found
144 agreement within $\sim 7\%$ for CHBr_3 , $\sim 3\%$ for CH_2Br_2 , and 15% for CH_3I (Andrews et al., 2016).

145 **2.3 UK Meteorological Office NAME Lagrangian Particle Dispersion Model**

146 The Lagrangian particle dispersion model, NAME (Jones, et al., 2007), is used to simulate the
147 transport of air masses in the Pacific troposphere and the TTL. Back trajectories are calculated with
148 particles being moved through the model atmosphere using operational analyses (0.352° longitude
149 and 0.235° latitude, i.e. ~ 25 km, with 31 vertical levels below 19 km) calculated by the
150 Meteorological Office's Unified Model at 3-hour intervals. This is supplemented by a random walk
151 turbulence scheme to represent dispersion by unresolved aspects of the flow (Davies et al., 2005).
152 For this analysis, the NAME model is used with the improved convection scheme (Meneguz and
153 Thomson, 2014) which simulates displacement of particles subject to convective motions more
154 realistically than previously (Meneguz et al., 2019). NAME is run backward in time to determine the
155 origin(s) of air measured at a particular location (WAS sample) along the ATTREX GH flight track.

156 15,000 particles are released from each point along the flight track where VSL halocarbons were
157 measured in WAS samples. To initialise the NAME model, particles are released randomly in a
158 volume with dimensions $0.1^\circ \times 0.1^\circ \times 0.3$ km centred on each sample. As particles are followed 12
159 days back in time, trajectories are filtered on the basis of first crossing into the boundary layer (1
160 km). Subsequently, the fraction of particles which crossed below 1 km is calculated for each WAS
161 measurement point (Ashfold et al., 2012). The NAME 1 km fractions are indicative of the boundary
162 layer air mass influence to the TTL. The 1 km boundary layer fractions are then used to
163 quantitatively estimate the VSL halocarbon contribution to the TTL from the boundary layer,
164 $[X]_{\text{BL_Contribution}}$. In order to compare the measured and modelled halocarbon values, estimates of the
165 contribution from the background troposphere, $[X]_{\text{BG_Contribution}}$ (i.e. air which has not come from the
166 boundary layer within 12 days) are made. The model estimate for the total halocarbon mixing ratio,
167 $[X]_{\text{NAME_TTL}}$, is thus given by Eq. (1):

$$168 \quad [X]_{\text{NAME_TTL}} = [X]_{\text{BL_Contribution}} + [X]_{\text{BG_Contribution}} \quad (1)$$

169 The methods for calculating $[X]_{\text{BL_Contribution}}$ and $[X]_{\text{BG_Contribution}}$ are now described.

170

171 2.3.1 NAME modelled boundary layer contribution

172 The contribution from the boundary layer, ($[X]_{BL_Contribution}$ - described above) to the VSLs in the
173 TTL can be estimated using

- 174 (i) the fractions of trajectories crossing below 1 km in the previous 12 days;
175 (ii) the transport times to the TTL calculated for each particle;
176 (iii) the initial concentration values for CH_3I , $CHBr_3$ and CH_2Br_2 ; and
177 (iv) their atmospheric lifetimes (to account for the photochemical removal along the trajectory).

178 More specifically, the boundary layer contribution to the TTL for the VSL halocarbons is calculated
179 using Eq. (2) and Eq. (3):

$$180 \quad [X]_{BL_Contribution,t} = [X]_{BL} \times fraction_t \times \exp(-t/\tau) \quad (2)$$

$$181 \quad [X]_{BL_Contribution} = \sum([X]_{BL_Contribution,t}) \quad (3)$$

182 Equation (2) gives the boundary layer contribution to the TTL for a given tracer, X (where X could
183 be CH_3I , $CHBr_3$, CH_2Br_2), at model output time step, t. The model output time step used is 6 hours,
184 from t = 0 (particle release) to t = 48 (end of a 12 day run). $[X]_{BL}$ stands for the initial boundary layer
185 concentration of a given tracer - assigned to each particle which crossed below 1 km (Table 1).
186 $Fraction_t$ is a number of particles which first crossed 1 km in a model output time step, t, over a total
187 number of particles released, and $\exp(-t/\tau)$ is a term for the photochemical loss (where τ stands for
188 atmospheric lifetime of a respective VSL halocarbon). Equation (3) gives the boundary layer
189 contribution that is the sum of boundary layer contribution components in all model output time
190 steps (for t = 1 to 48).

191 Equation (2) calculates the decay of each tracer after it leaves the boundary layer (0-1 km) which is
192 valid for a well-mixed boundary layer. Since 15,000 particles are released for each AWAS sample,
193 contributions from each particle from below 1 km in the previous 12 days are summed. Decay times,
194 τ , of 4, 15 and 94 days for CH_3I , $CHBr_3$ and CH_2Br_2 , respectively, are used (i.e. constant chemical
195 loss rate) (Carpenter et al., 2014). Thus, a particle getting to the TTL in 1 day contributes more of a
196 given tracer to that air mass than a particle taking 10 days. Once this chemical loss term was taken
197 into account, the NAME trajectories can be used to calculate the contribution of convection of air
198 masses from the boundary layer within the preceding 12 days.

199 The initial boundary layer concentrations are derived from the CAST and CONTRAST WAS
200 measurements taken in the West Pacific in the same period of January-March 2014 as for the
201 ATTREX measurements in the TTL (Table 1). These observed means are used in model calculations,
202 and the similarity between them and literature values reported in Carpenter et al. (2014) is seen, with
203 lower values for $CHBr_3$ only.

204 2.3.2 NAME modelled background contribution

205 To compare our model results against the AWAS observations, the background contribution,
206 $[X]_{BG_Contribution}$ (meaning the contribution from the fraction of trajectories which do not cross below
207 1 km within 12 days) needs to be accounted for. This requires estimates for the fraction of
208 trajectories from the free troposphere, which is $(1 - fraction_{BL})$, Eq. (4), and an estimate of the
209 halocarbon mixing ratio in that fraction, $[X]_{BG}$, Eq. (5) i.e.

$$210 \quad fraction_{BL} = \sum(fraction_t) \quad (4)$$

$$211 \quad [X]_{BG_Contribution} = (1 - fraction_{BL}) \times [X]_{BG} \quad (5)$$

212 Since each sample has 15,000 back-trajectories associated with it, some of which came from below 1
213 km and some of which did not, a definition as to which air samples are considered as boundary layer
214 and which are considered background is required. Two approaches are tested which use the NAME

215 calculations to identify AWAS samples in all flights (2013 and 2014) with low convective influence
216 by (i) filtering for air masses with boundary layer fraction values less than 1, 5 or 10 %; or (ii)
217 selecting the lowest 10 % of boundary layer fractions. Then, the CH₃I, CHBr₃ and CH₂Br₂ AWAS
218 observations, corresponding to the boundary layer fraction values less than 1, 5 or 10 %, or the
219 lowest 10 % of boundary layer fractions, are averaged to provide CH₃I, CHBr₃ and CH₂Br₂
220 background mixing ratios. These two approaches are explored below (Sect. 3.1.2).

221 **2.3.3 The effect of assuming constant lifetimes**

222 The lifetimes of the halocarbons are not the same in the boundary layer and the TTL (Carpenter et al,
223 2014). The assumption of constant lifetime in a 12 day trajectory is evaluated by calculating the
224 difference between idealised trajectories which had 2, 4, 6, 8, and 10 days in the boundary layer and
225 10, 8, 6, 4, and 2 days in the upper troposphere. Lifetimes for the boundary layer and for the upper
226 troposphere for each gas were taken from Carpenter et al. (2014). (Lifetimes for higher altitudes are
227 not available therein). The difference found between the two extreme cases are 6% (CHBr₃), 3%
228 (CH₂Br₂) and 25% (CH₃I). The assumption is thus valid for the two brominated species.

229 This assumption is more robust than it might seem at first glance. The boundary layer fraction is
230 calculated using 12 day trajectories in which there is little loss of CH₂Br₂ whether a lifetime of 94 or
231 150 days is taken. The most important factor in determining the amount lofted into the TTL is thus
232 the original mixing ratio which is only slightly modulated by the chemical loss in 12 days. The
233 longer lifetime is absorbed implicitly, and taken into account in the background contribution. The
234 same arguments apply for CHBr₃, though the effect is a bit larger. The largest difference is seen for
235 CH₃I. However, the difference matters much less for CH₃I because only 4-5% remains after the full
236 12 days which is much smaller than the uncertainties in this analysis so that much shorter trajectories
237 are used to validate the new convection scheme.
238

239 **3 Analysis of ATTREX 2014 Research Flight 02**

240 We start by showing our results from a single ATTREX 2014 research flight, RF02, to illustrate the
241 method. This is followed by analysing all research flights together for ATTREX 2014 and 2013 in
242 Sect. 4, and calculating the modelled contribution of active bromine from CHBr₃ and CH₂Br₂ to the
243 TTL (Sect. 5).

244 **3.1 Individual ATTREX 2014 Flight: Research Flight 02**

245 Figure 1 shows the vertical distribution of CH₃I, CHBr₃ and CH₂Br₂ in the TTL observed during
246 research flight, RF02, during ATTREX 2014. Held on 16-17 February 2014, RF02 was conducted in
247 a confined area east of Guam (12-14° N, 145-147° E) due to a faulty primary satellite
248 communications system for Global Hawk command and control (Jensen, et al., 2017). Twenty six
249 vertical profiles through TTL were made, with 86 AWAS measurements taken in total. A high
250 degree of variability of CH₃I in the TTL was observed (from > 0.4 ppt at 14-15 km, to near-zero ppt
251 values at 17-18 km). Each profile, in general, showed a gradation in CH₃I distribution in the TTL.
252 Higher values were measured in the lower TTL up to 16 km, with values decreasing with altitude.
253 The same pattern was observed for CHBr₃ and CH₂Br₂, with the highest concentrations measured in
254 the lower TTL (14-15 km), and the lowest at 17-18 km.

255 **3.1.1 NAME modelled boundary layer contribution**

256 Figure 2(a) shows the vertical distribution of the boundary layer air contribution to the TTL
257 (corresponding to the AWAS measurement locations along the RF02 flight track). It reveals higher
258 boundary layer air influence in the lower TTL, decreasing with altitude (similarly to the VSL
259 halocarbon observations). Cumulatively, the highest fractions from below 1 km are found for the
260 lower TTL (14-15 km). A noticeable decrease occurs between the lower and upper TTL (15 to 17

261 km). From 16 km up, little influence (indicated by <10 % and <5 % 1 km fractions of trajectories
262 below 1 km for 16-17 km and 17-18 km, respectively) of the low-level air masses is seen.

263 Figure 2(b) shows all NAME runs for RF02 grouped into four 1 km TTL bins: 14-15 km, 15-16 km,
264 16-17 km and 17-18 km. In the 14-15 km bin, most particles from the low troposphere arrived in the
265 preceding 4 days with many in the preceding 2 days. This represents the fast vertical uplift of the low
266 tropospheric air masses to the lower TTL. At 15-16 km, two particle populations are observed: the
267 first group results from recent vertical uplift, while the second group has been in the upper
268 troposphere for longer than a couple of days (see Fig. 2c in Navarro et al., 2015 for similar example).
269 Above 16 km, the overwhelming majority (>90 %) of the released particles are calculated to be in the
270 TTL for the previous 12 days, with negligible evidence for transport from the low troposphere. This
271 shows the dominance of the long-range, horizontal transport for the 16-17 and 17-18 km NAME runs
272 (also shown in Navarro et al., 2015).

273 Figure 3 shows the locations at which trajectories crossed 1 km, thereby indicating boundary layer
274 source regions for the RF02 TTL air masses. Boundary layer sources in the West and Central Pacific
275 are the most important for the lowest TTL bin (14-15 km, Fig. 3a) in this flight. The Maritime
276 Continent, the Northern Australia coast, the Indian Ocean and the equatorial band of the African
277 continent increase in relative importance as altitude increases, though the overall contribution of
278 recent boundary layer air masses decreases with increasing altitude.

279 Figure 4 shows the NAME modelled boundary layer contribution to the TTL for CH₃I, CHBr₃ and
280 CH₂Br₂ during RF02. It is important to note that this contribution corresponds to uplift from below 1
281 km in the preceding 12 days, the length of the trajectories. The calculated boundary layer
282 contributions for CH₃I, CHBr₃ and CH₂Br₂ from the 1 km fractions are highest at 14-15 km,
283 dropping off with altitude. Almost no boundary layer contribution is found for 17-18 km (with values
284 close to 0 ppt).

285 3.1.2 NAME modelled background contribution

286 Here we explore the two approaches summarised in Sect. 2.3.2 for estimating the CHBr₃ and CH₂Br₂
287 background mixing ratios. Similar values are seen in ATTREX 2013 and 2014. Less variation is
288 observed for CH₂Br₂ due to its longer atmospheric lifetime.

289 ATTREX 2013 and 2014 are treated separately in the analysis presented below due to the difference
290 in CH₃I background estimates. The approach using the lowest 10 % of the boundary layer fractions is
291 used to estimate the background contribution for the 2014 flights as not enough data meet the former
292 condition due to the proximity of the flights to strong convection. The background values, inferred
293 from all the ATTREX 2014 flights, are used in the individual flight calculations as again there are
294 not enough data from an individual flight to make background calculations for that flight. In
295 ATTREX 2013 we use the boundary layer fractions less than 5 % approach for the CH₃I background
296 estimation. The ATTREX 2014 background estimates should be taken as upper limits as it is hard to
297 identify samples with no convective influence in 2014. This is especially true for the lower TTL
298 since the ATTREX 2014 flights were close to the region of strong convection.

299 Figure 5 shows the VSL background mixing ratios calculated for the ATTREX campaigns in 2013
300 and 2014. In ATTREX 2013, low CH₃I background mixing ratios are found. All approaches show
301 similar background mixing ratios. In 2014, higher CH₃I background mixing ratios are calculated due
302 to ubiquity of air from recent, vertical uplift. No boundary layer fractions less than 1 % are found for
303 the 14-17 km bins, and less than 5 % for the 14-15 km.

304 3.1.3 NAME modelled total concentrations

305 The NAME boundary layer and background contribution estimates are added to give an estimate for
306 total halocarbon mixing ratio, [X]_{NAME_TTL}, (Eq. (1)), for comparison with the AWAS observations.

307 Figure 6 and Table 2 show the vertical distribution of NAME-based estimates for CH₃I, CHBr₃ and
308 CH₂Br₂ in the TTL for RF02. The sums of the NAME CH₃I, CHBr₃ and CH₂Br₂ boundary layer and
309 background contribution estimates agree well with the AWAS observations for all the 1 km TTL
310 bins (compared with Fig. 1).

311 At 14-15 km, the modelled boundary layer contribution of CH₃I is similar to the observations,
312 indicating recent, rapid convective uplift. This provides evidence that the improved convection
313 scheme provides a realistic representation of particle displacement via deep convection. At higher
314 altitudes, the background contribution is more important and, indeed, the modelled total CH₃I values
315 are greater than the observations. This overestimate of the background contribution results from the
316 difficulty of identifying samples with no convective influence in ATTREX 2014. This problem is
317 most important for CH₃I with its very short lifetime.

318 CHBr₃ drops off slower with altitude than CH₃I and quicker than CH₂Br₂. At 14-15 km, the
319 boundary layer contribution accounts for ~ 50 % of the modelled sums of CHBr₃ and CH₂Br₂, but
320 less than 5 % for CHBr₃ and CH₂Br₂ at 17-18 km. For the upper TTL, the background contribution
321 estimates constitute over 85 % of the modelled sums, thus taking on more importance.

322

323 **4 The role of transport in the VSL halocarbon distribution in the TTL**

324 The role of transport in the CH₃I, CHBr₃ and CH₂Br₂ distribution in the TTL is examined in this
325 section by applying the NAME based analysis introduced in Sect. 3 to all CH₃I, CHBr₃ and CH₂Br₂
326 AWAS observations in the ATTREX 2013 and 2014 campaigns.

327 In ATTREX 2013, six flights surveyed the East Pacific TTL in February-March 2013. Four flights
328 went west from Dryden Flight Research Centre to the area south of Hawaii, reaching 180° longitude.
329 Little influence of convective activity was observed. Most samples with strong boundary layer
330 influence were observed in air masses that had originated over the West Pacific and the Maritime
331 Continent, where it was uplifted to the TTL and transported horizontally within the TTL (Navarro et
332 al., 2015). Two flights sampled the TTL near the Central and South American coast. Few convective
333 episodes were observed. The sampled air had predominantly a small boundary layer air signature
334 from the West Pacific and the Maritime Continent.

335 In ATTREX 2014, two transit flights and six research flights were made in the West Pacific in
336 January-February 2014. This period coincided with the active phase of Madden-Julian Oscillation
337 (MJO) and increased activity of tropical cyclones. A large influence of recent convective events is
338 observed (Navarro et al., 2015), reflected in the elevated CH₃I and CHBr₃ mixing ratios and the high
339 values of NAME fractions of trajectories below 1 km. All three aircraft flew together in 2014 and so
340 there is a more complete set of measurements from the ground up. Accordingly, this year is
341 discussed first.

342 **4.1 VSL halocarbon distribution in the TTL: ATTREX 2014**

343 Figure 7 shows the vertical distribution of the observations and of the modelled boundary layer
344 contribution and total mixing ratios for CH₃I, CHBr₃ and CH₂Br₂ for all the ATTREX 2014 flights
345 (using only the AWAS measurements made from 20° N southward). As in RF02, CH₃I is highest in
346 the lower TTL, dropping off with altitude. Large flight-to-flight variability in CH₃I measurements is
347 seen. The fraction of NAME particles that travel below 1 km in the previous 12 days (Table 3) are
348 highest at 14-15 km (mean of 57 %) and decrease with altitude in a similar fashion. The CH₃I
349 boundary layer contribution explains most of the observations for the 14-15 and 15-16 km layers.
350 Disparities in observed and modelled CH₃I arise from 16 km up. Estimated background values are
351 very low, oscillating between 0 and the limit of detection of the AWAS instrument for the iodinated
352 short-lived organic substances, 0.01 ppt. The sums of the CH₃I boundary layer and background

353 contribution estimates show good agreement with AWAS observations for all the TTL 1 km
354 segments (Table 3).

355 The good agreement for the 14-15 km and 15-16 km layers can be attributed to the improved
356 representation of deep convection in NAME, provided by the new convection scheme (Meneguz et
357 al., 2019). However, there is an underestimation of the boundary layer contribution to the upper TTL
358 levels (16-17 and 17-18 km) which we attribute to the new convection scheme not working as well at
359 these altitudes. This is consistent with a known tendency of the Unified Model to underestimate the
360 depth of deepest convection in the tropics (Walters, et al., 2019). Both the CH₃I AWAS observations
361 and the modelled sums are higher than reported previously in the literature (Carpenter et al., 2014)
362 for all the TTL segments. This may be explained by sampling the TTL in a region of high convective
363 activity. This result gives confidence in the quality of the new convection scheme and hence in
364 similar calculations of convective influence on the longer-lived CHBr₃ and CH₂Br₂.

365 The highest CHBr₃ and CH₂Br₂ concentrations were observed in the lower TTL (14-15 km),
366 dropping off more slowly with altitude than CH₃I. The weight of the modelled boundary layer
367 contribution estimates to the modelled total amounts varies from approximately 50% at 14-15 km
368 (unlike for CH₃I where over 85 % of the modelled sum is attributed to the boundary layer
369 contribution at 14-15 km) to < 20% at 17-18 km. The sums of the modelled boundary layer and
370 background contributions are in good agreement with the CHBr₃ and CH₂Br₂ AWAS observations.
371 The ATTREX observations and the NAME modelled sums are within the range of values reported in
372 the literature (Carpenter et al., 2014).

373 **4.2 VSL halocarbon distribution in the TTL: ATTREX 2013**

374 Figure 8 shows the vertical distribution for CH₃I, CHBr₃ and CH₂Br₂ in the TTL, observed and
375 modelled from the ATTREX 2013 flights. Only AWAS measurements taken south of 20°N are used.
376 Much lower CH₃I values are found in 2013 than in 2014 (Fig. 7). The NAME 1 km fractions are
377 considerably lower (~fourfold), and the corresponding CH₃I boundary layer contribution shows
378 values close to the limit of detection of the AWAS instrument for CH₃I. The background
379 contribution comprises over 85-90 % of the sums of the modelled CH₃I estimate in the TTL. Good
380 agreement is found between the AWAS observations and the sum of the modelled boundary layer
381 and background contributions. Both the observed and modelled values are in the low end of the CH₃I
382 concentrations reported by the WMO 2014 Ozone Assessment (Carpenter et al., 2014).

383 The ATTREX 2013 mixing ratios are lower for CHBr₃ and higher CH₂Br₂ than shown in Fig. 7 for
384 2014. The NAME calculated CHBr₃ and CH₂Br₂ boundary layer contributions are small, constituting
385 approximately 10 % of the NAME modelled sums for 14-15 km, and less for the upper TTL
386 segments. The background contribution estimates comprise over 85 % of the modelled sums. Good
387 agreement is found between the sums of the modelled boundary layer and background contributions
388 and the CHBr₃ and CH₂Br₂ AWAS observations.

389 **4.3 ATTREX 2013 and 2014: Inter-campaign comparison**

390 Clear differences in the vertical distributions of CH₃I in the TTL are found in ATTREX 2013 and
391 2014. CH₃I estimates, corresponding to high values in the NAME modelled 1 km fractions, are high
392 in 2014, whereas in 2013 almost no CH₃I is estimated to be in the TTL. This is due to the minimal
393 contribution of the boundary layer air within the previous 12 days: ATTREX 2013 was in the East
394 Pacific away from the main region of strong convection. Longer transport timescales result from
395 horizontal transport and were more important in ATTREX 2013, with much less recent convective
396 influence than in ATTREX 2014. More chemical removal of CH₃I and CHBr₃ thus took place,
397 leading to lower concentrations in the East Pacific TTL.

398 The trajectories are analysed to investigate the timescales for vertical transport by calculating how
399 long it took particles to go from below 1 km to the TTL. In 2013, almost no episodes of recent rapid
400 vertical uplift are found, with most particles taking 8 days and more to cross the 1 km. This is

401 indicative of the dominant role of long-range horizontal transport. In 2014, by way of contrast, a
402 considerable number of trajectories (10's of per cent) come from below 1 km in less than 4 days,
403 representing the 'young' air masses being brought from the low troposphere via recent and rapid
404 vertical uplift.

405 The spatial variability in the boundary layer mixing ratios corresponding to different source strengths
406 coupled with the variation in atmospheric transport pathways and transport timescales can explain
407 the differences in the distribution of the NAME 1 km fractions in the TTL. In 2014 (2013), higher
408 (lower) boundary layer fractions corresponded well with higher (lower) CH₃I and CHBr₃ values in
409 the TTL, especially with the highest concentrations occurring for the flights with the most convective
410 influence and the highest fractions of particles arriving within the 4 days.

411 In 2014, the western and central Pacific is the dominant source origin of boundary layer air to the
412 TTL (Navarro et al., 2015). Increased tropical cyclone activity in this area (particularly Faxai 28
413 February – 6 March 2014 and Lusi 7-17 March 2014) and the strong signal from the Madden Julian
414 Oscillation (MJO - an intraseasonal phenomenon characterised by an eastward spread of large
415 regions of enhanced and suppressed tropical rainfall, mainly observed over the Indian and Pacific
416 Ocean) related convection contributed to the more frequent episodes of strong and rapid vertical
417 uplifts of the low-level air to the TTL. A significant contribution is also seen from the central Indian
418 Ocean, marking the activity of the Fobane tropical cyclone (6-14 February 2014). Minimal
419 contribution from the other remote sources (Indian Ocean, African continental tropical band) is
420 found (Anderson et al., 2016; Jensen et al., 2017; Newton et al., 2018).

421 **5 How much do VSL bromocarbons contribute to the bromine budget in the TTL?**

422 The NAME modelled CHBr₃ and CH₂Br₂ estimates in the TTL are used to calculate how much
423 bromine from the VSL bromocarbons, Br-VSL_{org}, is found in the lower stratosphere, based on how
424 much enters the TTL in the form of bromocarbons (Navarro et al. (2015)). CHBr₃ and CH₂Br₂ are
425 the dominant short-lived organic bromocarbons, and the minor bromocarbons: CH₂BrCl, CHBr₂Cl
426 and CHBrCl₂ are excluded here (their combined contribution is less than 1 ppt to Br-VSL_{org} at 14-18
427 km, Navarro et al., 2015). The NAME modelled CHBr₃ and CH₂Br₂ estimates are multiplied by the
428 number of bromine atoms (bromine atomicity), and then summed to yield the total of Br-VSL_{org}.

429 Figure 9 shows the contribution of CHBr₃ and CH₂Br₂, the two major VSL bromocarbons
430 contributing to the bromine budget in the TTL. For ATTREX 2013 and 2014, similar contributions
431 of CHBr₃ and CH₂Br₂ to Br-VSL_{org} are found in the lower TTL. In 2014, CHBr₃ in the lower TTL
432 was abundant enough to contribute as much Br-VSL_{org} as CH₂Br₂. A combination of larger boundary
433 layer air influence in the TTL and shorter mean transport times to reach the TTL result in the
434 observed higher CHBr₃ contribution to the Br-VSL_{org} in the lower TTL in 2014, than in 2013. The
435 CH₂Br₂ contribution dominates in the upper TTL due to its longer atmospheric lifetime.

436 Good agreement is found between the bromine loading from the VSL bromocarbons, inferred from
437 the NAME modelled estimates initialised with BAe-146 and GV measurements, and the Global
438 Hawk AWAS observations. Higher organic bromine loading is seen around the cold point tropopause
439 (16-17 km) in ATTREX 2014.

440 Using the upper troposphere measurements taken during the SHIVA campaign in the western Pacific
441 in November-December 2011, Sala et al. (2014) calculated an estimate for VSLs (CHBr₃, CH₂Br₂,
442 CHBrCl₂, CH₂BrCl, CHBr₂Cl) contribution to the organic bromine at the level of zero radiative
443 heating (15.0 - 15.6 km). Air masses reaching this level are expected to reach the stratosphere. This
444 VSLs mean mixing ratio estimate of 2.88 (+/- 0.29) ppt (2.35 ppt for CHBr₃ and CH₂Br₂, excluding
445 minor short-lived bromocarbons) is lower due to a lower contribution from CHBr₃ estimate (0.22 ppt
446 compared to the CHBr₃ estimate for NAME / ATTREX in Table 5). Our estimates of the
447 contribution of CHBr₃ and CH₂Br₂ to the organic bromine at the LZRH are slightly higher largely
448 than those in Sala et al. (2014) due to a higher estimate for a shorter-lived CHBr₃.

449 Several papers use the same measurements from the combined ATTREX/CAST/CONTRAST
450 campaign in 2014 and from the other ATTREX phases. Navarro et al. (2015) report slightly higher
451 bromine loading from the Br-VSL_{org} at the tropopause level (17 km) in the West Pacific, 2014 than
452 in the East Pacific, 2013 (the Br-VSL_{org} values from the AWAS observations were of 3.27 (+/-0.47)
453 and 2.96 (+/-0.42) ppt, respectively). The minor short-lived organic bromine substances were
454 included in the analysis of Navarro et al. (2015), accounting for the higher Br-VSL_{org}. Butler et al.
455 (2018), report a mean mole fraction and range of 0.46 (0.13-0.72) ppt and 0.88 (0.71-1.01) ppt of
456 CHBr₃ and CH₂Br₂ being transported to the TTL during January and February 2014. This is
457 consistent with a contribution of 3.14 (1.81-4.18) ppt of organic bromine to the TTL over the region
458 of the campaign. The analysis of the injection of brominated VSLs into the TTL by Wales et al.
459 (2018) using the CAM-chem-SD model combined with a steady state photochemical box model and
460 CONTRAST and ATTREX data found that 2.9 +/- 0.6 ppt of bromine enters the stratosphere via
461 organic source gas injection of VSLs. The NAME modelled results presented here (Fig. 9, Table 5)
462 are thus in good agreement with the values reported by Navarro et al. (2015), Butler et al. (2018) and
463 Wales et.al. (2018).

464

465 **6 Summary and Discussion**

466 We have used the NAME trajectory model in backward mode to assess the contribution of recent
467 convection to the mixing ratios of three short-lived halocarbons, CH₃I, CHBr₃ and CH₂Br₂. 15,000
468 back-trajectories are computed for each measurement made with the whole air samples on the NASA
469 Global Hawk in ATTREX 2013 and 2014, and the fraction that originated below 1 km is calculated
470 for each sample. A steep drop-off in this fraction is observed between 14-15 km and 17-18 km. Low
471 level measurements of CH₃I, CHBr₃ and CH₂Br₂ from the FAAM BAe-146 and the NCAR GV are
472 used in conjunction with these trajectories and an assumed photochemical decay time to provide
473 estimates of the amount of each gas reaching the TTL from below 1 km. Comparison of these
474 modelled estimates with the CH₃I measurements shows good agreement with the observations at the
475 lower altitudes in the TTL values, with less good agreement at altitudes > 16 km, though it should be
476 noted that the amounts are very small here. The lifetime of CH₃I is 3-5 days, and so there is a > 90 %
477 decay in the 12 day trajectories. The comparison between the modelled and measured CH₃I thus
478 indicates that the NAME convection scheme is realistic up to the lower TTL but less good at
479 reproducing the small number of extreme convective events that penetrate to the upper TTL.

480 In order to perform similar calculations for the longer-lived bromocarbons, an estimate of the
481 background free tropospheric concentration is required. This is found by considering bromocarbon
482 values in samples where there was only a small influence from the boundary layer, i.e. where very
483 few NAME trajectories passed below 1 km. This is possible in 2013 when the ATTREX flights were
484 away from the region of strong convection, but much harder in 2014 when (as planned!) the flights
485 were heavily influenced by convection. By summing the boundary layer and background
486 contributions, an estimate of the total bromocarbon mixing ratio is obtained.

487 The resulting modelled estimates are found to be in generally good agreement with the ATTREX
488 measurements. In other words, a high degree of consistency is found between the low altitude
489 halocarbon measurements made on the BAe-146 and GV and the high altitude measurements made
490 on the Global Hawk when they are connected using trajectories calculated by the NAME dispersion
491 model with its updated convection scheme and driven by meteorological analyses with 25 km
492 horizontal resolution. There are some indications of the modelled convection not always reaching
493 quite high enough, but this is consistent with a known tendency of the Unified Model to
494 underestimate the depth of the deepest convection in the tropics.

495 The resolved winds are likely to be well represented, at least partly because the wind data is analysis
496 rather than forecast data. Hence we expect the main errors in the modelling to arise from the
497 representation of convection. Individual convective events are hard to model and can have significant

498 errors. However because the upper troposphere concentrations depend on a number of convective
499 events and we are considering a range of flights and measurement locations, our conclusions on
500 general behaviour should be robust. The consistency between the aircraft measurements and the
501 NAME simulations supports this.

502 In the above, the boundary layer contribution arises from trajectories which visit the boundary layer
503 within 12 days while the background contribution involves air that has been transported into the TTL
504 from outside the boundary layer on timescales up to 12 days. Sensitivity tests were performed in
505 which the trajectories were followed for longer than 12 days: the effect was to re-allocate some of
506 the air from the background category into the boundary layer contribution with no net change in the
507 total.

508 The approach using NAME trajectories and boundary layer measurements produces Br-VSL_{org}
509 estimates of 3.5 +/- 0.4 (3.3 +/- 0.4) ppt in the lower East (West) Pacific TTL (14-15 km) and 2.5 +/-
510 0.2 (2.4 +/-0.4) ppt in the upper East (West) Pacific TTL (17-18 km). These lie within the range of
511 the recent literature findings (Tegtmeier et al., 2012; Carpenter et al., 2014; Liang et al., 2014;
512 Navarro et al., 2015; Butler et al., 2017; Wales et al. 2018). The validation with the ATTREX
513 measurements provides confidence that a similar approach could be used for years when high
514 altitude measurements are not available assuming that realistic estimates of the background
515 tropospheric contributions can be obtained from either models or measurements.

516 Our study of boundary layer contribution of bromoform and dibromomethane into the TTL in the
517 West Pacific, using a combined approach of NAME Lagrangian dispersion modelling and CAST,
518 CONTRAST and ATTREX 2014 measurements, has successfully validated an updated convection
519 scheme for use with the NAME trajectory model. The previous parameterisation scheme was
520 reasonable for convection at mid-latitudes but was far too weak to represent the stronger tropical
521 convection. Comparison with the extensive CH₃I measurements made in this campaign provides
522 good support for its use in modelling transport in tropical convective systems. (New scheme:
523 [https://www.harmo.org/conferences/proceedings/ Madrid/publishedSections/H15-29.pdf](https://www.harmo.org/conferences/proceedings/Madrid/publishedSections/H15-29.pdf) - please
524 note the full paper is accessible upon request – contact Dr David Thomson from the UK Met Office,
525 Atmospheric Dispersion and Air Quality Unit).

526 This represents a considerable improvement on the earlier study by Ashfold et al. (2012) which used
527 the old convection scheme and found reasonable agreement up to and including the level of
528 maximum convective outflow, but not above, when compared to measurements in the East Pacific
529 from CR-AVE and TC4. The approach used by Ashfold et al. (2012) has been further extended so
530 that VSLs mixing ratios can be assigned to contributions from the boundary layer and from the
531 ‘background’ TTL.

532

533 **7 Data availability**

534 The CH₃I, CHBr₃ and CH₂Br₂ AWAS data from the NASA ATTREX measurements are available
535 online in the NASA ATTREX database (<https://espoarchive.nasa.gov/archive/browse/attrex>). The
536 CAST measurements are stored on the British Atmospheric Data Centre, which is part of the Centre
537 for Environmental Data archive at
538 <http://catalogue.ceda.ac.uk/uuid/565b6bb5a0535b438ad2fae4c852e1b3>. The CONTRAST AWAS
539 data are available through <http://catalog.eol.ucar.edu/contrast>. The NAME data are available from
540 the corresponding author upon request.

541

542 **8 Author Contribution**

543 The main part of the analysis was conducted by MF. EA and MN provided CH₃I, CHBr₃ and CH₂Br₂
544 AWAS measurements from the ATTREX and CONTRAST research flights. SA and LC provided
545 CH₃I, CHBr₃ and CH₂Br₂ measurements from the CAST campaign. MA designed initial scripts for
546 NAME runs and products. EM and DT developed the model code for improved convection scheme.
547 MF and NH prepared the manuscript with contributions from all co-authors, NH also supervised this
548 PhD work.

549

550 **9 Acknowledgements**

551 The authors would like to thank our NASA ATTREX, NCAR CONTRAST and NERC CAST
552 project partners and the technical teams. MF would like to thank Drs Michelle Cain, Alex Archibald,
553 Sarah Connors, Maria Russo and Paul Griffiths for their input on the NAME applications for flight
554 planning and post-flight modelling. The research was funded through the UK Natural Environment
555 Research Council CAST project (NE/J006246/1 and NE/J00619X/1), and MF was supported by a
556 NERC PhD studentship. EA acknowledges support from NASA grants NNX17AE43G,
557 NNX13AH20G and NNX10AOB3A. We acknowledge use of the NAME atmospheric dispersion
558 model and associated NWP meteorological datasets made available to us by the UK Met Office.

Table 2. ATTREX 2014 Research Flight 02: AWAS observations, modelled boundary layer contribution, the modelled total mixing ratios for CH₃I, CHBr₃ and CH₂Br₂. The boundary layer and background fractions means and standard deviations (in brackets) are given based on the measurements and modelled values for the samples collected during the flight.

Altitude [km]	AWAS [ppt]	Modelled Boundary Layer Contribution [ppt]	Modelled Total Mixing Ratio [ppt]
CH₃I			
17-18	0.06 (0.02)	0.00 (0.00)	0.06 (0.02)
16-17	0.09 (0.03)	0.00 (0.00)	0.06 (0.02)
15-16	0.17 (0.03)	0.04 (0.04)	0.12 (0.06)

832

Figure 3: Crossing location distribution maps for all the NAME runs released from 4 1 km TTL altitudes: 14-18 km. Strong influence of local boundary air is noted for a 14-15 km segment (lower TTL), whereas the boundary air from remote locations dominates for a 17-18 km segment (upper TTL), research flight 02, ATTREX 2014.

833
834

Figure 9: Contribution of CHBr_3 (star symbol) and CH_2Br_2 (square symbol) to the bromine budget in the TTL, inferred from the NAME modelled estimates (left) and AWAS observations (right); separately ATTREX 2014 (red) and 2013 (blue). Star and square symbols represent the bromine atomicity products from CHBr_3 and CH_2Br_2 , respectively. Diamonds show the bromine contribution from the VSL bromocarbons in the TTL (as a sum of the CHBr_3 and CH_2Br_2 bromine atomicity products).
