

## RESPONSES to comments of Anonymous Referee #1

This work is an attempt to constrain the BC emissions at high northern latitudes starting from four different inventories and applying a Bayesian inversion to the model Flexpart. The choices of emission inventories, of the surface stations and of ancillary BC data to independently optimize BC emissions are well explained. Additional information is gained through varying below-cloud and in-cloud scavenging to adapt BC-like tracers that are used to improve the a-posteriori BC concentrations simulated by Flexpart. This paper is well structured, the approach is interesting and the results are pertinent. I suggest that it can be published after several improvements to the wording that are outlined below. I also have a few suggestions for reinforcing the discussion.

**RESPONSE: We would like to acknowledge reviewer for his positive comments on our paper and his kind willingness to help improving this manuscript. We have tried to follow all of his suggestions.**

Lines 314-315 page 11: “The different scavenging coefficients used did not create a large variation in the monthly concentrations of BC. The best performance for the majority of the stations examined and most months was obtained for species 1, 2 and 10 (see Table 2).” This is a rather surprising result since wet scavenging is the main global sink for BC. Does that indicate that dry deposition is an important process for removing BC at high northern latitude, in that case why didn't the authors vary the efficiency of dry scavenging as well as wet scavenging? This aspect deserves several sentences in order to develop why the authors obtained such quantitative result.

**RESPONSE: The reviewer has a good point in his comment. However, still dry deposition is only 20% of the total as in most global models.**

**The small variability stems from the small perturbation of the wet scavenging parameters. When changing scavenging parameters of BC, except for conducting a sensitivity analysis and estimate uncertainty, our top priority was to select the best representative species for BC, hence scavenging coefficients should be realistic. This resulted in the aforementioned small variability. Of course, if we change these parameters drastically, the variability will increase, but then we do not have realistic values anymore. We have now tried to clarify this in the text (please check manuscript with Track Changes).**

Figure 7 shows that vertical profiles can be optimized by the Bayesian approach. Schwartz et al. (2013) illustrate well that modelled BC concentrations profiles are systematically overestimated in the mid- to high- troposphere over the remote Pacific. The biases are much less pronounced over source regions. What can be learned from this work about improving the model performances over remote regions?

**RESPONSE: The Bayesian approach forces emissions mathematically, in order to better match observations. Like we explain in section 3.4, the comparison to observations included in the inversion is not a sufficient indicator of the inversion's performance, as the inversion is designed to reduce the model-observation mismatches. The magnitude of the posterior reduction of the model mismatch to the observations is partly determined by the weighting given to the observations relative to the prior emissions. A much better performance indicator is the comparison of the posterior concentrations with observations that were not included in the inversion (independent observations).**

For this reason, we have chosen to compare our posterior emissions with profiles from the ACCACIA campaign, which were not included in the inversion, and they were available in public for year 2013. We did exactly the same for years 2014 and 2015. So, the use of these profiles was for validation only.

Now, likewise in Schwartz et al. (2013) paper, our model overestimates up to 3 times concentrations of BC at lower altitudes, while this overestimation becomes more intense at higher altitudes. What we claim in the paper is that the observed model overestimation decreases drastically when using the resulting a posteriori emissions that were calculated from our Bayesian inversion framework (based on ground-based measurements).

In the abstract, I recommend that the authors substitute “posterior emissions” with “a-posteriori emission estimates” since at this stage the reader does not know what “posterior emissions” refers to.

**RESPONSE:** We very well agree and have corrected the manuscript (see manuscript with Track Changes).

Reference: Schwarz JP, Samset BH, Perring AE, et al. Global-scale seasonally resolved black carbon vertical profiles over the Pacific. *Geophysical Research Letters*. 2013;40(20):5542-5547. doi:10.1002/2013GL057775.

Minor comments:

Page 10, line 265: NSD was never defined before, I assume it refers to ‘Normalized Standard Deviation’ but the reader should not have to guess.

**RESPONSE:** We appreciate for this comment. We also noticed that nRMSE is not defined in the same paragraph. We have now corrected both (see manuscript with Track Changes).

Page 12, lines 334 & 337: the stations BOS (Bösel) and WLD (Whaldof) are discussed but not shown in Fig. S3

**RESPONSE:** As shown in Table 1, 17, 13 and 24 stations with continuous measurements were used for 2013, 2014 and 2015, respectively. It is not possible to show the results for all of them. Therefore we decided to show the northernmost stations. However, if we only comment on what we show, we are only telling half of the truth. Specifically, commenting on what it is shown only would result on missing a very important statement that all prior emission datasets failed to reproduce the observations in central Europe during all years studied (2013, 2014 and 2015) implying either missing sources or highly uncertain measurements (end of second paragraph of section 3.2).

Page 12, line 343: change “by 23% at maximum” to “by a maximum of 23%”

**RESPONSE:** Corrected (see manuscript with Track Changes).

Page 12, lines 344-353: change: “NMSE values calculated for each of the four emission inventories were very low at the majority of the stations for which data existed in all the years of study (ZEP, SUM, TIK, BAR, MEL and LEI), when ECLIPSEv5 emissions were used, while at PAL all emission datasets performed well (Figure 5). At most of the Arctic stations, the simulations using ECLIPSEv5 reproduced the observations better

compared to the other inventories examined. This shows that the most appropriate emission dataset for our purpose is the ECLIPSEv5 inventory, as it is the only one that can capture the characteristically elevated concentrations of BC in the Arctic, which persist until spring, and are caused by anthropogenic emissions (Law and Stohl, 2007). A significant deficiency is found for TIK for reasons that were explained earlier (see section 3.1).” to “Normalized mean square error values calculated for each of the four emission inventories were very low at the majority of the stations for which data existed in all the years of study (ZEP, SUM, TIK, BAR, MEL and LEI), when ECLIPSEv5 emissions were used. In contrast, at PAL all emission datasets performed well (Figure 5). The observations of BC concentrations at Arctic stations were better reproduced in simulations using the ECLIPSEv5 than with any other inventories examined. Law and Stohl (2007) have documented that these elevated BC concentrations are caused by anthropogenic emissions. Black carbon concentrations at TIK are not well simulated for reasons given in section 3.1.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

Page 13, lines 366-367: change “Table 3 reports annual prior and posterior emissions of BC for different regions and 367 average emissions for the period 2013–2015.” To “Table 3 reports annual prior, posterior, and averaged over 2013-2015, BC emissions for different regions.”

**RESPONSE:** We have also corrected this sentence (please see manuscript with Track Changes).

Page 13, line 371 and everywhere in the remaining text: change “emissions of BC” to “BC emissions”.

**RESPONSE:** We have corrected the expression from page 13 onwards. To keep a level of diversity in the manuscript, we have kept the expression as it was before (“emissions of BC”) in the titles of sections and in the legends of figures (please see manuscript with Track Changes).

Page 14, line 410-411: change “The relative uncertainty of the inversion averaged over the period 2013 to 2015 was estimated to be 30%.” To “Averaged over the period 2013-2015, the relative uncertainty of the inversion was estimated to be 30%.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

Page 15, lines 458-460: change “In the same figures the differences between posterior and prior emissions (ECLIPSEv5) are shown (right panels) to indicate the biggest emission changes compared to the a priori dataset.” to “The right panel of the same figures shows the differences between posterior and prior emissions (ECLIPSEv5) and highlights the biggest emission changes compared to the a priori dataset.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

Page 16, line 464: change “... was seen in 60°N- 135°W” to “was located at 60°N, 135° W”.

**RESPONSE:** Corrected (see manuscript with Track Changes).

Page 16, lines 474-476: change “In this region four uranium mines are located that use diesel generators, diesel trucks, and likely also other diesel-powered machinery.” to “Uranium mines are located in this region. These mines use diesel generators, diesel trucks, and other diesel-powered machinery.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

Page 18, lines 544-545: change “By separating the inversion domain into continental regions, it is easily seen where biomass burning is important.” to “Separating the inversion domain into continental regions reveals where biomass burning is important.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

Page 18, line 550: change “. . . largest peak was already in April. . .” to “. . .larges peak appears in April. . .”

**RESPONSE:** Corrected (see manuscript with Track Changes).

Page 19, line 563-565: change “We performed a sensitivity study to assess the best representative species for BC in terms of scavenging and removal and the best representative emission inventory to be used as the prior information for our inversion.” to “We performed a sensitivity study to assess the best representative species for BC according to the efficiency of in-cloud and below-cloud scavenging, and the best representative emission inventory to be used as the prior information for our inversion.”

**RESPONSE:** Corrected according to reviewer’s suggestion (see manuscript with Track Changes).

## RESPONSES to comments of Anonymous Referee #2

This work by Evangeliou et al. performed a Bayesian inverse analysis of BC emission fluxes at northern high latitudes using ground-based observations and a Lagrangian particle model. The authors accounted for the uncertainties associated with BC wet removal with simulations using a range of scavenging parameters and prior emissions. The inversion found high BC emissions from gas flaring in Russia and Canada. The inversion also found that retrieved emission seasonality is different from that in emission inventory in N. America, N. Europe and N.Siberia. The topic is interesting and the paper is overall well organized but the method description still needs some clarification.

I support the publication of the paper if the following major comments are addressed.

**RESPONSE:** We would like to acknowledge reviewer's attempt to help improving this paper. We have tried to correct and answer his comments.

### Major comments

The paper lacks sufficient description about the specification of error covariance matrices, B and R, which are useful for readers to evaluate the validity of the inversion method.

**RESPONSE:** The diagonal elements of B (the variances) are the squares of the uncertainties of each grid cell where the uncertainties are calculated as a fraction of the total prior emission estimate with a lower limit. For R, normally this is a diagonal matrix (it only has off-diagonal elements if one uses the calculation of aggregation error). The diagonal elements of R are calculated as the quadratic sum of the observation, aggregation and background uncertainties. In our case we had zero for the background uncertainty (zero background for BC).

Details and specifications of the error covariance matrices can be found in Thompson and Stohl (2014). Prior to publication of this manuscript in ACPD, we were asked many times to change the methodology of the manuscript, in order to pass the similarity test. Therefore, we were encouraged to omit many methodological details that can be found in the aforementioned paper.

Thompson, R. L. and Stohl, A.: FLEXINVERT: an atmospheric Bayesian inversion framework for determining surface fluxes of trace species using an optimized grid, *Geosci. Model Dev.*, 7, 2223-2242, <https://doi.org/10.5194/gmd-7-2223-2014>, 2014.

How large is the observation errors and prior errors? Are they assumed to have any spatial/temporal correlations? Are model errors considered in R?

**RESPONSE:** As described in Thompson and Stohl (2014) paper the inversion code treats observation error in two ways. Either one can assign a constant observation error or take observation error directly from the continuous measurements. We have chosen the second option, because we think that observation errors that have been given by the instruments are far more realistic.

As described in the paper released for the ECLIPSE emissions by Klimont et al. (2017), there are different types of uncertainties in ECLIPSE that stem from the way that each calculation has been made. For example for residential combustion, there are uncertainties in assumptions about heat value of various biofuels. For emissions from waste burning large uncertainties are attributed to only scarce measurements and

difficulties in finding reliable data on waste collection, recycling, and disposal rates. Large uncertainties exist in fuel consumption, its allocation between uses and technologies, and emission factors. Several other sources of uncertainty are also mentioned in Klimont et al. (2017) paper. This makes impossible to estimate a fixed uncertainty of the prior. We have used a minimum and maximum error. Then the prior error is calculated as a fraction of the maximum value of each pixel and its 8 surrounding ones, and then sets ocean pixels to the minimum value (see previous comment and info in Thompson and Stohl, 2014).

Error covariance matrix B has spatial and temporal correlations (off-diagonal elements). About the model errors, these are represented by the ensemble of runs that we have performed. Each member of the ensemble has different scavenging settings, so the range of results from our ensemble represents the range due to the uncertainty in the scavenging settings, which in our case is the largest model error.

Klimont, Z., Kupiainen, K., Heyes, C., Purohit, P., Cofala, J., Rafaj, P., Borken-Kleefeld, J., and Schöpp, W.: Global anthropogenic emissions of particulate matter including black carbon, *Atmos. Chem. Phys.*, 17, 8681-8723, <https://doi.org/10.5194/acp-17-8681-2017>, 2017.

Also, I find the method description a little confusion. In Line 191, the authors claim that they conduct “ensemble of inversions” and conduct “the inversion for BC represented by 12 different scavenging coefficients and for four different prior emission datasets. However, in Line 358, “the posterior emissions were calculated for the best performing species and best prior emission inventory”. So, what are the results of “ensemble of inversions” used for? Are they used in Section 3.1 and 3.2 (The text of these two sections does not mention inversion. I assume that these are results from forward model simulations rather than inversion)? Or are they used for uncertainty estimation? If so, authors need to describe in the Method section how to compute the final uncertainty value from the ensemble inversions.

**RESPONSE:** We have changed “the posterior emissions were calculated for ...” with “the posterior emissions are presented for ...”. We present the results of posterior BC emissions for the best representative species and the best prior dataset. We use all inversion BC emissions (using 12 BC species and 4 prior datasets) to calculate uncertainty, as stated in the next sentences clearly. Describing how the model ensemble was used is just 1-2 sentences and, given that it would stand as a separate section in the methodology, we have decided to simply mention it in the Abstract, in the last sentence of Introduction and describe it in section 3.3.

The authors show that different wet removal parameters have little impact on simulated BC, which is interesting. But the authors can provide more information for readers to better evaluate this conclusion. (1) how BC aging and its hydrophilic/hydrophobic state is considered in the model? What is the uncertainty associated with this process? (2) what is the size of emitted BC, whether the size changes during transport, and is the simulation sensitive to the assumption of BC size? (3) are there evidence to support that the choices of parameter in Table 2 is adequate? (Grythe 2017 tested a larger ranges of parameters).

**RESPONSE:** (1) This has been already explained well in Grythe et al. paper referring to FLEXPART model. The level of detail of aerosol removal schemes in Lagrangian models is a limiting factor due to the Lagrangian model framework. A main consideration within

this framework is that each transported computational particle is independent of others. Extensions of this concept to allow for non-linear chemistry exist or FLEXPART (Cassiani, 2013), but the reference version of FLEXPART is a purely linear transport model. Within such a linear model, it is impossible to include aerosol processes, which depend on the aerosol concentration (e.g., coagulation or non-linear chemical reactions). Furthermore, to facilitate consistency between forward and backward runs of FLEXPART, parameterizations that depend on the age of the aerosol (i.e. time after emission for primary aerosols) should be avoided as well. This limits the level of sophistication that can be incorporated into an aerosol removal scheme. Nevertheless, a realistic treatment of aerosols is possible even with these limitations.

In other words, the aerosol ageing processes are not readily included in FLEXPART and the constant removal parameters cannot account for this transformation. However, this may not cause significant uncertainties as there are several observations that prove that BC is transformed very quickly into particles with aged, hydrophylic characteristics (e.g. Wittbom et al., 2014).

(2) In section 2.2 we state that we have used a logarithmic size distribution with an aerodynamic mean diameter of 0.25  $\mu\text{m}$ , a logarithmic standard deviation of 0.3 and a particle density of 1500  $\text{kg m}^{-3}$ . We also give a reference (Long et al., 2013). The reference explains very well the morphology and size of BC particles emitted in different steps (initial, after agglomeration, etc.). The change of the size during transport is accounted for using the logarithmic size distribution. Of course the simulation is sensitive to the size of particles, since changing the size distribution would also change the residence times of BC particles. However, we only examined the sensitivity to the new scavenging scheme that is used in FLEXPART and not to different particle sizes.

(3) The selection of parameters in Table 2 was done according to Grythe et al. (2017) paper. Like the reviewer says, Grythe et al. used a larger range of parameters. In our paper, when changing scavenging parameters of BC, except for conducting a sensitivity analysis and estimate uncertainties, our top priority was to select the best representative species for BC, hence scavenging coefficients should be realistic. Of course, if we change these parameters drastically (like in Grythe et al. paper), the variability of the posterior concentrations will increase. Though, this has been already done in Grythe et al. paper and, besides, we would not have realistic values anymore.

The uncertainty estimates do not account for model transport errors and instrument errors. Section 2.2 and Figure 1 (g)-(i) show that the footprint varies greatly spatially. One may wonder how does this affect the inversion uncertainty? Can transport errors be more important than the choice of prior emission inventory and scavenging parameters in some regions distant from surface sites? Are observations informative for these

regions? One of the major finding is gas flaring emissions from Russia but Figure 1 (g)-(i) show small footprint in these regions. Also, Figure 12 shows that locations of intensive gas flaring are shifted from prior inventory but Figure 1 (d)-(f) shows the inversion grid there is very coarse. It is worthwhile to check the posterior error covariance matrix to see how confident the inversion is about the conclusions?

RESPONSE: Model transport errors are not explicitly accounted for, but they are likely small compared to the error in the scavenging. We account for the scavenging error by running ensembles. And using e.g. inter-quartile range or SD over the ensemble to estimate your posterior uncertainty, then that already answers the question about how this affects the inversion uncertainty. As regards to the instrument errors, if the reviewer talks about measurements of BC, then these errors are included in the inversion. Each continuous measurement site gives concentrations plus measurement errors (see also previous comment).

Returning to scavenging errors, they are much more important than transport errors. This has been proved in Thompson et al. (2017) for the CH<sub>4</sub> inversion in high northern latitudes. There, GFS versus ECMWF meteorology are compared as a proxy for transport error and is found transport error to be relatively small in most cases (note this does not calculate the true transport error but gives some indication). In the attached figure R2\_F1, we show the error (in concentration units) calculated from all runs with different scavenging parameters for year 2013.

To answer the question about whether the observations are informative for remote sites, we can simply look at the footprints of Fig.1 in the manuscript for these observations. There, we can observe problems in 2014 in N. America due to the lack of measurements (already discussed in the paper) and over areas between Finland and Tiksi station (also discussed in the paper) for all years due to the same reason (lack of measurements).

Thompson, R. L., Sasakawa, M., Machida, T., Aalto, T., Worthy, D., Lavric, J. V., Lund Myhre, C., and Stohl, A.: Methane fluxes in the high northern latitudes for 2005–2013 estimated using a Bayesian atmospheric inversion, *Atmos. Chem. Phys.*, 17, 3553-3572, <https://doi.org/10.5194/acp-17-3553-2017>, 2017

Minor comments Abstract.

The writing of the abstract can be improved. Line 17-19 and 23-25 seem to be out of place.

RESPONSE: Corrected. The first sentence (L17-19) was transferred to the next paragraph where the main results are summarized and the second one (L23-25), which is rather methodology-related, was transferred to the first paragraph (see manuscript with Track Changes).

Line 37: main of atmospheric particular matter (?)

RESPONSE: Obviously a word is missing here, so we have corrected the sentence to: "Light absorbing species, such as black carbon (BC), are the main components of atmospheric particulate matter, affecting air quality, weather and climate." Please see manuscript with Track Changes.

Line 39: gas flaring is open high- temperature combustion of natural gas in the oil/gas field. This source may be worth mentioning here because relevance to the results.

RESPONSE: We agree that it is a very good idea to also include this source due to its relevance with the results. Please see section 1. Introduction in the manuscript with Track Changes.

Line 80: maybe worthwhile to compare the results with this emission dataset?

RESPONSE: The emissions dataset used in Popovicheva et al. paper is ECLIPSEv5 with GFED4, exactly the same with the ones used with the Bayesian inversion in the current paper.

Line 152: the removal efficiency depends on BC aging (hydrophilic/hydrophobic) and size. How are they treated in the particle model?

RESPONSE: See also previous comment on aging. Aerosol ageing processes are not readily included in FLEXPART and the constant removal parameters cannot account for this transformation. However, this may not cause significant uncertainties as there are several observations that prove that BC is transformed very quickly into particles with aged, hydrophylic characteristics (e.g. Wittbom et al., 2014).

Wittbom, C., Eriksson, A. C., Rissler, J., Carlsson, J. E., Roldin, P., Nordin, E. Z., Nilsson, P. T., Swietlicki, E., Pagels, J. H., and Svenningsson, B.: Cloud droplet activity changes of soot aerosol upon smog chamber ageing, *Atmos. Chem. Phys.*, 14, 9831–9854, doi:10.5194/acp-14-9831-2014, 2014.

Line 363-366: not clear how these uncertainties are individually computed and then combined. Equations are useful here. And it may also be a good idea to move the description in Method sections.

RESPONSE: We have clarified this now in section 3.3. Usually, one can combine two uncertainties from different processes by propagation and there are different methods to do this (see for example: <http://lectureonline.cl.msu.edu/~mmp/labs/error/e2.htm>).

Line 467-469: This type of uncertainty is not included in current uncertainty estimation but should be available by analyzing posterior error covariance matrix if B and R are properly assigned.

RESPONSE: Since we used an ensemble to calculate the posterior uncertainty, and take also into account the uncertainty due to scavenging, we do not have the error correlations. However, we can see the uncertainty for each grid cell in Whitehorse that is shown to be very high in 2013 and 2015, but not in 2014 (Fig.S5). If we also check the total footprint for all stations in 2014 (Fig. 1), we can easily understand that the coverage for this region is very poor. And this poor coverage is just due to the lack of measurements in this particular year, as we state in the manuscript.

Section 4.4: The inversed emission seasonality is very interesting. I'd suggest summarizing the major finding about the seasonality in the abstract.

RESPONSE: Corrected! A sentence with the most important findings was introduced in Abstract (see manuscript with Track Changes).

Line 553-555: what type of errors in the inversion?

RESPONSE: We agree with the reviewer. We do not really know what types of errors we have here. We have removed this comment. Please see last paragraph of section 4.4 in manuscript with Track Changes.

Table 3: “four different optimized emission estimates are given”? Are they prior or posterior emissions? I am confused.

RESPONSE: We acknowledge the reviewer for pointing out this typo error. We have corrected the legend.

In this Table, we present annual posterior emissions of BC for N. America, N. Europe, N. Siberia and the 2 flaring regions in Russia. They are highlighted as “Posterior (ECLIPSEv5)”, because they were calculated using best representative species and best prior inventory. For comparison, we give the respective emissions for the same 5 regions in the four prior datasets highlighted as “ACCMIPv5 (prior)”, “EDGAR-HTAPv2.2 (prior)”, “MACCity (prior)” and “ECLIPSEv5 (prior)”.

Figure 1: It’s impossible to read labels in panels (a)-(c). It may be a good idea to use the projection in Figure 6 for reader to compare different figures easily.

RESPONSE: The real goal of (a) – (c) panels there is to just show the density of the measurement stations that were used each year. All the characteristics, locations and instrument types can be seen in Table 1. Switching the projection to Mercator as suggested by the reviewer does not improve or solve the problem (see attached Figure R2\_F2), so we would like to keep the current projection, which is consistent with the rest of the panels in Fig. 1

Figure 2: Use a consistent projection for panels (a)-(g) and Figure 6 so readers can compare easily.

RESPONSE: We see the point of the reviewer, although that’s the main reason that we also present the difference between posterior and prior emissions in Figure 6; so the readers can compare easily.

We have corrected Figure 2 as suggested, although we doubt that one will be able to distinguish different source locations on such a complex Figure.

Figure 3 and 4: Two figures provide very similar information. Consider removing one.

RESPONSE: These 2 different pictures are used for different reasons in the text. They also use 2 different statistics and having 2 statistics is always better than having only one. Since there are no space limitations in ACP, we would prefer to keep both of them as an additional evidence of our findings within the text.

Figure 7 - 9: These evaluations are quite interesting. But since the inversion is done with ECLIPSEv5, it is a fair comparison between posterior emissions with averaged RMSE from four emission inventories. RMSEpri from ECLIPSEv5 should be listed as well.

RESPONSE: Corrected!! We have introduced RMSE values for ECLIPSE as well, as suggested by the reviewer.

Figure 9: The difference between posterior and ECLIPSEv5 is very small, which may be indicative that the observations are not informative to emissions in this region. See major comments for uncertainty estimations.

RESPONSE: We agree with the reviewer that lack of observations there constrains sources poorly in areas between Finland up to Tiksi station pushing the inversion towards prior emissions. However, there is no solution for this.

Figure 11-12: “Black rectangles show vegetation fires adopted from Hao et al.” Choose another color. Black color is already used for map borders. Also, they are better referred to as dots rather than rectangles.

**RESPONSE:** Corrected! We have introduced dark green points to represent fire spots. See Track Changes manuscript.

Figure 13: The prior emissions plotted in panel d (N.Siberia) of Figure 13 seems to be wrong as they are much lower than the annual total emissions reported in Table 3.

**RESPONSE:** Again, thanks a lot for pointing out this mistake. We had accidentally plotted another area, where N. Siberia should be. We have now corrected it! Please see Track Changes.

12 **Abstract**

13 This paper presents the results of BC inversions at high northern latitudes (>50°N) for  
14 the 2013–2015 period. A sensitivity analysis was performed to select the best representative  
15 species for BC and the best a priori emission dataset. The same model ensemble was used to  
16 assess the uncertainty of the a posteriori emissions of BC due to scavenging and removal and  
17 due to the use of different a priori emission inventory. A posteriori concentrations of BC  
18 simulated over Arctic regions were compared with independent observations from flight and  
19 ship campaigns showing, in all cases, smaller bias, which in turn witnesses the success of the  
20 inversion. The annual a posteriori emissions of BC at latitudes above 50°N were estimated as  
21 560±171 kt yr<sup>-1</sup>, significantly smaller than in ECLIPSEv5 (745 kt yr<sup>-1</sup>), which was used and  
22 the a priori information in the inversions of BC. The average relative uncertainty of the  
23 inversions was estimated to be 30%.

24 A posteriori emissions of BC in North America are driven by anthropogenic sources,  
25 while biomass burning appeared to be less significant as it is also confirmed by satellite  
26 products. In North Europe, a posteriori emissions were estimated to be half compared to the a  
27 priori ones, with the highest releases to be in megacities and due to biomass burning in  
28 Eastern Europe. The largest emissions of BC in Siberia were calculated along the transect  
29 between Yekaterinsburg and Chelyabinsk. The optimised emissions of BC were high close to  
30 the gas flaring regions in Russia and in Western Canada (Alberta), where numerous power  
31 and oil/gas production industries operate. Flaring emissions in Nenets-Komi oblast (Russia)  
32 were estimated to be much lower than in the a priori emissions, while in Khanty-Mansiysk  
33 (Russia) they remained the same after the inversions of BC. Increased emissions in the  
34 borders between Russia and Mongolia are probably due to biomass burning in villages along  
35 the Trans-Siberian Railway. The maximum BC emissions in high northern latitudes (>50°N)  
36 were calculated for summer months due to biomass burning and they are controlled by  
37 seasonal variations in Europe and Asia, while North America showed a much smaller  
38 variability.

## 60 1 Introduction

61 | Light absorbing species, such as black carbon (BC), are the main components of  
62 | atmospheric particulate matter, affecting air quality, weather and climate. BC originates from  
63 | the incomplete combustion of fossil fuels (primarily coal and diesel), from open high-  
64 | temperature combustion of natural gas in the oil/gas field (gas flaring), as well as from the  
65 | burning of biomass and biofuels. BC particles affect cloud formation and precipitation as they  
66 | act as cloud condensation nuclei in their hydrophilic form (Wang et al., 2016). BC is also a  
67 | major driver of climate change contributing to global warming with a radiative forcing at the  
68 | top of the atmosphere ranging between 0.17 and 0.71 W m<sup>-2</sup> (Bond et al., 2013; Myhre et al.,  
69 | 2013; Wang et al., 2014). BC deposited in Arctic snow surfaces in concentrations of up to 30  
70 | ng g<sup>-1</sup> can reduce snow albedo by 1–3% (Hegg et al., 2009) in fresh snow and up to 3 times  
71 | more as snow ages and the BC particles become more concentrated (Clarke and Noone,  
72 | 1985). Airborne BC also warms the air and reduces tropical cloudiness by absorbing the  
73 | incoming solar radiation (Ackerman, 2000). It also reduces atmospheric visibility and  
74 | increases aerosol optical depth (Jinhuan and Liquan, 2000). From a health perspective, BC  
75 | particles, generally being sub-micron in size, can penetrate into the lungs and cause  
76 | pulmonary diseases (e.g., Wang et al., 2014).

77 | To improve understanding about how BC affects climate and to develop effective  
78 | policies to tackle BC's associated environmental problems requires accurate knowledge of the  
79 | emissions and their spatiotemporal distribution. Most commonly, BC emission inventory  
80 | datasets are built by “bottom up” approaches, which are based on activity data and emission  
81 | factors and proxy information for spatial disaggregation, but these methods are considered to  
82 | have large uncertainties (Cao et al., 2006). Numerous global or regional emission inventories  
83 | of BC have been constructed previously (Bond et al., 2004; Schaap et al., 2004; Streets et al.,  
84 | 2003); nevertheless, emission uncertainties contribute significantly to the overall uncertainty  
85 | of modelled concentrations of BC. Emission uncertainties affect even more significantly  
86 | regional/episodic simulations, as in many cases emissions deviate from the annual mean.  
87 | Such studies represent a useful tool to improve our understanding of the relationship between  
88 | observed concentrations of BC and BC emissions. Furthermore, BC emissions have their  
89 | most pronounced effect on the regional scale due to the relatively short atmospheric lifetime  
90 | of BC (Hodnebrog et al., 2014; Samset et al., 2014),.

91 | The relative differences between different emission inventories are largest for the high  
92 | latitudes (AMAP, 2015) and particularly in high-latitude Russia where emission information  
93 | is poor. For this area, a new satellite-based high-resolution inventory showed that BC

Nikolaos Evangeliou 24/9/2018 11:25

Deleted: components,

Nikolaos Evangeliou 24/9/2018 11:23

Deleted: is

96 emissions from Biomass Burning (BB) might have been 3.5 times higher than emissions  
97 given in the Global Fire Emissions Database (GFEDv4) (Hao et al., 2016), if more realistic  
98 emission factors are used (May et al., 2014). Furthermore, new sources of BC in the same  
99 area have been identified recently. For example, emissions from gas flaring by the oil industry  
100 have been missing from most emission inventories and may be an important source of BC at  
101 high latitudes (Stohl et al., 2013). For instance, in 2008 Russia was responsible for nearly one  
102 third of the gas flared globally (Elvidge et al., 2009). However, the gas flaring source is  
103 highly uncertain. For example, based on isotopic measurements, Winiger et al. (2017)  
104 reported recently that the contribution from gas flaring to BC measured at Tiksi in Siberia is  
105 lower than estimated by Stohl et al. (2013), while recently published bottom-up inventories  
106 (Huang et al., 2015; Huang and Fu, 2016) suggested even higher gas flaring emissions.  
107 Finally, Popovicheva et al. (2017) reported that one existing emission dataset of BC captured  
108 surface concentrations in the Russian Arctic quite efficiently.

109 In this study, we estimated the BC emissions at high northern latitudes using  
110 atmospheric observations of BC in a Bayesian inversion framework. Emissions were  
111 estimated for the region north of 50°N because this is the region with the largest influence on  
112 Arctic surface concentrations (Klonecki, 2003; Stohl, 2006). We determine the emissions  
113 with monthly time resolution for the years 2013, 2014 and 2015. We first describe the  
114 observation data, the transport model and the Bayesian inversion technique used, as well as  
115 the prior emission information. We then assess the sensitivity of the transport model to  
116 different scavenging coefficients (below-cloud and in-cloud) for BC and to different emission  
117 inventories. We finally present optimised BC emissions, discuss these results in comparison  
118 with independent estimates and calculate the uncertainty of the inversions with respect to  
119 different scavenging parameters used for BC and using four different prior emission datasets.

## 120 **2 Methodology**

### 121 **2.1 Observation network**

122 Atmospheric observations of BC were retrieved from the World Data Centre for  
123 Aerosols (<http://ebas.nilu.no>) and from the International Arctic Systems For Observing The  
124 Atmosphere (<http://www.esrl.noaa.gov/psd/iasoa/>). An overview of the stations used in this  
125 paper can be found in [Table 1](#) and [Figure 1a–c](#). The selected measurements were performed  
126 with different types of instruments that may differ substantially. When measurements are

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Table 1

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 1

129 based on light absorption we refer to Equivalent BC (EBC), while measurements based on  
130 thermal-optical methods refer to elemental carbon (EC) (Petzold et al., 2013).

131 At Alert (ALT), Appalachian (APP), Asprveten (ASP), Birkenes (BIR), East Trout  
132 Lake (ETL), South Great Planes (SGP), Steamboat Springs (COL), Trinidad Head (TRI) and  
133 Whistler (WHI) measurements were performed with particle soot absorption photometers  
134 (PSAPs). At Annaberg-Buchholz (ANB), Bösel (BOS), Cabauw Zijdeweg (CAB), Hyytiälä  
135 (HYY), Leipzig (LEI), Melpitz (MEL), Nepal Climate Observatory (NEP), Pallas (PAL), Ústí  
136 n.L.-mesto (ULM) and Waldhof (WLD) the particle light absorption coefficient was  
137 measured by multi-angle absorption photometers (MAAP; Petzold and Schönlinner, 2004),  
138 which are in excellent agreement with other particle light absorption photometers such as a  
139 photoacoustic sensor (e.g., Muller et al., 2011). In the MAAP instrument, particles are  
140 continuously sampled on filter tape, with loaded spots subsequently analysed by Raman  
141 spectroscopy to derive the particle mass concentration of soot (Nordmann et al., 2013). The  
142 cut-off sizes of the different MAAP instruments varied between 1 and 10  $\mu\text{m}$ . Continuous  
143 light absorption photometers (CLAP, Model PSAP; 565 nm) were used at Barrow (BAR),  
144 Bondville (BON), Gosan (GOS), K-pusztá (KPU), BEO Moussala (MOU) and Summit  
145 (SUM). Although these instruments were calibrated to measure the aerosol absorption  
146 coefficient, a previous study at this site revealed that a value of  $10 \text{ m}^2 \text{ g}^{-1}$  is a reasonable  
147 conversion factor to determine the BC concentration (Gelencsér et al., 2000). Aethalometers  
148 were used at Tiksi (TIK) and Zeppelin (ZEP).

149 All these stations measure the particle light absorption coefficients of different size  
150 fractions of the aerosol at wavelengths around 530–550 nm. Then the light absorption  
151 coefficients are converted to EBC mass concentrations under certain assumptions (Petzold et  
152 al., 2013). This is done externally for instruments such as MAAP, CLAP, PSAP etc. using a  
153 mass absorption efficiency of  $10 \text{ m}^2 \text{ g}^{-1}$  (Bond and Bergstrom, 2006). For aethalometers, the  
154 conversion is done internally by the instrument. All station measurements are routinely  
155 filtered to remove influence from local sources.

## 156 **2.2 Source – Receptor Relationships (SRRs)**

157 We used the Lagrangian Particle Dispersion Model (LPDM), FLEXible PARTicle  
158 dispersion model (FLEXPART) (Stohl et al., 1998, 2005) to model atmospheric transport.  
159 Using LPDMs to model particle or trace gas concentrations has several advantages over  
160 Eulerian models, namely they can have quasi-infinite resolution and they are not subject to  
161 numerical diffusion. Thus they can provide better resolved source-receptor relationship (SRR)

162 fields, which describe the relationship between the sensitivity of a “receptor” to a “source”  
163 element, as described by Seibert and Frank (2004). SRRs for the lowest model level are often  
164 called footprint emission sensitivities or even just footprints.

165 SRRs were calculated using FLEXPART version 10 in a backwards mode (see Stohl et al., 2005)  
166 in which computational particles are released backward in time from the  
167 observation sites (receptors). When the number of observation sites is smaller than the  
168 number of unknown flux grid cells this mode is computationally more efficient than forward  
169 calculations. Furthermore, backward simulations can be initiated exactly at the measurement  
170 point without initial diffusion of information into a grid cell. This important advantage of  
171 LPDMs also facilitates high spatial resolution of the model output around the measurement  
172 sites. As meteorological input data, European Centre for Medium-Range Weather Forecasts  
173 operational meteorological analyses were used with 137 vertical levels and a horizontal  
174 resolution of  $0.5^\circ \times 0.5^\circ$ . Retroplumes were calculated at hourly intervals at each of the  
175 receptors. 40,000 particles for each retroplume were released and followed 30 days backwards  
176 in time. This should be a sufficiently long time in order to include almost all contributions to  
177 BC concentration at the receptor given the atmospheric lifetime of BC (in the range of 2–10  
178 days, Benkovitz et al., 2004; Koch and Hansen, 2005; Park et al., 2005; Textor et al., 2006).

179 The treatment of scavenging is a major uncertainty for modelling BC (Browse et al.,  
180 2012). Therefore, an ensemble of 12 model simulations was performed each with different  
181 BC tracers having different in-cloud and below-cloud scavenging properties (Table 2). This  
182 method allows the sensitivity of the SRRs (produced by FLEXPART) to scavenging to be  
183 quantified. Table 2 shows the different below-cloud and in-cloud scavenging parameters  
184 used within the model in the sensitivity runs. For all tracers, we assumed a logarithmic size  
185 distribution with an aerodynamic mean diameter of  $0.25 \mu\text{m}$ , a logarithmic standard deviation  
186 of 0.3 and a particle density of  $1500 \text{ kg m}^{-3}$  (Long et al., 2013). The dry deposition scheme in  
187 FLEXPART is based on the resistance analogy (Slinn 1982). The present version of the  
188 model uses the precipitation rate from ECMWF to determine below-cloud scavenging and the  
189 cloud liquid water and ice content, precipitation rate and cloud depth from ECMWF to  
190 calculate in-cloud scavenging (see Grythe et al., 2017).

191 The SRR at the lowest model layer (in seconds) (Figure 1g–i) can be multiplied with  
192 gridded emission fluxes from a BC emission inventory (in  $\text{kg m}^{-2} \text{ s}^{-1}$ ) distributed over the  
193 layer depth (100 m). This gives the prior concentration of BC at the receptor point (in  $\text{ng m}^{-3}$ ).

### 197 2.3 Bayesian inversion

198 The inversion methodology used in the present study, FLEXINVERT, is described fully  
199 in Thompson and Stohl (2014) and has been already used in studies of CH<sub>4</sub>, HFC-125, HFC-  
200 134a and SF<sub>6</sub> (Brunner et al., 2017; Thompson et al., 2015, 2017). Since atmospheric  
201 transport and deposition are linear operations, they can be described as a Jacobian matrix of  
202 SRRs (**H**). The BC concentrations (**y**) can then be modelled given an estimate of the  
203 emissions (**x**) as follows:

$$204 \quad \mathbf{y} = \mathbf{H}(\mathbf{x}) + \boldsymbol{\varepsilon} \quad (1)$$

205 where  $\boldsymbol{\varepsilon}$  is an error associated with model representation, such as the modelled transport and  
206 deposition as well as the measurements. Since **H** is generally not invertible (or may have no  
207 unique inverse), statistical optimization methods are used, which require prior information for  
208 regularization. According to Bayesian statistics, the problem can be expressed as the  
209 maximization of the probability density function of the emissions given the prior information  
210 and observations and is equivalent to finding the minimum of the cost function:

$$211 \quad \mathbf{J}(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}_b) + \frac{1}{2}(\mathbf{y} - \mathbf{H}\mathbf{x})^T \mathbf{R}^{-1}(\mathbf{y} - \mathbf{H}\mathbf{x}) \quad (2)$$

212 where **B** and **R** are the error covariance matrices for the prior emissions and the observations,  
213 respectively. The error in the observation space also accounts for model representation errors  
214 that are not related to the BC emissions. The emissions that minimize the cost function can be  
215 found by solving the first order derivative of equation (2). Hence, the following equation can  
216 be derived for the most probable emissions, **x** (for details see e.g. Tarantola, 2005):

$$217 \quad \mathbf{x} = \mathbf{x}_b + \mathbf{B}\mathbf{H}^T(\mathbf{H}\mathbf{B}\mathbf{H}^T + \mathbf{R})^{-1}(\mathbf{y} - \mathbf{H}\mathbf{x}_b) \quad (3)$$

218 In this study, the state vector contains the monthly unknown surface emissions on the  
219 grid of variable resolution (Figure 1d–f) and has a resolution of between 1.0°×1.0° and  
220 8.0°×8.0°. The total number of emission variables to be determined was 1422 for 2013, 1404  
221 for 2014 and 1436 for 2015. The posterior error covariance matrix, **A**, is equivalent to the  
222 inverse of the second derivative of the cost function. However, to account for the uncertainty  
223 in the scavenging parameters and different prior information, we instead conduct ensemble of  
224 inversions to estimate the posterior uncertainty in order to account for the systematic errors.  
225 To do this, we conduct the inversion for BC represented by 12 different scavenging  
226 coefficients (see Table 2) and for four different prior emission datasets, and do this for each of  
227 the three years of our study (2013–2015). The resulting model ensemble (12×4=48) for each  
228 year defines the posterior uncertainty due to scavenging and use of different a priori  
229 information (section 3.3).

Nikolaos Evangeliou 27/9/2018 11:26  
Deleted: Figure 1

Nikolaos Evangeliou 27/9/2018 11:26  
Deleted: Table 2

232 Since negative values for the posterior emissions are mathematically possible but  
233 physically unlikely, we applied a subsequent inequality constraint on the emissions following  
234 the method of Thacker (2007). This is a truncated Gaussian approach in which inequality  
235 constraints are applied as error-free “observations”:

$$236 \quad \hat{\mathbf{x}} = \mathbf{x} + \mathbf{A}\mathbf{P}^T(\mathbf{P}\mathbf{A}\mathbf{P}^T)^{-1}(\mathbf{c} - \mathbf{P}\mathbf{x}) \quad (4)$$

237 where  $\mathbf{A}$  is the posterior error covariance matrix,  $\mathbf{P}$  is a matrix operator to select the variables  
238 that violate the inequality constraint, and  $\mathbf{c}$  is a vector of the inequality constraint, which in  
239 this case is zero.

240 The emissions were solved on an irregular grid, which has been optimized based on the  
241 SRRs to give higher resolution ( $1.0^\circ \times 1.0^\circ$ ) in regions where there is strong contribution  
242 from emission sources to BC concentrations and lower ( $8.0^\circ \times 8.0^\circ$ ) where there is a weak  
243 contribution (Stohl et al., 2009). Then, the results are interpolated onto a uniform grid of  
244  $1.0^\circ \times 1.0^\circ$  resolution from  $180^\circ\text{W}$  to  $180^\circ\text{E}$  and  $50^\circ\text{N}$  to  $90^\circ\text{N}$  and are given at monthly time  
245 resolution for 2013, 2014 and 2015. To constrain emissions of BC monthly, a temporal  
246 correlation scale length between flux time-steps equal to 90 days was set.

## 247 2.4 A priori emission information

248 In the present study, the emission inventories ECLIPSE (Evaluating the CLimate and  
249 Air Quality ImPacts of ShortlivEd Pollutants) version 5 (Klimont et al., 2017) (available here:  
250 [http://www.iiasa.ac.at/web/home/research/researchPrograms/air/Global\\_emissions.html](http://www.iiasa.ac.at/web/home/research/researchPrograms/air/Global_emissions.html)),  
251 EDGAR (Emissions Database for Global Atmospheric Research) version HTAP\_V2.2  
252 (Janssens-Maenhout et al., 2015) (available here:  
253 <http://edgar.jrc.ec.europa.eu/methodology.php#>), ACCMIP (Emissions for Atmospheric  
254 Chemistry and Climate Model Intercomparison Project) version 5 (Lamarque et al., 2013)  
255 (available here: [http://accent.aero.jussieu.fr/ACCMIP\\_metadata.php](http://accent.aero.jussieu.fr/ACCMIP_metadata.php)) and MACCcity  
256 (Monitoring Atmospheric Composition & Climate / megaCITY - Zoom for the ENvironment)  
257 (Wang et al., 2014) (available here: [http://accent.aero.jussieu.fr/MACC\\_metadata.php](http://accent.aero.jussieu.fr/MACC_metadata.php)) were  
258 used as the prior emission estimates of BC (see Figure 2).

259 The ECLIPSE emission inventory (Figure 2a) accounts for waste burning, industrial  
260 combustion and processing, surface transportation that also includes power plants, energy  
261 conversion and extraction that also includes gas flaring, residential and commercial  
262 combustion.

263 The HTAP\_V2 dataset (Figure 2b) consists of high-resolution gridded emissions of BC  
264 based on nationally reported emissions combined with regional scientific inventories. It

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 2

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 2

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 2

268 includes the sources of aviation, inland waterways and marine shipping, energy production  
269 other than electricity generation, industrial processes, solvent production and application,  
270 electricity generation, ground transport, buildings heating, cooling, equipment, and waste  
271 disposal or incineration.

272 The ACCMIP simulations use the BC emission inventory covering the historical period  
273 (1850–2000) provided by (Lamarque et al., 2010), which is built for the climate model  
274 simulations in CMIP5 (Figure 2c). Anthropogenic emissions are mainly based on Bond et al.  
275 (2004) but apply new emission factors. The year 2000 dataset was used for harmonization  
276 with the future emissions determined by Integrated Assessment Models (IAMs) for the four  
277 Representative Concentration Pathways (RCP4.5, RCP6, and RCP8.5). They include  
278 emissions from energy production and distribution, industry (combustion and non-  
279 combustion), transportation, maritime transport and aviation, residential and commercial  
280 combustion and solvent extraction, agricultural production and waste treatment.

281 MACCity (Figure 2d) was built as an extension of the historical emissions dataset of  
282 ACCMIP. It provides monthly averaged sectorial emissions for each year during the 1960-  
283 2010 period. This dataset was based on the decadal ACCMIP emissions for 1960-2000 and  
284 the 2005 and 2010 emissions provided by RCP 8.5. This scenario was chosen since it  
285 included some information on recent emissions at the regional scale in Europe and North  
286 America. The emission sectors are consistent with Lamarque et al. (2010).

287 Emissions from biomass burning were adopted from the Global Fire Emissions  
288 Database, Version 4 (GFEDv4) (Giglio et al., 2013) and implemented to each of the four  
289 emission inventories for 2013, 2014 and 2015. Emissions from gas flaring are only included  
290 in ECLIPSEv5 inventory.

### 291 3 Results

#### 292 3.1 Sensitivity to scavenging and selection of the best representative species 293 for BC

294 The comparison of the simulated and observed concentrations for the 12 different BC  
295 tracers (see Table 2) is shown in Taylor diagrams in Figure 3, for ECLIPSEv5 and in Figure S  
296 1, for ACCMIPv5, EDGAR\_HTAPv2.2 and MACCity, only for those stations that had  
297 continuous measurements for all the years of our study (2013–2015) namely ZEP, SUM, TIK,  
298 BAR, PAL, CAB, MEL and LEI (see Table 1). For all the different BC species,

Deleted: Table 1

305 concentrations of BC were calculated using the FLEXPART SRR and the four different  
306 emission datasets for 2013, 2014 and 2015.

307 Correlations of modelled and observed surface concentrations of BC were high (>0.5)  
308 only at stations ALT, MEL and LEI that present low [normalised standard deviation \(NSD\)](#)  
309 values (<1) and low [normalised root mean square error \(nRMSE\)](#) values. All NSD values  
310 were below 1.5 except at TIK and ULM stations (see [Figure 3](#), and [Figure S 1](#)). In general,  
311 dispersion models fail to reproduce BC concentrations close to TIK station (Eckhardt et al.,  
312 2015; Evangeliou et al., 2016), as the station has been reported to receive pollution from local  
313 anthropogenic sources (Asmi et al., 2016). ULM station is located on the border between  
314 Germany and the Czech Republic and was shown previously to be strongly affected by BC  
315 emissions from residential combustion sources (Schladitz et al., 2015). The model-  
316 observation mismatches ( $[model - observations]/observations$ ) due to the use of 12  
317 different species for BC can be seen in [Figure S 2](#), for the years 2013, 2014 and 2015. These  
318 values are average concentrations from the use of the four different emissions inventories  
319 (ECLIPSEv5, ACCMIPv5, EDGAR\_HTAPv2.2 and MACCity). The extreme perturbation of  
320 the scavenging coefficients of BC caused an average relative model-observation mismatch  
321 (normalised against observations) of about 39% in 2013 ([Figure S 2](#)) at all stations.

322 Similar to 2013, 12 species with different scavenging parameters were used for BC  
323 following [Table 2](#), in 2014 and the comparison with observations is shown in Taylor diagrams  
324 in [Figure 3](#), using ECLIPSEv5 emissions and in [Figure S 1](#), using ACCMIPv5,  
325 EDGAR\_HTAPv2.2 and MACCity for the common stations. The comparison of surface  
326 simulated concentrations with observations showed NSD values above one, high nRMSE  
327 values and correlation coefficients below 0.5 in at most of the stations. The main difference  
328 from year 2013 is that the model-observation mismatches for the surface concentrations of the  
329 12 BC species was estimated to be 32% in 2014 ([Figure S 2](#)), in contrast to 39% in 2013. The  
330 same deficiency of the model to capture the spring and summer concentrations of BC was  
331 observed. The calculated mismatches were very low in at most of the lower latitude stations  
332 and increased towards the remote Arctic ones ([Figure S 2](#)).

333 Finally, in 2015 the comparison of surface concentrations for each of the 12 different  
334 BC species using the four different datasets (ECLIPSEv5, ACCMIPv5, EDGAR\_HTAPv2.2  
335 and MACCity) with observations showed again the same pattern as in the previous years with  
336 most of the NSD values to be above unity, high nRMSE values and low Pearson coefficients  
337 ([Figure 3](#), and [Figure S 1](#)). The model-observation mismatches of BC concentrations ([Figure S](#)  
338 [2](#)) were estimated as high as 43% for the stations where full measurements existed for the

351 three years of the study (2013–2015). Like in the previous years, the model failed to  
352 reproduce surface concentrations of BC at some of the remote stations of the Arctic.

353 We used the NMSE (Normalised Mean Square Error) to select the most representative  
354 BC tracer species. The NMSE is an estimator of the overall deviations between predicted and  
355 measured values. It is defined as:

356 
$$NMSE = \frac{1}{N} \sum_i \frac{(O_i - P_i)^2}{\bar{P}_i \bar{O}_i} \quad (5)$$

357 where  $O_i$  and  $P_i$  are observed and predicted concentrations, N the number of observations for  
358 which we assess the predicted values, while the overbar indicates the mean over the number  
359 of observations for  $O_i$  and  $P_i$ . Contrary to the relative mismatches, in the NMSE the squared  
360 deviations (absolute values) are summed instead of the differences. For this reason, the  
361 NMSE generally shows the most striking differences among models. NMSE is a highly  
362 selective statistical quantity that can give large differences between models that perform  
363 similarly for other statistical measures. The lower the NMSE value, the better the  
364 performance of the model. On the other hand, high NMSE values do not necessarily mean  
365 that a model is completely wrong as the errors could be due to shifts in time and/or space.  
366 Moreover, it must be pointed out that NMSE is sensitive to outliers (Poli and Cirillo, 1993).

367 The calculated monthly average NMSE values for the 12 species using ECLIPSEv5 as  
368 the emission input can be seen in [Figure 4](#) for year 2013–2015. The different scavenging  
369 coefficients used did not create a large variability in the monthly BC concentrations, This was  
370 caused due to the small perturbation of the scavenging coefficients. A more drastic change of  
371 wet scavenging would have caused BC concentrations to change more, as wet scavenging  
372 dominates removal and deposition of BC by approximately 80%. However, considering that  
373 the selection of the best representative species for BC was top priority, an effort to set realistic  
374 values to the scavenging coefficients was made. The best performance for the majority of the  
375 stations examined and most months was obtained for species 1, 2 and 10 (see [Table 2](#)). In  
376 terms of model response over the Arctic stations, a better performance was achieved for  
377 species 1 than for the other two. Therefore, we have chosen species 1 as our reference species  
378 for all subsequent analyses and the inversions. It should be noted here that the same test was  
379 performed using ACCMIPv5, EDGAR\_HTAPv2.2 and MACCity emissions. Although the  
380 results were worse, the best-performed species for BC were again 1, 2 and 10.

385 **3.2 Sensitivity to different prior information and selection of the best prior**  
386 **emission inventory**

387 In this section we assess the impact of using the different prior emission inventories for  
388 BC and select the most appropriate one for our BC inversions. For this analysis, the best  
389 performing species 1 for BC (see [Table 2](#)) was chosen and the monthly relative model –  
390 observation mismatches ( $([model - observations]/observations)$ ) for all stations and  
391 years separated were calculated using all four inventories and are depicted in [Figure S 3](#).

392 The largest monthly relative model-observation mismatches for the a priori simulated  
393 concentrations of BC in 2013 were calculated for stations located close to 50°N (BOS, CAB  
394 MEL, LEI, ULM, ANB). The average model-observation mismatch for all stations was 15%  
395 for 2013. Similar results were found for 2014 for the prior simulated BC concentrations with  
396 the largest relative mismatches recorded at mid-latitude stations where the BC concentrations  
397 were very high due to large anthropogenic emissions (BOS, CAB, MEL, LEI). On average,  
398 the relative model-observation mismatch was as high as 23% for the year 2014. Finally, in  
399 2015, again the highest monthly relative mismatches of the a priori BC concentrations were  
400 estimated for the stations of high anthropogenic influence (CAB, MEL, LEI, WLD). The  
401 average relative model-observation mismatch in 2015 was only 19%, much lower than all  
402 previous years. The fact that all prior emission datasets used failed to reproduce the  
403 observations in central Europe during all years studied (2013, 2014 and 2015), whereas other  
404 stations at mid-latitudes were reproduced well, might imply either missing sources or highly  
405 uncertain measurements ([Figure S 3](#)). The use of different emission dataset changes simulated  
406 concentrations by a maximum of 23%.

407 Normalized mean square error (NMSE) values calculated for each of the four emission  
408 inventories were very low at the majority of the stations for which data existed in all the years  
409 of study (ZEP, SUM, TIK, BAR, MEL and LEI), when ECLIPSEv5 emissions were used.In  
410 contrast, at PAL all emission datasets performed well ([Figure 5](#)). [The observations of BC](#)  
411 concentrations at Arctic stations were better reproduced in simulations using the ECLIPSEv5  
412 than with any other inventories examined.Law and Stohl (2007) have documented that these  
413 elevated BC concentrations are caused by anthropogenic emissions. Black carbon  
414 concentrations at TIK are not well simulated for reasons given in section 3.1.

415 **3.3 Optimised (a posteriori) emissions of BC and associated uncertainty**

416 The optimised annual emissions of BC together with the associated posterior gridded  
417 uncertainty and the difference between posterior and prior emissions averaged for the 2013–

443 | 2015 period can be seen in [Figure 6](#). The posterior emissions [are presented](#) for the best  
444 | performing species (species 1) of BC and the best prior emissions inventory (ECLIPSEv5).  
445 | The total posterior uncertainty was calculated as the standard deviation of the posterior  
446 | emissions calculated for the 12 BC species with different scavenging coefficients for four  
447 | different emission datasets as prior information for each of the three years (12×4=48  
448 | inversions, see section [2.2](#)). The total uncertainty is a [propagation](#) of the deposition  
449 | uncertainty (represented by the posterior emissions using 12 perturbed BC species with  
450 | different scavenging coefficients) and the uncertainty due to the use of different prior  
451 | information (represented by the posterior emissions using the four different emission  
452 | datasets). [Table 3](#), reports annual prior, posterior, and averaged over 2013-2015, BC emissions  
453 | [for different regions](#). Five different regions are accounted for, namely North America, North  
454 | Europe (including European Russia), North Siberia, Nenets-Komi (Russia) and Khanty-  
455 | Mansiysk district (Russia).

456 | The optimised emissions show some constant hot-spot areas that persist throughout all  
457 | three years and which are attributed to anthropogenic [BC emissions](#). For instance, emissions  
458 | in the Nenets – Komi region close to the Yamal peninsula in Russia or in Khanty Mansiysk  
459 | region of Northwestern Siberia have been reported to originate to a large extent from gas  
460 | flaring (Popovicheva et al., 2017; Stohl et al., 2013; Winiger et al., 2017). Other areas that are  
461 | characterised by large anthropogenic emissions are in Western Canada (Alberta), where more  
462 | than 100 power industries burn fossil fuels and more than 50 oil and gas production and oil  
463 | refining industries operate. In addition, one of the largest oil sands deposits are found in  
464 | Northern Alberta and in the McMurray area, which contains about 168 billion barrels of oil  
465 | (Heins, 2000). Cheng et al. (2018) found high concentrations of BC (more than 1000 ng m<sup>-3</sup>)  
466 | in the Canadian oil sands region at altitudes of up to 2 km during a flight campaign.

467 | The optimised [BC emissions](#) in North America for the 2013–2015 period were between  
468 | 149 and 193 kt y<sup>-1</sup> (average ± 1-sigma error: 174±58 kt y<sup>-1</sup>), in the same order with the prior  
469 | emissions in ECLIPSEv5 (148–182 kt y<sup>-1</sup>) and slightly higher than ACCMIPv5,  
470 | EDGAR\_HTAPv2.2 and MACCity (116–150 kt y<sup>-1</sup>). In Northern Europe we estimated that  
471 | 124–238 kt y<sup>-1</sup> of BC were released (average ± 1-sigma error: 170±59 kt y<sup>-1</sup>), which is less  
472 | than half the ECLIPSEv5 emissions (352–381 kt y<sup>-1</sup>), about 35% lower than the ACCMIPv5  
473 | and MACCity emissions (241 – 256 kt y<sup>-1</sup>) and in the same order as the EDGAR\_HTAPv2.2  
474 | emissions (163–175 kt y<sup>-1</sup>). Posterior [BC emissions](#) were higher in North Siberia for the 3-  
475 | year period (130–291 kt y<sup>-1</sup>, average ± 1-sigma error: 217±69 kt y<sup>-1</sup>) compared with  
476 | ECLIPSEv5 (187–238 kt y<sup>-1</sup>), ACCMIPv5 (127–178 kt y<sup>-1</sup>), EDGAR\_HTAPv2.2 (108–159 kt

490  $y^{-1}$ ) or MACCity (129–179  $kt\ y^{-1}$ ). Larger changes in the BC emissions were calculated in  
491 Russian territories that are known to be important gas flaring sources (Stohl et al., 2013). BC  
492 emissions in the Nenets-Komi oblast were between 14 and 17  $kt\ y^{-1}$  (average  $\pm$  1-sigma error:  
493  $15\pm 5\ kt\ y^{-1}$ ), about 40% lower than the respective emissions in ECLIPSEv5 ( $\approx 25\ kt\ y^{-1}$ ), the  
494 only prior dataset that took gas flaring into account there. This could be due to the decreasing  
495 magnitude of the flaring emissions in the last few years (see Huang and Fu, 2016). Finally, in  
496 Khanty-Mansiysk BC emissions were 28–37  $kt\ y^{-1}$  (average  $\pm$  1-sigma error:  $32\pm 8\ kt\ y^{-1}$ )  
497 compared to 25  $kt\ yr^{-1}$  in ECLIPSEv5, whereas in the other datasets that do not include BC  
498 emissions due to flaring, BC emissions were negligible. However, the posterior Khanty-  
499 Mansiysk emissions are shifted further east compared to the prior.

500 The annual posterior BC emissions at latitudes above 50°N were estimated as  $560\pm 171$   
501  $kt\ yr^{-1}$  averaged for the 2013–2015 time period ( $523\pm 92\ kt\ yr^{-1}$  in 2013,  $608\pm 104\ kt\ yr^{-1}$  in  
502 2014 and  $549\pm 100\ kt\ yr^{-1}$  in 2015, respectively). For the same area and period, BC emissions  
503 in ECLIPSEv5 were  $745\ kt\ yr^{-1}$ , in ACCMIPv5  $533\ kt\ yr^{-1}$ , in EDGAR\_HTAPv2.2  $437\ kt\ yr^{-1}$ ,  
504 while in MACCity they were  $538\ kt\ yr^{-1}$ . The annual posterior absolute uncertainty can be  
505 seen in Figure 6b. As it was explained before, this uncertainty is a combination of the  
506 uncertainty due to scavenging and due to the use of different prior information in the  
507 inversions of BC. Averaged over the period 2013-2015, the relative uncertainty of the  
508 inversion was estimated to be 30%. The uncertainty due to different scavenging coefficients  
509 in the BC species used was 25%, while the uncertainty due to the use of different prior  
510 emissions was only 5%.

### 511 3.4 Validation of the posterior emissions of BC

512 The concentrations of BC at eight measurement stations simulated with the posterior  
513 (optimised) BC emissions can be seen in Figure S 4. As expected, BC concentrations match  
514 the observations significantly better than using any of the a priori datasets with correlation  
515 coefficients above 0.6 for most of the stations. At the same time, NSD values were close to  
516 unity or lower and the nRMSE values below 1.5 at most of the stations shown in Figure S 4.  
517 However, the comparison to observations included in the inversion is not a sufficient  
518 indicator of the inversion's performance, as the inversion is designed to reduce the model-  
519 observation mismatches. The magnitude of the posterior reduction of the model mismatch to  
520 the observations is partly determined by the weighting given to the observations relative to  
521 the prior emissions. A much better performance indicator is the comparison of the posterior

Deleted: Figure S 4

534 concentrations with observations that were not included in the inversion (independent  
535 observations).

536 For this reason, we compared posterior BC concentrations with observations from the  
537 ACCACIA (Aerosol-Cloud Coupling and Climate Interactions in the Arctic) flight campaign,  
538 which was conducted near Zeppelin station, Ny-Ålesund, for 3 days in March 2013 (Sinha et  
539 al., 2017). This campaign was chosen because it was conducted during one year for which  
540 inversion results are available (2013). The results are shown in [Figure 7](#), for the prior  
541 simulated concentrations of BC using four different emission datasets (ACCMIPv5,  
542 ECLIPSEv5, EDGAR\_HTAPv2.2 and MACCity) and the posterior simulated BC  
543 concentrations. In all profiles, use of the optimised [BC emissions](#) results in a better agreement  
544 between modeled concentrations and observations compared to the prior simulated BC  
545 concentrations, while the RMSE (not normalised) values decrease substantially. However, the  
546 Pearson's correlation coefficients were below 0.5.

547 To assess the performance of the inversions of BC in 2014, we used an independent  
548 dataset from a ship campaign that took place in the North Atlantic and Baltic Seas in June and  
549 August 2014 ([Figure 8](#)) provided by Shevchenko et al. (2016). Although the measurements  
550 may sometimes be affected by the ship's exhaust, the posterior RMSE was 34% lower than  
551 the average RMSE using four different a priori emission datasets (ACCMIPv5, ECLIPSEv5,  
552 EDGAR\_HTAPv2.2 and MACCity), supporting the view that the inversion improved the  
553 emissions for 2014.

554 To validate the 2015 inversions of BC, measurements from a ship campaign over the  
555 Russian Arctic were used (Popovicheva et al., 2017) and the results are shown in [Figure 9](#).  
556 The cruise started from the port of Arkhangelsk in the Northwestern European Russia,  
557 reached the Bolshevik Island in the higher Russian Arctic and returned following more or less  
558 the same pathway. The calculated RMSE of the posterior BC concentrations with the  
559 measurements taken during the cruise was about 10% lower than the respective RMSE from  
560 the prior simulated concentrations of BC (average for all prior simulated emissions). This  
561 shows that the optimised emissions improved BC concentrations over the Russian Arctic.  
562 Some episodic peaks of BC throughout the ship cruise, however, were poorly captured.

Deleted: emissions of BC

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 8

Nikolaos Evangeliou 27/9/2018 11:26

Deleted: Figure 9

#### 569 4.1 BC emissions in North America

570 The spatial distribution of the optimised BC emissions in North America averaged for  
571 the 3-year period is depicted in [Figure 10](#), and the annual posterior emissions for 2013, 2014  
572 and 2015 are shown in [Figure S 5](#). The right panel of the same figures shows the differences  
573 between posterior and prior emissions (ECLIPSEv5) and highlights the biggest emission  
574 changes compared to the a priori dataset.

575 The most characteristic locations of sources between 2013 and 2015 lie in Alberta,  
576 where most of the large oil-producing industries operate ([Figure 10](#), and [Figure S 5](#)). The  
577 highest emission source was located in 60°N–135°W in 2013 and 2015, but not in 2014. This  
578 spot corresponds to the location of Whitehorse, which is the capital and only city of Yukon,  
579 and the largest city in Northern Canada. The area involves mining activities (mainly for gold)  
580 and three natural gas wells, while biomass in the form of cordwood and pellets is used for  
581 space heating (Yukon Government, 2018). The fact that near-zero BC emissions were  
582 calculated in Whitehorse in 2014 might be due to the lack of available measurements in North  
583 America, which in turn results in poorly constrained posterior BC emissions. Another similar  
584 hotspot area that is more intense in 2013 and 2015, but not in 2014 is located in Yellowknife  
585 north of Great Slave Lake (62.5°N–115°W, [Figure S 5](#)). The city is known for gold and  
586 diamond mining and an oil-driven power plant (Northwest Territories Power Corporation,  
587 <https://www.ntpc.com>). Finally, another characteristic hotspot emission region of BC is seen  
588 southeast of Lake Athabasca (57°N–108°W, [Figure 10](#)). Uranium mines are located in this  
589 region. These mines use diesel generators, diesel trucks, and other diesel-powered machinery.  
590 Exactly in this location, the Visible Infrared Imaging Radiometer Suite (VIIRS) showed  
591 relatively strong night-time light sources  
592 ([https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-](https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-11864816&layers=B0FFFTFFFT)  
593 [11864816&layers=B0FFFTFFFT](https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-11864816&layers=B0FFFTFFFT)).

#### 594 4.2 BC emissions in Northern Europe

595 The posterior BC emissions in Northern Europe averaged for the period 2013–2015 can  
596 be seen in [Figure 11](#), together with the difference between prior (ECLIPSEv5) and posterior  
597 BC emissions, while the posterior emissions for each individual year are shown in [Figure S 6](#).  
598 The location of the gas flaring facilities are also presented in the same figures together with  
599 vegetation fires from the FEINE (Fire Emission Inventory– northern Eurasia) inventory (Hao  
600 et al., 2016). The latter combines the MODIS thermal anomalies products (MOD14 and  
601 MYD14) and the MODIS top-of-the-atmosphere-calibrated reflectance product (MOD02) to

624 map and date burn scars that are screened for false detections. Land cover classification of  
625 burned areas are taken from the MODIS land cover change product (MOD12) (Friedl et al.,  
626 2010). This dataset is considered more realistic than GFED4 due to the emission factors used  
627 for BC (May et al., 2014) and the different approach of burned area calculation (see Hao et  
628 al., 2016).

629 | The highest posterior **BC emissions** are calculated for the Moscow megacity at 55°N–  
630 37.5°E, Berlin 52°N–14°E, Warsaw 52°N–21°E, Kyiv 50°N–30°E, Saint Petersburg 60°N–  
631 30°E, while London is slightly misplaced to the west (Figure 11). The Scandinavian countries  
632 have the lowest emissions, although domestic heating there can also be important (Andersen  
633 and Jespersen, 2016). The difference between prior and posterior emissions show that  
634 vegetation fires have a large impact on the BC emissions especially in Eastern Europe. In  
635 particular in 2015, the inversion produces large emission increases exactly where a large  
636 number of fire hot spots were found (see Figure S 6).

### 637 4.3 BC emissions in North Siberia

638 | Figure 12 illustrates the average posterior **BC emissions** in Western Siberia for the  
639 2013–2015 period together with the difference between the prior (ECLIPSEv5) and the  
640 posterior **BC emissions**, while Figure S 7 shows the respective **BC emissions** for each year  
641 individually, together with the flaring facilities and the vegetation fires similarly to the  
642 previous section.

643 | The prior **BC emissions** from flaring in Nenets-Komi oblast are confirmed by the  
644 inversion, although the emissions are shifted further east, while the flaring emissions in  
645 Khanty-Mansiysk are probably underestimated in ECLIPSEv5 (see also Table 3). Vegetation  
646 fires are shown to correlate well with BC emissions for 2013 (60°N –70°N) and 2014 (50°N–  
647 60°N) (Figure S 7), but not in 2015. Hotspots of high emissions were found in Dudinka  
648 (88°E–70°N), a town on the Yenisei River and the administrative center of Taymyrsky  
649 Dolgano-Nenetsky District of Krasnoyarsk Krai, Russia, due to the Norilsk Mining and  
650 Smelting Factory extracting coal and ores. Furthermore, increase posterior **BC emissions** were  
651 estimated across the line that connects some important Russian cities (Yekaterinsburg to  
652 Chelyabinsk, 60°E–55°N). These cities have been reported to contribute large amounts of BC  
653 mainly from transportation (see Evangeliou et al., 2018). Another hotspot exists at 108°E–  
654 58°N that corresponds to VIIRS night-time lights  
655 ([https://www.lightpollutionmap.info/#zoom=5.69666666666666656&lat=8239438&lon=12096  
656 227&layers=B0FFFFTFFFT](https://www.lightpollutionmap.info/#zoom=5.69666666666666656&lat=8239438&lon=12096227&layers=B0FFFFTFFFT)). These emissions are attributed to flaring as four facilities are

Deleted: emissions of BC

669 | collocated there (see [Figure 12](#)). Finally, high [BC emissions](#) originate from the Nizhny  
670 | Novgorod oblast (44°E–55°N). The oblast ranks seventh in Russia in industrial output.  
671 | Processing industries predominate in the local economy. The leading sectors of more than 650  
672 | industries are engineering and metalworking, followed by chemical and petrochemical  
673 | industries and forestry, woodworking, and paper industries and one facility that flare gas  
674 | (GGFR, [Figure 12](#)).

675 | In the western part of Siberia, there are numerous sources of average or low intensity.  
676 | However, there no known anthropogenic sources there. At the lowest part of the inversion  
677 | domain, in the borders of Russia with Mongolia, the posterior emissions showed a large  
678 | increase ([Figure 6](#)). These emissions are prevalent along the Trans-Siberian Railway. Human  
679 | activities in the villages along the railway have been highlighted to be the major cause of the  
680 | fires there.

#### 681 | 4.4 Seasonal variability of BC emissions

682 | The monthly optimised [BC emissions](#) are shown in [Figure 13](#), for the three years of  
683 | study (2013–2015) for the entire area north of 50°N, and separately for areas north of 50°N in  
684 | North America, North Europe, North Siberia, Nenets-Komi oblast (Russia) and Khanty-  
685 | Mansiysk (Russia). The last two regions are known to have large emissions from gas flaring.  
686 | In the same figure the prior emissions from ECLIPSEv5, EDGAR\_HTAPv2.2, ACCMIPv5  
687 | and MACCity are plotted for comparison.

688 | The total posterior [BC emissions](#) (>50°N) show large seasonal variation ([Figure 13a](#)).  
689 | The maximum emissions were calculated for summer months (July in 2013 and June in 2014  
690 | and 2015). In these months large emissions from biomass burning have been reported both in  
691 | GFED4 (see burned area in Giglio et al., 2013), as well as in the FEINE inventory for  
692 | Northern Eurasia (Hao et al., 2016). [Separating the inversion domain into continental regions](#)  
693 | [reveals where biomass burning is important](#). For instance, in North America ([Figure 13b](#)),  
694 | although GFED4 that is included in all the prior emission datasets, shows a large emission  
695 | peak for BC in summer implying that fires are important, our optimised emissions show a  
696 | significantly smaller variability. This was not the case for North Europe ([Figure 13c](#)) where  
697 | the largest seasonal [BC emissions](#) were found in July for 2013 and in May for 2015, while in  
698 | 2014 the largest peak [appeared](#) in April. This is not seen in the prior emission datasets, which  
699 | show weak monthly variation. The largest seasonal variations were calculated for Northern  
700 | Siberia ([Figure 13d](#)) and [BC emissions](#) there control the overall seasonal pattern for the total  
701 | optimised [BC emissions](#) (>50°N). A large month-to-month variability was estimated in the

720 Nenets-Komi oblast (Figure 13e), but no clear seasonal pattern. Finally, the largest monthly  
721 BC emissions in Khanty-Mansiysk oblast of Russia (Figure 13f) were calculated in April for  
722 2013, July for 2014 and June for 2015 showing that a large share in the BC emissions in this  
723 region originate from biomass burning since the region is located at mid-latitudes (60°N–  
724 65°N) and is vulnerable to open fires.

## 725 5 Conclusions

726 We have optimised BC emissions at high northern latitudes (>50°N) for the 2013–2015  
727 period using a Bayesian inversion tool, an atmospheric transport model and network of  
728 continuous measurements of BC. We performed a sensitivity study to assess the best  
729 representative species for BC according to the efficiency of in-cloud and below-cloud  
730 scavenging, and the best representative emission inventory to be used as the prior information  
731 for our inversion.

732 The perturbation of scavenging coefficients for BC in the simulated concentrations  
733 creates a relative model–observation mismatch of 32%–43% for the three years of study,  
734 whereas the use of different emission inventories has a less significant effect in the simulated  
735 concentrations showing a relative model–observation mismatch of 15%–23%.

736 The posterior BC emissions show characteristic hot-spots throughout all three years in  
737 the Nenets – Komi region close to the Yamal peninsula in Russia or in Khanty Mansiysk  
738 region of Northwestern Siberia, where gas flaring facilities are located and in Western Canada  
739 (Alberta), where more than 150 power and oil/gas production industries operate. The annual  
740 posterior BC emissions at latitudes above 50°N were estimated as  $560 \pm 171$  kt yr<sup>-1</sup>,  
741 significantly smaller than in ECLIPSEv5 (745 kt yr<sup>-1</sup>), which was used and the prior  
742 information in the inversions of BC (best representative emission dataset).

743 The uncertainty of the inversions was assessed using a model ensemble represented by  
744 12 different scavenging coefficients for BC and four different prior emission datasets  
745 (12×4=48) for each of the three years of our study. We calculate a relative uncertainty of the  
746 inversion of 30% for the three years of our study.

747 The posterior simulated concentrations of BC showed a better agreement with  
748 independent observations adopted from flight and ship campaigns over the Arctic presenting,  
749 in all cases, up to three times lower RMSE values.

750 In North America, the posterior emissions were found similar to the a priori ones driven  
751 by anthropogenic sources, while biomass burning appeared to be insignificant. This was  
752 confirmed by satellite products that showed weak existence of active fire hot-spots.

Deleted: emissions of BC

Nikolaos Evangeliou 20/9/2018 16:04

Deleted: emissions of BC

767 In North Europe, posterior emissions were estimated to be half compared to the prior  
768 ones, with the highest releases to be in megacities and due to biomass burning in Eastern  
769 Europe.

770 Finally, in North Siberia the larger emissions were calculated along the transect  
771 between Yekaterinsburg and Chelyabinsk, while flaring in Nenets-Komi oblast is probably  
772 overestimated in the a priori emissions. Increased emissions in the borders between Russia  
773 and Mongolia are probably due to biomass burning in villages along the Trans-Siberian  
774 Railway.

775

776 **Data availability.** All data generated for the present publication are stored on NIRD  
777 (<https://www.uio.no/english/services/it/research/storage/nird-sigma.html>) (project NS9419K)  
778 and can be obtained from the corresponding author upon request.

780 **Competing financial interests.** The authors declare no competing financial interests.

781

782 **Acknowledgements.** We would like to acknowledge the project entitled “Emissions of  
783 Short-Lived Climate Forcers near and in the Arctic (SLICFONIA)”, which was funded by the  
784 NORRUSS research program (Project ID: 233642) and the project entitled “The Role of  
785 Short-Lived Climate Forcers in the Global Climate” funded by the KLIMAFORSK program  
786 (Project ID: 235548) of the Research Council of Norway. Also the Research Council of  
787 Norway strategic institute initiatives (SIS) project “SOCA-Signals from the Arctic Ocean in  
788 the Atmosphere” is acknowledged. We also acknowledge partial support by the AMAP  
789 secretariat, as this work shall contribute to the next AMAP assessment on short-lived climate  
790 forcers. Work was performed at the Nordic Centre of Excellence eSTICC (eScience Tools for  
791 Investigating Climate Change in northern high latitudes), supported by NordForsk grant  
792 57001. We thank IIASA (especially Chris Heyes and Zig Klimont) for providing the  
793 ECLIPSEv5 emission dataset for BC. Computational and storage resources for the  
794 FLEXPART simulations were provided by NOTUR (NN9419K) and NIRD (NS9419K). All  
795 results can be accessed upon request to the corresponding author of this manuscript.

796

797 **Author contributions.** NE performed the simulations, analyses and wrote the paper, RLT  
798 helped in the adaptation of FLEXINVERT for BC and commented on the paper, SE helped in  
799 the implementation of the experiments and AS coordinated, commented and wrote parts of  
800 the paper.

FIGURES & LEGENDS

1097

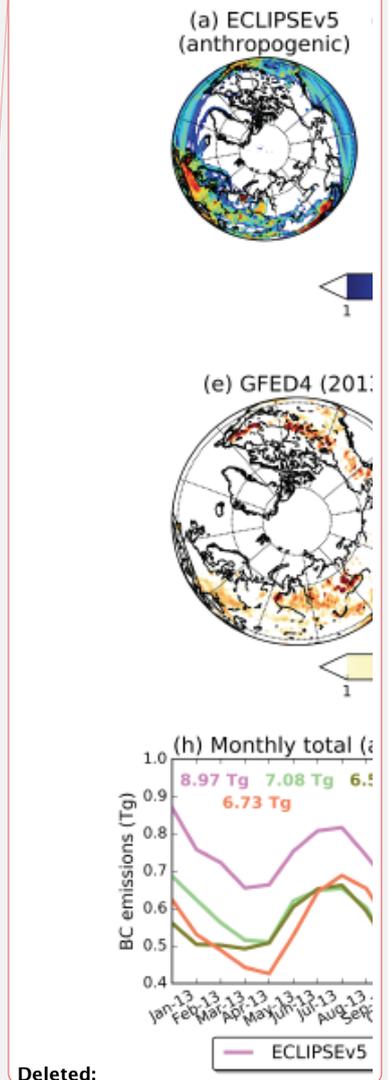

1098 **Figure 1.** Observation network used for the present inversion (a, b and c), and variable-  
1099 resolution grid used for the inversion (d, e, and f) also showing the location of the observation  
1100 sites (red stars) for 2013–2015 period. Sensitivity to the surface emissions (i.e., the footprint  
1101 emission sensitivity or equivalently source-receptor relationship) integrated over all  
1102 observation sites and all time steps (g, h and i) for the years 2013, 2014 and 2015 (units of  
1103 log(ns)).

1104  
 1105 **Figure 2.** (a–d) Anthropogenic emissions of BC in the inversion domain ( $>50^\circ\text{N}$ ) from  
 1106 ECLIPSEv5, EDGAR\_HTAPv2.2, ACCMIPv5 and MACCity (anthropogenic emissions are  
 1107 assumed to be constant throughout every year). (e–g) Biomass burning emissions from  
 1108 GFED4 for 2013, 2014 and 2015 (Giglio et al., 2013). (h) Monthly total (anthropogenic and  
 1109 biomass burning) **BC emissions** north of  $50^\circ\text{N}$  from 2013 to 2015 from the four prior  
 1110 inventories used for the inversion. Coloured numbers correspond to total annual BC from  
 1111 each emission inventory.

**COMPARISON OF PRIOR SIMULATED CONCENTRATIONS (ECLIPSEv5)  
(YEARS 2013-2015)**

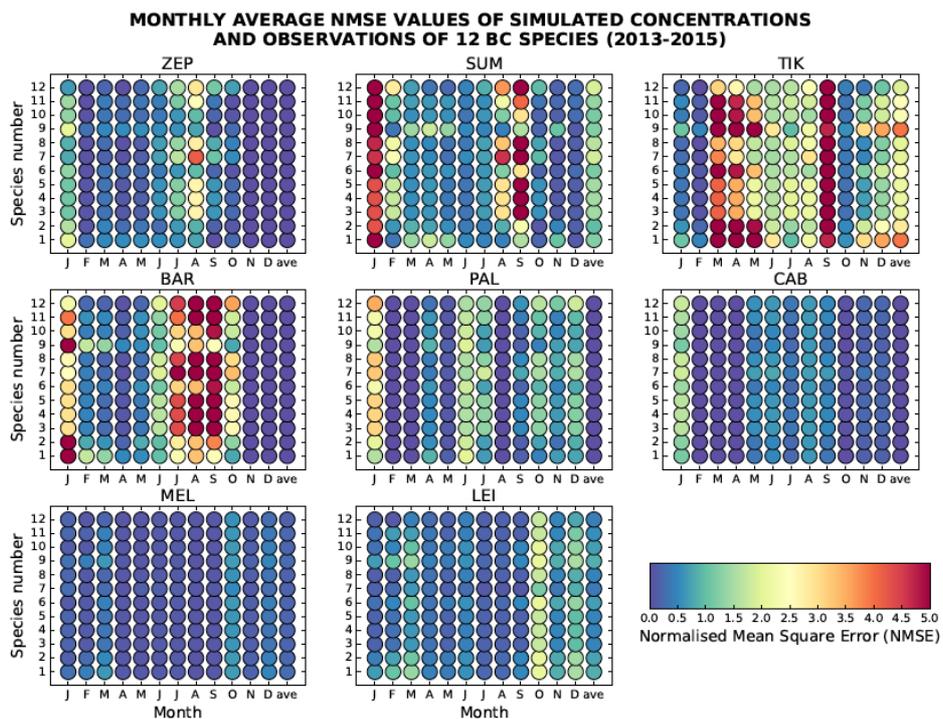

1115

1116 **Figure 3.** Taylor diagrams for the comparison of the prior (ECLIPSEv5) simulated  
 1117 concentrations with observations for all years (2013 – 2015) for 12 BC species with different  
 1118 scavenging coefficients (Table 2). The radius indicates standard deviations normalised  
 1119 against the mean concentration (NSD); the azimuthal angle the Pearson correlation  
 1120 coefficient, while the normalised (against observation) root mean square error (nRMSE) in  
 1121 the simulated concentrations is proportional to the distance from the point on the x-axis  
 1122 identified as “reference” (grey contours).

1133 **Figure 5.** Monthly average NMSE values due to use of different emission inventories  
 1134 (ECLIPSEv5, ACCMIPv5, EDGAR\_HTAPv2.2, MACCcity) for the eight stations with  
 1135 complete data in the period 2013–2015. The annual mean is denoted as “ave”).

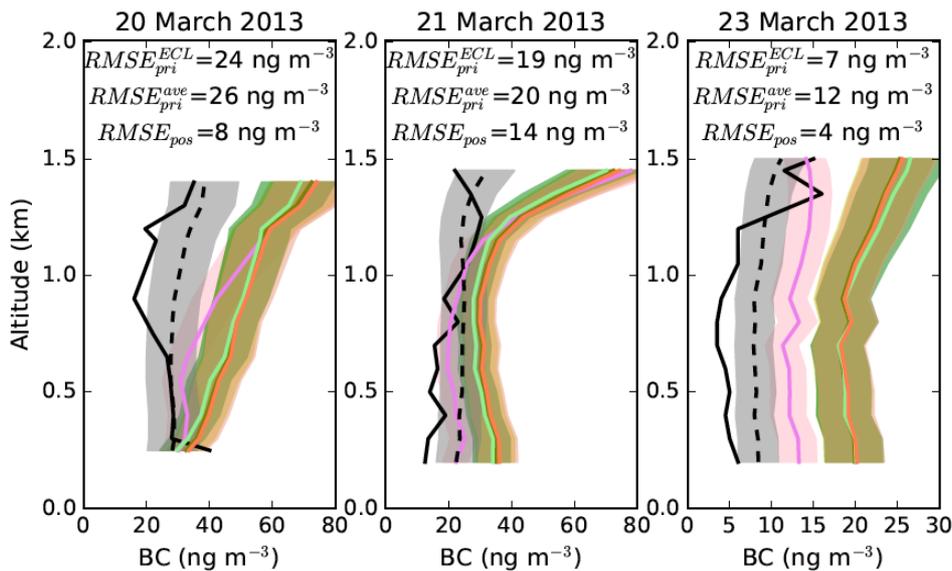

1136

1137  
 1138 **Figure 6.** (a) Annual posterior emissions of BC in areas >50°N averaged for the period 2013–  
 1139 2015, (b) average posterior uncertainty due to scavenging and use of different prior emissions  
 1140 for the same period. (c) Difference between posterior and prior emissions for 2013–2015.

1141

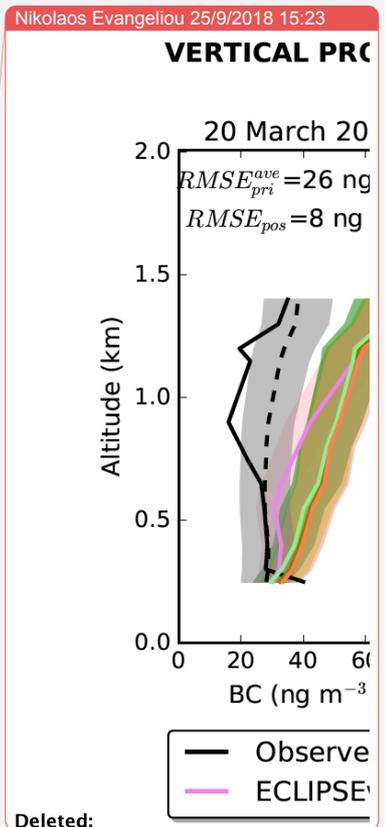

### VERTICAL PROFILES OF BC (ACCACIA FLIGHT CAMPAIGN)

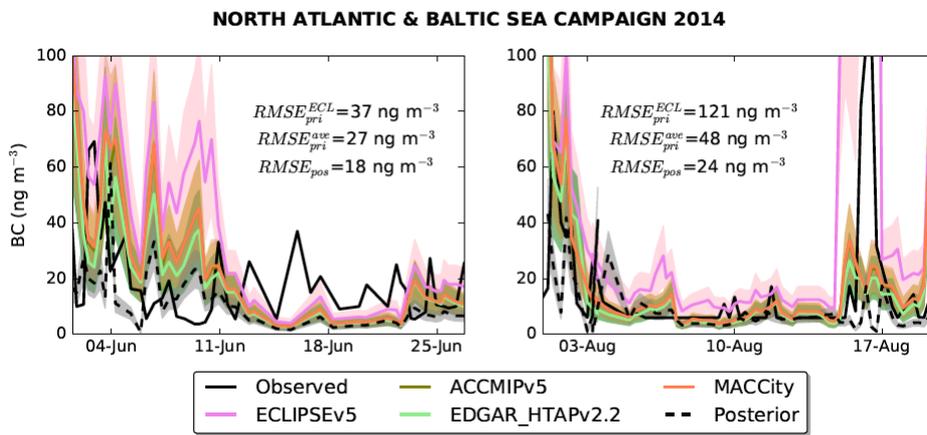

1142

1143 **Figure 7.** Comparison of prior (ECLIPSEv5, ACCMIPv5, EDGAR HTAPv2.2 and  
 1144 MACCity) and posterior simulated concentrations of BC with observations from the  
 1145 ACCACIA flight campaign near Zeppelin station, Ny-Ålesund in 2013 adopted from Sinha et  
 1146 al. (2017). The variability of the prior concentrations (shaded area) was calculated as the  
 1147 standard deviation of BC concentrations from the 12 species with different scavenging  
 1148 coefficients as shown in [Table 2](#). Uncertainties of the posterior concentrations are due to  
 1149 scavenging and use of 4 different a priori datasets (section 3.4). RMSE values are computed  
 1150 for ECLIPSEv5 concentrations, all prior concentrations (average) and posterior simulated BC  
 1151 concentrations.

1152

Nikolaos Evangeliou 27/9/2018 11:26  
 Deleted: Table 2

1155

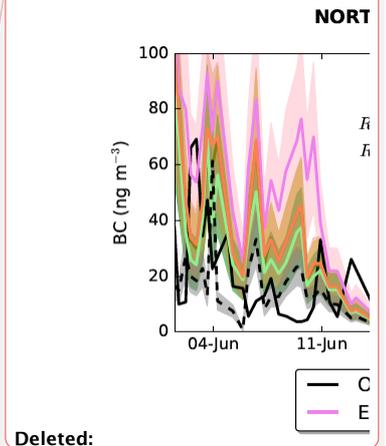

1156 **Figure 8.** Comparison of prior (ECLIPSEv5, ACCMIPv5, EDGAR HTAPv2.2 and  
 1157 MACCity) and posterior simulated concentrations of BC with observations from a ship  
 1158 campaign in North Atlantic and Baltic Seas in 2014 adopted from Shevchenko et al. (2016).  
 1159 The variability of the prior concentrations (shaded area) was calculated as the standard  
 1160 deviation of BC concentrations from the 12 species with different scavenging coefficients as  
 1161 shown in [Table 2](#). Uncertainties of the posterior concentrations are due to scavenging and use  
 1162 of 4 different a priori datasets (section 3.4). RMSE values are computed for ECLIPSEv5  
 1163 concentrations, all prior concentrations (average) and posterior simulated BC concentrations.

1215 **Figure 13.** Monthly posterior emissions of BC shown for all regions located (a)  $>50^{\circ}\text{N}$ , (b) in  
 1216 North America ( $>50^{\circ}\text{N}$ ), (c) North Europe ( $>50^{\circ}\text{N}$ ), (d) North Siberia ( $>50^{\circ}\text{N}$ ), (e) Nenets-  
 1217 Komi oblast ( $>50^{\circ}\text{N}$ , Russia) and (f) Khanty-Mansiysk oblast ( $>50^{\circ}\text{N}$ , Russia) for the 2013–  
 1218 2015 period. Monthly prior emissions of BC from ECLIPSEv5, EDGAR-HTAPv2.2,  
 1219 ACCMIPv5 and MACCity emissions inventories are also shown for the same regions and  
 1220 time period. The uncertainty of the posterior emissions of BC stems from the use of different  
 1221 scavenging coefficients and different prior emission datasets (see section 3.3).

1223 **SUPPLEMENTARY FIGURES & LEGENDS**

1224

1225 **Figure S 1.** Taylor diagrams for the comparison of the prior simulated concentrations with  
1226 observations for all years (2013 – 2015) for 12 BC species with different scavenging  
1227 coefficients (**Table 2**). The radius indicates standard deviations normalised against the mean  
1228 concentration (NSD); the azimuthal angle the Pearson correlation coefficient, while the  
1229 normalised (against observation) root mean square error (nRMSE) in the simulated  
1230 concentrations is proportional to the distance from the point on the x-axis identified as  
1231 “reference” (grey contours). The results refer to the use of ACCMIPv5, EDGAR\_HTAPv2.2  
1232 and MACCity as the prior emissions.

1233

1234 **Figure S 2.** Monthly average relative model-observation mismatches  
1235 ( $[\text{model} - \text{observations}] / \text{observations}$ ) for prior simulated (average values from all  
1236 four inventories used) concentrations of BC due to the perturbation of scavenging parameters  
1237 according to **Table 2**, for the inversions of 2013, 2014 and 2015.

1238

1239 **Figure S 3.** Monthly average model-observation mismatches ( $[\text{model} - \text{observations}] /$   
1240  $\text{observations}$ ) for prior simulated concentrations of BC (best species) due to use for four  
1241 different emission inventories (ECLIPSEv5, ACCMIPv5, EDGAR\_HTAPv2.2 and  
1242 MACCity) for the inversions of 2013, 2014 and 2015.

1243

1244 **Figure S 4.** Taylor diagrams for the comparison of the posterior simulated concentrations  
1245 with observations for all years (2013 – 2015). The radius indicates standard deviations  
1246 normalised against the mean concentration (NSD); the azimuthal angle the Pearson  
1247 correlation coefficient, while the normalised (against observation) root mean square error  
1248 (nRMSE) in the simulated concentrations is proportional to the distance from the point on the  
1249 x-axis identified as “observed” (grey contours).

1250
