12 **Abstract**

13 This paper presents the results of BC inversions at high northern latitudes ($>50^{\circ}\text{N}$) for
14 the 2013–2015 period. A sensitivity analysis was performed to select the best representative
15 species for BC and the best prior emission dataset. The same model ensemble was used to
16 assess the uncertainty of the posterior emissions of BC due to scavenging and removal and
17 due to the use of different prior emission inventory. The optimised emissions of BC were high
18 close to the gas flaring regions in Russia and in Western Canada (Alberta), where numerous
19 power and oil/gas production industries operate. The annual posterior emissions of BC at
20 latitudes above 50°N were estimated as 560 ± 171 kt yr⁻¹, significantly smaller than in
21 ECLIPSEv5 (745 kt yr⁻¹), which was used and the prior information in the inversions of BC.
22 The average relative uncertainty of the inversions was estimated to be 30%.

23 Posterior concentrations of BC simulated over Arctic regions were compared with
24 independent observations from flight and ship campaigns showing, in all cases, smaller bias,
25 which in turn witnesses the success of the inversion. Posterior emissions of BC in North
26 America are driven by anthropogenic sources, while biomass burning appeared to be less
27 significant as it is also confirmed by satellite products. In North Europe, posterior emissions
28 were estimated to be half compared to the prior ones, with the highest releases to be in
29 megacities and due to biomass burning in Eastern Europe. The largest emissions of BC in
30 Siberia were calculated along the transect between Yekaterinsburg and Chelyabinsk. Flaring
31 emissions in Nenets-Komi oblast (Russia) were estimated to be much lower than in the prior
32 emissions, while in Khanty-Mansiysk (Russia) they remained the same after the inversions of
33 BC. Increased emissions in the borders between Russia and Mongolia are probably due to
34 biomass burning in villages along the Trans-Siberian Railway.

35

36 1 Introduction

37 Light absorbing components, such as black carbon (BC), is the main of atmospheric
38 particulate matter, affecting air quality, weather and climate. BC originates from the
39 incomplete combustion of fossil fuels (primarily coal and diesel) as well as from the burning
40 of biomass and biofuels. BC particles affect cloud formation and precipitation as they act as
41 cloud condensation nuclei in their hydrophilic form (Wang et al., 2016). BC is also a major
42 driver of climate change contributing to global warming with a radiative forcing at the top of
43 the atmosphere ranging between 0.17 and 0.71 W m⁻² (Bond et al., 2013; Myhre et al., 2013;
44 Wang et al., 2014). BC deposited in Arctic snow surfaces in concentrations of up to 30 ng g⁻¹
45 can reduce snow albedo by 1–3% (Hegg et al., 2009) in fresh snow and up to 3 times more as
46 snow ages and the BC particles become more concentrated (Clarke and Noone, 1985).
47 Airborne BC also warms the air and reduces tropical cloudiness by absorbing the incoming
48 solar radiation (Ackerman, 2000). It also reduces atmospheric visibility and increases aerosol
49 optical depth (Jinhuan and Liquan, 2000). From a health perspective, BC particles, generally
50 being sub-micron in size, can penetrate into the lungs and cause pulmonary diseases (e.g.,
51 Wang et al., 2014).

52 To improve understanding about how BC affects climate and to develop effective
53 policies to tackle BC's associated environmental problems requires accurate knowledge of the
54 emissions and their spatiotemporal distribution. Most commonly, BC emission inventory
55 datasets are built by “bottom up” approaches, which are based on activity data and emission
56 factors and proxy information for spatial disaggregation, but these methods are considered to
57 have large uncertainties (Cao et al., 2006). Numerous global or regional emission inventories
58 of BC have been constructed previously (Bond et al., 2004; Schaap et al., 2004; Streets et al.,
59 2003); nevertheless, emission uncertainties contribute significantly to the overall uncertainty
60 of modelled concentrations of BC. Emission uncertainties affect even more significantly
61 regional/episodic simulations, as in many cases emissions deviate from the annual mean.
62 Such studies represent a useful tool to improve our understanding of the relationship between
63 observed concentrations of BC and BC emissions. Furthermore, BC emissions have their
64 most pronounced effect on the regional scale due to the relatively short atmospheric lifetime
65 of BC (Hodnebrog et al., 2014; Samset et al., 2014),.

66 The relative differences between different emission inventories are largest for the high
67 latitudes (AMAP, 2015) and particularly in high-latitude Russia where emission information
68 is poor. For this area, a new satellite-based high-resolution inventory showed that BC
69 emissions from Biomass Burning (BB) might have been 3.5 times higher than emissions

70 given in the Global Fire Emissions Database (GFEDv4) (Hao et al., 2016), if more realistic
71 emission factors are used (May et al., 2014). Furthermore, new sources of BC in the same
72 area have been identified recently. For example, emissions from gas flaring by the oil industry
73 have been missing from most emission inventories and may be an important source of BC at
74 high latitudes (Stohl et al., 2013). For instance, in 2008 Russia was responsible for nearly one
75 third of the gas flared globally (Elvidge et al., 2009). However, the gas flaring source is
76 highly uncertain. For example, based on isotopic measurements, Winiger et al. (2017)
77 reported recently that the contribution from gas flaring to BC measured at Tiksi in Siberia is
78 lower than estimated by Stohl et al. (2013), while recently published bottom-up inventories
79 (Huang et al., 2015; Huang and Fu, 2016) suggested even higher gas flaring emissions.
80 Finally, Popovicheva et al. (2017) reported that one existing emission dataset of BC captured
81 surface concentrations in the Russian Arctic quite efficiently.

82 In this study, we estimated the BC emissions at high northern latitudes using
83 atmospheric observations of BC in a Bayesian inversion framework. Emissions were
84 estimated for the region north of 50°N because this is the region with the largest influence on
85 Arctic surface concentrations (Klonecki, 2003; Stohl, 2006). We determine the emissions
86 with monthly time resolution for the years 2013, 2014 and 2015. We first describe the
87 observation data, the transport model and the Bayesian inversion technique used, as well as
88 the prior emission information. We then assess the sensitivity of the transport model to
89 different scavenging coefficients (below-cloud and in-cloud) for BC and to different emission
90 inventories. We finally present optimised BC emissions, discuss these results in comparison
91 with independent estimates and calculate the uncertainty of the inversions with respect to
92 different scavenging parameters used for BC and using four different prior emission datasets.

93 **2 Methodology**

94 **2.1 Observation network**

95 Atmospheric observations of BC were retrieved from the World Data Centre for
96 Aerosols (<http://ebas.nilu.no>) and from the International Arctic Systems For Observing The
97 Atmosphere (<http://www.esrl.noaa.gov/psd/iasoa/>). An overview of the stations used in this
98 paper can be found in Table 1 and Figure 1a–c. The selected measurements were performed
99 with different types of instruments that may differ substantially. When measurements are
100 based on light absorption we refer to Equivalent BC (EBC), while measurements based on
101 thermal-optical methods refer to elemental carbon (EC) (Petzold et al., 2013).

102 At Alert (ALT), Appalachian (APP), Asprveten (ASP), Birkenes (BIR), East Trout
103 Lake (ETL), South Great Planes (SGP), Steamboat Springs (COL), Trinidad Head (TRI) and
104 Whistler (WHI) measurements were performed with particle soot absorption photometers
105 (PSAPs). At Annaberg-Buchholz (ANB), Bösel (BOS), Cabauw Zijdeweg (CAB), Hyytiälä
106 (HYY), Leipzig (LEI), Melpitz (MEL), Nepal Climate Observatory (NEP), Pallas (PAL), Ústí
107 n.L.-mesto (ULM) and Waldhof (WLD) the particle light absorption coefficient was
108 measured by multi-angle absorption photometers (MAAP; Petzold and Schönlinner, 2004),
109 which are in excellent agreement with other particle light absorption photometers such as a
110 photoacoustic sensor (e.g., Muller et al., 2011). In the MAAP instrument, particles are
111 continuously sampled on filter tape, with loaded spots subsequently analysed by Raman
112 spectroscopy to derive the particle mass concentration of soot (Nordmann et al., 2013). The
113 cut-off sizes of the different MAAP instruments varied between 1 and 10 μm . Continuous
114 light absorption photometers (CLAP, Model PSAP; 565 nm) were used at Barrow (BAR),
115 Bondville (BON), Gosan (GOS), K-pusztá (KPU), BEO Moussala (MOU) and Summit
116 (SUM). Although these instruments were calibrated to measure the aerosol absorption
117 coefficient, a previous study at this site revealed that a value of $10 \text{ m}^2 \text{ g}^{-1}$ is a reasonable
118 conversion factor to determine the BC concentration (Gelencsér et al., 2000). Aethalometers
119 were used at Tiksi (TIK) and Zeppelin (ZEP).

120 All these stations measure the particle light absorption coefficients of different size
121 fractions of the aerosol at wavelengths around 530–550 nm. Then the light absorption
122 coefficients are converted to EBC mass concentrations under certain assumptions (Petzold et
123 al., 2013). This is done externally for instruments such as MAAP, CLAP, PSAP etc. using a
124 mass absorption efficiency of $10 \text{ m}^2 \text{ g}^{-1}$ (Bond and Bergstrom, 2006). For aethalometers, the
125 conversion is done internally by the instrument. All station measurements are routinely
126 filtered to remove influence from local sources.

127 **2.2 Source – Receptor Relationships (SRRs)**

128 We used the Lagrangian Particle Dispersion Model (LPDM), FLEXible PARTicle
129 dispersion model (FLEXPART) (Stohl et al., 1998, 2005) to model atmospheric transport.
130 Using LPDMs to model particle or trace gas concentrations has several advantages over
131 Eulerian models, namely they can have quasi-infinite resolution and they are not subject to
132 numerical diffusion. Thus they can provide better resolved source-receptor relationship (SRR)
133 fields, which describe the relationship between the sensitivity of a “receptor” to a “source”

134 element, as described by Seibert and Frank (2004). SRRs for the lowest model level are often
135 called footprint emission sensitivities or even just footprints.

136 SRRs were calculated using FLEXPART version 10 in a backwards mode (see Stohl et
137 al., 2005) in which computational particles are released backward in time from the
138 observation sites (receptors). When the number of observation sites is smaller than the
139 number of unknown flux grid cells this mode is computationally more efficient than forward
140 calculations. Furthermore, backward simulations can be initiated exactly at the measurement
141 point without initial diffusion of information into a grid cell. This important advantage of
142 LPDMs also facilitates high spatial resolution of the model output around the measurement
143 sites. As meteorological input data, European Centre for Medium-Range Weather Forecasts
144 operational meteorological analyses were used with 137 vertical levels and a horizontal
145 resolution of $0.5^\circ \times 0.5^\circ$. Retroplumes were calculated at hourly intervals at each of the
146 receptors. 40,000 particles for each retroplume were released and followed 30 days backwards
147 in time. This should be a sufficiently long time in order to include almost all contributions to
148 BC concentration at the receptor given the atmospheric lifetime of BC (in the range of 2–10
149 days, Benkovitz et al., 2004; Koch and Hansen, 2005; Park et al., 2005; Textor et al., 2006).

150 The treatment of scavenging is a major uncertainty for modelling BC (Browse et al.,
151 2012). Therefore, an ensemble of 12 model simulations was performed each with different
152 BC tracers having different in–cloud and below–cloud scavenging properties (Table 2). This
153 method allows the sensitivity of the SRRs (produced by FLEXPART) to scavenging to be
154 quantified. Table 2 shows the different below–cloud and in–cloud scavenging parameters
155 used within the model in the sensitivity runs. For all tracers, we assumed a logarithmic size
156 distribution with an aerodynamic mean diameter of $0.25 \mu\text{m}$, a logarithmic standard deviation
157 of 0.3 and a particle density of 1500 kg m^{-3} (Long et al., 2013). The dry deposition scheme in
158 FLEXPART is based on the resistance analogy (Slinn 1982). The present version of the
159 model uses the precipitation rate from ECMWF to determine below-cloud scavenging and the
160 cloud liquid water and ice content, precipitation rate and cloud depth from ECMWF to
161 calculate in-cloud scavenging (see Grythe et al., 2017).

162 The SRR at the lowest model layer (in seconds) (Figure 1g–i) can be multiplied with
163 gridded emission fluxes from a BC emission inventory (in $\text{kg m}^{-2} \text{ s}^{-1}$) distributed over the
164 layer depth (100 m). This gives the prior concentration of BC at the receptor point (in ng m^{-3}).

165 2.3 Bayesian inversion

166 The inversion methodology used in the present study, FLEXINVERT, is described fully
167 in Thompson and Stohl (2014) and has been already used in studies of CH₄, HFC-125, HFC-
168 134a and SF₆ (Brunner et al., 2017; Thompson et al., 2015, 2017). Since atmospheric
169 transport and deposition are linear operations, they can be described as a Jacobian matrix of
170 SRRs (**H**). The BC concentrations (**y**) can then be modelled given an estimate of the
171 emissions (**x**) as follows:

$$172 \quad \mathbf{y} = \mathbf{H}(\mathbf{x}) + \boldsymbol{\varepsilon} \quad (1)$$

173 where $\boldsymbol{\varepsilon}$ is an error associated with model representation, such as the modelled transport and
174 deposition as well as the measurements. Since **H** is generally not invertible (or may have no
175 unique inverse), statistical optimization methods are used, which require prior information for
176 regularization. According to Bayesian statistics, the problem can be expressed as the
177 maximization of the probability density function of the emissions given the prior information
178 and observations and is equivalent to finding the minimum of the cost function:

$$179 \quad \mathbf{J}(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}_b) + \frac{1}{2}(\mathbf{y} - \mathbf{H}\mathbf{x})^T \mathbf{R}^{-1}(\mathbf{y} - \mathbf{H}\mathbf{x}) \quad (2)$$

180 where **B** and **R** are the error covariance matrices for the prior emissions and the observations,
181 respectively. The error in the observation space also accounts for model representation errors
182 that are not related to the BC emissions. The emissions that minimize the cost function can be
183 found by solving the first order derivative of equation (2). Hence, the following equation can
184 be derived for the most probable emissions, **x** (for details see e.g. Tarantola, 2005):

$$185 \quad \mathbf{x} = \mathbf{x}_b + \mathbf{B}\mathbf{H}^T(\mathbf{H}\mathbf{B}\mathbf{H}^T + \mathbf{R})^{-1}(\mathbf{y} - \mathbf{H}\mathbf{x}_b) \quad (3)$$

186 In this study, the state vector contains the monthly unknown surface emissions on the
187 grid of variable resolution (Figure 1d–f) and has a resolution of between 1.0°×1.0° and
188 8.0°×8.0°. The total number of emission variables to be determined was 1422 for 2013, 1404
189 for 2014 and 1436 for 2015. The posterior error covariance matrix, **A**, is equivalent to the
190 inverse of the second derivative of the cost function. However, to account for the uncertainty
191 in the scavenging parameters and different prior information, we instead conduct ensemble of
192 inversions to estimate the posterior uncertainty in order to account for the systematic errors.
193 To do this, we conduct the inversion for BC represented by 12 different scavenging
194 coefficients (see Table 2) and for four different prior emission datasets, and do this for each of
195 the three years of our study (2013–2015). The resulting model ensemble (12×4=48) for each
196 year defines the posterior uncertainty due to scavenging and use of different a priori
197 information (section 3.3).

198 Since negative values for the posterior emissions are mathematically possible but
199 physically unlikely, we applied a subsequent inequality constraint on the emissions following
200 the method of Thacker (2007). This is a truncated Gaussian approach in which inequality
201 constraints are applied as error-free “observations”:

$$202 \quad \hat{\mathbf{x}} = \mathbf{x} + \mathbf{A}\mathbf{P}^T(\mathbf{P}\mathbf{A}\mathbf{P}^T)^{-1}(\mathbf{c} - \mathbf{P}\mathbf{x}) \quad (4)$$

203 where \mathbf{A} is the posterior error covariance matrix, \mathbf{P} is a matrix operator to select the variables
204 that violate the inequality constraint, and \mathbf{c} is a vector of the inequality constraint, which in
205 this case is zero.

206 The emissions were solved on an irregular grid, which has been optimized based on the
207 SRRs to give higher resolution ($1.0^\circ \times 1.0^\circ$) in regions where there is strong contribution
208 from emission sources to BC concentrations and lower ($8.0^\circ \times 8.0^\circ$) where there is a weak
209 contribution (Stohl et al., 2009). Then, the results are interpolated onto a uniform grid of
210 $1.0^\circ \times 1.0^\circ$ resolution from 180°W to 180°E and 50°N to 90°N and are given at monthly time
211 resolution for 2013, 2014 and 2015. To constrain emissions of BC monthly, a temporal
212 correlation scale length between flux time-steps equal to 90 days was set.

213 **2.4 A priori emission information**

214 In the present study, the emission inventories ECLIPSE (Evaluating the CLimate and
215 Air Quality ImPacts of ShortlivEd Pollutants) version 5 (Klimont et al., 2017) (available here:
216 http://www.iiasa.ac.at/web/home/research/researchPrograms/air/Global_emissions.html),
217 EDGAR (Emissions Database for Global Atmospheric Research) version HTAP_V2.2
218 (Janssens-Maenhout et al., 2015) (available here:
219 <http://edgar.jrc.ec.europa.eu/methodology.php#>), ACCMIP (Emissions for Atmospheric
220 Chemistry and Climate Model Intercomparison Project) version 5 (Lamarque et al., 2013)
221 (available here: http://accent.aero.jussieu.fr/ACCMIP_metadata.php) and MACCity
222 (Monitoring Atmospheric Composition & Climate / megaCITY - Zoom for the ENvironment)
223 (Wang et al., 2014) (available here: http://accent.aero.jussieu.fr/MACC_metadata.php) were
224 used as the prior emission estimates of BC (see Figure 2).

225 The ECLIPSE emission inventory (Figure 2a) accounts for waste burning, industrial
226 combustion and processing, surface transportation that also includes power plants, energy
227 conversion and extraction that also includes gas flaring, residential and commercial
228 combustion.

229 The HTAP_V2 dataset (Figure 2b) consists of high-resolution gridded emissions of BC
230 based on nationally reported emissions combined with regional scientific inventories. It

231 includes the sources of aviation, inland waterways and marine shipping, energy production
232 other than electricity generation, industrial processes, solvent production and application,
233 electricity generation, ground transport, buildings heating, cooling, equipment, and waste
234 disposal or incineration.

235 The ACCMIP simulations use the BC emission inventory covering the historical period
236 (1850–2000) provided by (Lamarque et al., 2010), which is built for the climate model
237 simulations in CMIP5 (Figure 2c). Anthropogenic emissions are mainly based on Bond et al.
238 (2004) but apply new emission factors. The year 2000 dataset was used for harmonization
239 with the future emissions determined by Integrated Assessment Models (IAMs) for the four
240 Representative Concentration Pathways (RCP4.5, RCP6, and RCP8.5). They include
241 emissions from energy production and distribution, industry (combustion and non-
242 combustion), transportation, maritime transport and aviation, residential and commercial
243 combustion and solvent extraction, agricultural production and waste treatment.

244 MACCity (Figure 2d) was built as an extension of the historical emissions dataset of
245 ACCMIP. It provides monthly averaged sectorial emissions for each year during the 1960-
246 2010 period. This dataset was based on the decadal ACCMIP emissions for 1960-2000 and
247 the 2005 and 2010 emissions provided by RCP 8.5. This scenario was chosen since it
248 included some information on recent emissions at the regional scale in Europe and North
249 America. The emission sectors are consistent with Lamarque et al. (2010).

250 Emissions from biomass burning were adopted from the Global Fire Emissions
251 Database, Version 4 (GFEDv4) (Giglio et al., 2013) and implemented to each of the four
252 emission inventories for 2013, 2014 and 2015. Emissions from gas flaring are only included
253 in ECLIPSEv5 inventory.

254 **3 Results**

255 **3.1 Sensitivity to scavenging and selection of the best representative species** 256 **for BC**

257 The comparison of the simulated and observed concentrations for the 12 different BC
258 tracers (see Table 2) is shown in Taylor diagrams in Figure 3 for ECLIPSEv5 and in Figure S
259 1 for ACCMIPv5, EDGAR_HTAPv2.2 and MACCity, only for those stations that had
260 continuous measurements for all the years of our study (2013–2015) namely ZEP, SUM, TIK,
261 BAR, PAL, CAB, MEL and LEI (see Table 1). For all the different BC species,

262 concentrations of BC were calculated using the FLEXPART SRR and the four different
263 emission datasets for 2013, 2014 and 2015.

264 Correlations of modelled and observed surface concentrations of BC were high (>0.5)
265 only at stations ALT, MEL and LEI that present low NSD values (<1) and low nRMSE
266 values. All NSD values were below 1.5 except at TIK and ULM stations (see Figure 3 and
267 Figure S 1). In general, dispersion models fail to reproduce BC concentrations close to TIK
268 station (Eckhardt et al., 2015; Evangeliou et al., 2016), as the station has been reported to
269 receive pollution from local anthropogenic sources (Asmi et al., 2016). ULM station is
270 located on the border between Germany and the Czech Republic and was shown previously to
271 be strongly affected by BC emissions from residential combustion sources (Schladitz et al.,
272 2015). The model-observation mismatches ($[model - observations]/observations$) due to
273 the use of 12 different species for BC can be seen in Figure S 2 for the years 2013, 2014 and
274 2015. These values are average concentrations from the use of the four different emissions
275 inventories (ECLIPSEv5, ACCMIPv5, EDGAR_HTAPv2.2 and MACCity). The extreme
276 perturbation of the scavenging coefficients of BC caused an average relative model-
277 observation mismatch (normalised against observations) of about 39% in 2013 (Figure S 2) at
278 all stations.

279 Similar to 2013, 12 species with different scavenging parameters were used for BC
280 following Table 2 in 2014 and the comparison with observations is shown in Taylor diagrams
281 in Figure 3 using ECLIPSEv5 emissions and in Figure S 1 using ACCMIPv5,
282 EDGAR_HTAPv2.2 and MACCity for the common stations. The comparison of surface
283 simulated concentrations with observations showed NSD values above one, high nRMSE
284 values and correlation coefficients below 0.5 in at most of the stations. The main difference
285 from year 2013 is that the model-observation mismatches for the surface concentrations of the
286 12 BC species was estimated to be 32% in 2014 (Figure S 2), in contrast to 39% in 2013. The
287 same deficiency of the model to capture the spring and summer concentrations of BC was
288 observed. The calculated mismatches were very low in at most of the lower latitude stations
289 and increased towards the remote Arctic ones (Figure S 2).

290 Finally, in 2015 the comparison of surface concentrations for each of the 12 different
291 BC species using the four different datasets (ECLIPSEv5, ACCMIPv5, EDGAR_HTAPv2.2
292 and MACCity) with observations showed again the same pattern as in the previous years with
293 most of the NSD values to be above unity, high nRMSE values and low Pearson coefficients
294 (Figure 3 and Figure S 1). The model-observation mismatches of BC concentrations (Figure S
295 2) were estimated as high as 43% for the stations where full measurements existed for the

296 three years of the study (2013–2015). Like in the previous years, the model failed to
297 reproduce surface concentrations of BC at some of the remote stations of the Arctic.

298 We used the NMSE (Normalised Mean Square Error) to select the most representative
299 BC tracer species. The NMSE is an estimator of the overall deviations between predicted and
300 measured values. It is defined as:

$$301 \quad NMSE = \frac{1}{N} \sum_i \frac{(O_i - P_i)^2}{\overline{P_i} \overline{O_i}} \quad (5)$$

302 where O_i and P_i are observed and predicted concentrations, N the number of observations for
303 which we assess the predicted values, while the overbar indicates the mean over the number
304 of observations for O_i and P_i . Contrary to the relative mismatches, in the NMSE the squared
305 deviations (absolute values) are summed instead of the differences. For this reason, the
306 NMSE generally shows the most striking differences among models. NMSE is a highly
307 selective statistical quantity that can give large differences between models that perform
308 similarly for other statistical measures. The lower the NMSE value, the better the
309 performance of the model. On the other hand, high NMSE values do not necessarily mean
310 that a model is completely wrong as the errors could be due to shifts in time and/or space.
311 Moreover, it must be pointed out that NMSE is sensitive to outliers (Poli and Cirillo, 1993).

312 The calculated monthly average NMSE values for the 12 species using ECLIPSEv5 as
313 the emission input can be seen in Figure 4 for year 2013–2015. The different scavenging
314 coefficients used did not create a large variation in the monthly concentrations of BC. The
315 best performance for the majority of the stations examined and most months was obtained for
316 species 1, 2 and 10 (see Table 2). In terms of model response over the Arctic stations, a better
317 performance was achieved for species 1 than for the other two. Therefore, we have chosen
318 species 1 as our reference species for all subsequent analyses and the inversions. It should be
319 noted here that the same test was performed using ACCMIPv5, EDGAR_HTAPv2.2 and
320 MACCity emissions. Although the results were worse, the best-performed species for BC
321 were again 1, 2 and 10.

322 **3.2 Sensitivity to different prior information and selection of the best prior** 323 **emission inventory**

324 In this section we assess the impact of using the different prior emission inventories for
325 BC and select the most appropriate one for our BC inversions. For this analysis, the best
326 performing species 1 for BC (see Table 2) was chosen and the monthly relative model –
327 observation mismatches ($([model - observations]/observations)$) for all stations and
328 years separated were calculated using all four inventories and are depicted in Figure S 3.

329 The largest monthly relative model-observation mismatches for the a priori simulated
330 concentrations of BC in 2013 were calculated for stations located close to 50°N (BOS, CAB
331 MEL, LEI, ULM, ANB). The average model-observation mismatch for all stations was 15%
332 for 2013. Similar results were found for 2014 for the prior simulated BC concentrations with
333 the largest relative mismatches recorded at mid-latitude stations where the BC concentrations
334 were very high due to large anthropogenic emissions (BOS, CAB, MEL, LEI). On average,
335 the relative model-observation mismatch was as high as 23% for the year 2014. Finally, in
336 2015, again the highest monthly relative mismatches of the a priori BC concentrations were
337 estimated for the stations of high anthropogenic influence (CAB, MEL, LEI, WLD). The
338 average relative model-observation mismatch in 2015 was only 19%, much lower than all
339 previous years. The fact that all prior emission datasets used failed to reproduce the
340 observations in central Europe during all years studied (2013, 2014 and 2015), whereas other
341 stations at mid-latitudes were reproduced well, might imply either missing sources or highly
342 uncertain measurements (Figure S 3). The use of different emission dataset changes simulated
343 concentrations by 23% at maximum.

344 NMSE values calculated for each of the four emission inventories were very low at the
345 majority of the stations for which data existed in all the years of study (ZEP, SUM, TIK,
346 BAR, MEL and LEI), when ECLIPSEv5 emissions were used, while at PAL all emission
347 datasets performed well (Figure 5). At most of the Arctic stations, the simulations using
348 ECLIPSEv5 reproduced the observations better compared to the other inventories examined.
349 This shows that the most appropriate emission dataset for our purpose is the ECLIPSEv5
350 inventory, as it is the only one that can capture the characteristically elevated concentrations
351 of BC in the Arctic, which persist until spring, and are caused by anthropogenic emissions
352 (Law and Stohl, 2007). A significant deficiency is found for TIK for reasons that were
353 explained earlier (see section 3.1).

354 **3.3 Optimised (a posteriori) emissions of BC and associated uncertainty**

355 The optimised annual emissions of BC together with the associated posterior gridded
356 uncertainty and the difference between posterior and prior emissions averaged for the 2013–
357 2015 period can be seen in Figure 6. The posterior emissions were calculated for the best
358 performing species (species 1) of BC and the best prior emissions inventory (ECLIPSEv5).
359 The total posterior uncertainty was calculated as the standard deviation of the posterior
360 emissions calculated for the 12 BC species with different scavenging coefficients for four
361 different emission datasets as prior information for each of the three years ($12 \times 4 = 48$

362 inversions, see section 2.2). The total uncertainty is a combination of the deposition
363 uncertainty (represented by the posterior emissions using 12 perturbed BC species with
364 different scavenging coefficients) and the uncertainty due to the use of different prior
365 information (represented by the posterior emissions using the four different emission
366 datasets). Table 3 reports annual prior and posterior emissions of BC for different regions and
367 average emissions for the period 2013–2015. Five different regions are accounted for, namely
368 North America, North Europe (including European Russia), North Siberia, Nenets-Komi
369 (Russia) and Khanty-Mansiysk district (Russia).

370 The optimised emissions show some constant hot-spot areas that persist throughout all
371 three years and which are attributed to anthropogenic emissions of BC. For instance,
372 emissions in the Nenets – Komi region close to the Yamal peninsula in Russia or in Khanty
373 Mansiysk region of Northwestern Siberia have been reported to originate to a large extent
374 from gas flaring (Popovicheva et al., 2017; Stohl et al., 2013; Winiger et al., 2017). Other
375 areas that are characterised by large anthropogenic emissions are in Western Canada
376 (Alberta), where more than 100 power industries burn fossil fuels and more than 50 oil and
377 gas production and oil refining industries operate. In addition, one of the largest oil sands
378 deposits are found in Northern Alberta and in the McMurray area, which contains about 168
379 billion barrels of oil (Heins, 2000). Cheng et al. (2018) found high concentrations of BC
380 (more than 1000 ng m⁻³) in the Canadian oil sands region at altitudes of up to 2 km during a
381 flight campaign.

382 The optimised emissions of BC in North America for the 2013–2015 period were
383 between 149 and 193 kt y⁻¹ (average ± 1-sigma error: 174±58 kt y⁻¹), in the same order with
384 the prior emissions in ECLIPSEv5 (148–182 kt y⁻¹) and slightly higher than ACCMIPv5,
385 EDGAR_HTAPv2.2 and MACCity (116–150 kt y⁻¹). In Northern Europe we estimated that
386 124–238 kt y⁻¹ of BC were released (average ± 1-sigma error: 170±59 kt y⁻¹), which is less
387 than half the ECLIPSEv5 emissions (352–381 kt y⁻¹), about 35% lower than the ACCMIPv5
388 and MACCity emissions (241 – 256 kt y⁻¹) and in the same order as the EDGAR_HTAPv2.2
389 emissions (163–175 kt y⁻¹). Posterior emissions of BC were higher in North Siberia for the 3-
390 year period (130–291 kt y⁻¹, average ± 1-sigma error: 217±69 kt y⁻¹) compared with
391 ECLIPSEv5 (187–238 kt y⁻¹), ACCMIPv5 (127–178 kt y⁻¹), EDGAR_HTAPv2.2 (108–159 kt
392 y⁻¹) or MACCity (129–179 kt y⁻¹). Larger changes in the emissions of BC were calculated in
393 Russian territories that are known to be important gas flaring sources (Stohl et al., 2013).
394 Emissions of BC in the Nenets-Komi oblast were between 14 and 17 kt y⁻¹ (average ± 1-
395 sigma error: 15±5 kt y⁻¹), about 40% lower than the respective emissions in ECLIPSEv5 (≈25

396 kt yr^{-1}), the only prior dataset that took gas flaring into account there. This could be due to the
397 decreasing magnitude of the flaring emissions in the last few years (see Huang and Fu, 2016).
398 Finally, in Khanty-Mansiysk emissions of BC were $28\text{--}37 \text{ kt yr}^{-1}$ (average ± 1 -sigma error:
399 $32\pm 8 \text{ kt yr}^{-1}$) compared to 25 kt yr^{-1} in ECLIPSEv5, whereas in the other datasets that do not
400 include emissions of BC due to flaring, BC emissions were negligible. However, the posterior
401 Khanty-Mansiysk emissions are shifted further east compared to the prior.

402 The annual posterior emissions of BC at latitudes above 50°N were estimated as
403 $560\pm 171 \text{ kt yr}^{-1}$ averaged for the 2013–2015 time period ($523\pm 92 \text{ kt yr}^{-1}$ in 2013, $608\pm 104 \text{ kt}$
404 yr^{-1} in 2014 and $549\pm 100 \text{ kt yr}^{-1}$ in 2015, respectively). For the same area and period, BC
405 emissions in ECLIPSEv5 were 745 kt yr^{-1} , in ACCMIPv5 533 kt yr^{-1} , in EDGAR_HTAPv2.2
406 437 kt yr^{-1} , while in MACCity they were 538 kt yr^{-1} . The annual posterior absolute
407 uncertainty can be seen in Figure 6b. As it was explained before, this uncertainty is a
408 combination of the uncertainty due to scavenging and due to the use of different prior
409 information in the inversions of BC. The relative uncertainty of the inversion averaged over
410 the period 2013 to 2015 was estimated to be 30%. The uncertainty due to different scavenging
411 coefficients in the BC species used was 25%, while the uncertainty due to the use of different
412 prior emissions was only 5%.

413 3.4 Validation of the posterior emissions of BC

414 The concentrations of BC at eight measurement stations simulated with the posterior
415 (optimised) emissions of BC can be seen in Figure S 4. As expected, BC concentrations
416 match the observations significantly better than using any of the a priori datasets with
417 correlation coefficients above 0.6 for most of the stations. At the same time, NSD values were
418 close to unity or lower and the nRMSE values below 1.5 at most of the stations shown in
419 Figure S 4. However, the comparison to observations included in the inversion is not a
420 sufficient indicator of the inversion's performance, as the inversion is designed to reduce the
421 model-observation mismatches. The magnitude of the posterior reduction of the model
422 mismatch to the observations is partly determined by the weighting given to the observations
423 relative to the prior emissions. A much better performance indicator is the comparison of the
424 posterior concentrations with observations that were not included in the inversion
425 (independent observations).

426 For this reason, we compared posterior BC concentrations with observations from the
427 ACCACIA (Aerosol-Cloud Coupling and Climate Interactions in the Arctic) flight campaign,
428 which was conducted near Zeppelin station, Ny-Ålesund, for 3 days in March 2013 (Sinha et

429 al., 2017). This campaign was chosen because it was conducted during one year for which
430 inversion results are available (2013). The results are shown in Figure 7 for the prior
431 simulated concentrations of BC using four different emission datasets (ACCMIPv5,
432 ECLIPSEv5, EDGAR-HTAPv2.2 and MACCity) and the posterior simulated BC
433 concentrations. In all profiles, use of the optimised emissions of BC results in a better
434 agreement between modeled concentrations and observations compared to the prior simulated
435 BC concentrations, while the RMSE (not normalised) values decrease substantially. However,
436 the Pearson's correlation coefficients were below 0.5.

437 To assess the performance of the inversions of BC in 2014, we used an independent
438 dataset from a ship campaign that took place in the North Atlantic and Baltic Seas in June and
439 August 2014 (Figure 8) provided by Shevchenko et al. (2016). Although the measurements
440 may sometimes be affected by the ship's exhaust, the posterior RMSE was 34% lower than
441 the average RMSE using four different a priori emission datasets (ACCMIPv5, ECLIPSEv5,
442 EDGAR-HTAPv2.2 and MACCity), supporting the view that the inversion improved the
443 emissions for 2014.

444 To validate the 2015 inversions of BC, measurements from a ship campaign over the
445 Russian Arctic were used (Popovicheva et al., 2017) and the results are shown in Figure 9.
446 The cruise started from the port of Arkhangelsk in the Northwestern European Russia,
447 reached the Bolshevik Island in the higher Russian Arctic and returned following more or less
448 the same pathway. The calculated RMSE of the posterior BC concentrations with the
449 measurements taken during the cruise was about 10% lower than the respective RMSE from
450 the prior simulated concentrations of BC (average for all prior simulated emissions). This
451 shows that the optimised emissions improved BC concentrations over the Russian Arctic.
452 Some episodic peaks of BC throughout the ship cruise, however, were poorly captured.

453 **4 Discussion**

454

455 **4.1 BC emissions in North America**

456 The spatial distribution of the optimised emissions of BC in North America averaged
457 for the 3-year period is depicted in Figure 10 and the annual posterior emissions for 2013,
458 2014 and 2015 are shown in Figure S 5. In the same figures the differences between posterior
459 and prior emissions (ECLIPSEv5) are shown (right panels) to indicate the biggest emission
460 changes compared to the a priori dataset.

461 The most characteristic locations of sources between 2013 and 2015 lie in Alberta,
462 where most of the large oil-producing industries operate (Figure 10 and Figure S 5). The
463 highest emission source was seen in 60°N–135°W in 2013 and 2015, but not in 2014. This
464 spot corresponds to the location of Whitehorse, which is the capital and only city of Yukon,
465 and the largest city in Northern Canada. The area involves mining activities (mainly for gold)
466 and three natural gas wells, while biomass in the form of cordwood and pellets is used for
467 space heating (Yukon Government, 2018). The fact that near-zero emissions of BC were
468 calculated in Whitehorse in 2014 might be due to the lack of available measurements in North
469 America, which in turn results in poorly constrained posterior emissions of BC. Another
470 similar hotspot area that is more intense in 2013 and 2015, but not in 2014 is located in
471 Yellowknife north of Great Slave Lake (62.5°N–115°W, Figure S 5). The city is known for
472 gold and diamond mining and an oil-driven power plant (Northwest Territories Power
473 Corporation, <https://www.ntpc.com>). Finally, another characteristic hotspot emission region
474 of BC is seen southeast of Lake Athabasca (57°N–108°W, Figure 10). In this region four
475 uranium mines are located that use diesel generators, diesel trucks, and likely also other
476 diesel-powered machinery. Exactly in this location, the Visible Infrared Imaging Radiometer
477 Suite (VIIRS) showed relatively strong night-time light sources
478 ([https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-](https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-11864816&layers=B0FFFTFFFT)
479 [11864816&layers=B0FFFTFFFT](https://www.lightpollutionmap.info/#zoom=5&lat=8255540&lon=-11864816&layers=B0FFFTFFFT)).

480 **4.2 BC emissions in Northern Europe**

481 The posterior emissions of BC in Northern Europe averaged for the period 2013–2015
482 can be seen in Figure 11 together with the difference between prior (ECLIPSEv5) and
483 posterior BC emissions, while the posterior emissions for each individual year are shown in
484 Figure S 6. The location of the gas flaring facilities are also presented in the same figures
485 together with vegetation fires from the FEINE (Fire Emission Inventory– northern Eurasia)
486 inventory (Hao et al., 2016). The latter combines the MODIS thermal anomalies products
487 (MOD14 and MYD14) and the MODIS top-of-the-atmosphere-calibrated reflectance product
488 (MOD02) to map and date burn scars that are screened for false detections. Land cover
489 classification of burned areas are taken from the MODIS land cover change product
490 (MOD12) (Friedl et al., 2010). This dataset is considered more realistic than GFED4 due to
491 the emission factors used for BC (May et al., 2014) and the different approach of burned area
492 calculation (see Hao et al., 2016).

493 The highest posterior emissions of BC are calculated for the Moscow megacity at
494 55°N–37.5°E, Berlin 52°N–14°E, Warsaw 52°N–21°E, Kyiv 50°N–30°E, Saint Petersburg
495 60°N–30°E, while London is slightly misplaced to the west (Figure 11). The Scandinavian
496 countries have the lowest emissions, although domestic heating there can also be important
497 (Andersen and Jespersen, 2016). The difference between prior and posterior emissions show
498 that vegetation fires have a large impact on the BC emissions especially in Eastern Europe. In
499 particular in 2015, the inversion produces large emission increases exactly where a large
500 number of fire hot spots were found (see Figure S 6).

501 4.3 BC emissions in North Siberia

502 Figure 12 illustrates the average posterior emissions of BC in Western Siberia for the
503 2013–2015 period together with the difference between the prior (ECLIPSEv5) and the
504 posterior emissions of BC, while Figure S 7 shows the respective emissions of BC for each
505 year individually, together with the flaring facilities and the vegetation fires similarly to the
506 previous section.

507 The prior emissions of BC from flaring in Nenets-Komi oblast are confirmed by the
508 inversion, although the emissions are shifted further east, while the flaring emissions in
509 Khanty-Mansiysk are probably underestimated in ECLIPSEv5 (see also Table 3). Vegetation
510 fires are shown to correlate well with BC emissions for 2013 (60°N–70°N) and 2014 (50°N–
511 60°N) (Figure S 7), but not in 2015. Hotspots of high emissions were found in Dudinka
512 (88°E–70°N), a town on the Yenisei River and the administrative center of Taymyrsky
513 Dolgano-Nenetsky District of Krasnoyarsk Krai, Russia, due to the Norilsk Mining and
514 Smelting Factory extracting coal and ores. Furthermore, increase posterior emissions of BC
515 were estimated across the line that connects some important Russian cities (Yekaterinsburg to
516 Chelyabinsk, 60°E–55°N). These cities have been reported to contribute large amounts of BC
517 mainly from transportation (see Evangeliou et al., 2018). Another hotspot exists at 108°E–
518 58°N that corresponds to VIIRS night-time lights
519 ([https://www.lightpollutionmap.info/#zoom=5.69666666666666656&lat=8239438&lon=12096](https://www.lightpollutionmap.info/#zoom=5.69666666666666656&lat=8239438&lon=12096227&layers=B0FFFTFFFT)
520 [227&layers=B0FFFTFFFT](https://www.lightpollutionmap.info/#zoom=5.69666666666666656&lat=8239438&lon=12096227&layers=B0FFFTFFFT)). These emissions are attributed to flaring as four facilities are
521 collocated there (see Figure 12). Finally, high emissions of BC originate from the Nizhny
522 Novgorod oblast (44°E–55°N). The oblast ranks seventh in Russia in industrial output.
523 Processing industries predominate in the local economy. The leading sectors of more than 650
524 industries are engineering and metalworking, followed by chemical and petrochemical

525 industries and forestry, woodworking, and paper industries and one facility that flare gas
526 (GGFR, Figure 12).

527 In the western part of Siberia, there are numerous sources of average or low intensity.
528 However, there no known anthropogenic sources there. At the lowest part of the inversion
529 domain, in the borders of Russia with Mongolia, the posterior emissions showed a large
530 increase (Figure 6). These emissions are prevalent along the Trans-Siberian Railway. Human
531 activities in the villages along the railway have been highlighted to be the major cause of the
532 fires there.

533 **4.4 Seasonal variability of BC emissions**

534 The monthly optimised emissions of BC are shown in Figure 13 for the three years of
535 study (2013–2015) for the entire area north of 50°N, and separately for areas north of 50°N in
536 North America, North Europe, North Siberia, Nenets-Komi oblast (Russia) and Khanty-
537 Mansiysk (Russia). The last two regions are known to have large emissions from gas flaring.
538 In the same figure the prior emissions from ECLIPSEv5, EDGAR_HTAPv2.2, ACCMIPv5
539 and MACCity are plotted for comparison.

540 The total posterior emissions of BC (>50°N) show large seasonal variation (Figure 13a).
541 The maximum emissions were calculated for summer months (July in 2013 and June in 2014
542 and 2015). In these months large emissions from biomass burning have been reported both in
543 GFED4 (see burned area in Giglio et al., 2013), as well as in the FEINE inventory for
544 Northern Eurasia (Hao et al., 2016). By separating the inversion domain into continental
545 regions, it is easily seen where biomass burning is important. For instance, in North America
546 (Figure 13b), although GFED4 that is included in all the prior emission datasets, shows a
547 large emission peak for BC in summer implying that fires are important, our optimised
548 emissions show a significantly smaller variability. This was not the case for North Europe
549 (Figure 13c) where the largest seasonal emissions of BC were found in July for 2013 and in
550 May for 2015, while in 2014 the largest peak was already in April. This is not seen in the
551 prior emission datasets, which show weak monthly variation. The largest seasonal variations
552 were calculated for Northern Siberia (Figure 13d) and emissions of BC there control the
553 overall seasonal pattern for the total optimised emissions of BC (>50°N). A large month-to-
554 month variability was estimated in the Nenets-Komi oblast (Figure 13e) likely as a
555 consequence of errors in the inversion, but no clear seasonal pattern. Finally, the largest
556 monthly emissions of BC in Khanty-Mansiysk oblast of Russia (Figure 13f) were calculated
557 in April for 2013, July for 2014 and June for 2015 showing that a large share in the emissions

558 of BC in this region originate from biomass burning since the region is located at mid-
559 latitudes (60°N–65°N) and is vulnerable to open fires.

560 **5 Conclusions**

561 We have optimised emissions of BC at high northern latitudes (>50°N) for the 2013–
562 2015 period using a Bayesian inversion tool, an atmospheric transport model and network of
563 continuous measurements of BC. We performed a sensitivity study to assess the best
564 representative species for BC in terms of scavenging and removal and the best representative
565 emission inventory to be used as the prior information for our inversion.

566 The perturbation of scavenging coefficients for BC in the simulated concentrations
567 creates a relative model–observation mismatch of 32%–43% for the three years of study,
568 whereas the use of different emission inventories has a less significant effect in the simulated
569 concentrations showing a relative model–observation mismatch of 15%–23%.

570 The posterior emissions of BC show characteristic hot-spots throughout all three years
571 in the Nenets – Komi region close to the Yamal peninsula in Russia or in Khanty Mansiysk
572 region of Northwestern Siberia, where gas flaring facilities are located and in Western Canada
573 (Alberta), where more than 150 power and oil/gas production industries operate. The annual
574 posterior emissions of BC at latitudes above 50°N were estimated as 560 ± 171 kt yr⁻¹,
575 significantly smaller than in ECLIPSEv5 (745 kt yr⁻¹), which was used and the prior
576 information in the inversions of BC (best representative emission dataset).

577 The uncertainty of the inversions was assessed using a model ensemble represented by
578 12 different scavenging coefficients for BC and four different prior emission datasets
579 (12×4=48) for each of the three years of our study. We calculate a relative uncertainty of the
580 inversion of 30% for the three years of our study.

581 The posterior simulated concentrations of BC showed a better agreement with
582 independent observations adopted from flight and ship campaigns over the Arctic presenting,
583 in all cases, up to three times lower RMSE values.

584 In North America, the posterior emissions were found similar to the a priori ones driven
585 by anthropogenic sources, while biomass burning appeared to be insignificant. This was
586 confirmed by satellite products that showed weak existence of active fire hot-spots.

587 In North Europe, posterior emissions were estimated to be half compared to the prior
588 ones, with the highest releases to be in megacities and due to biomass burning in Eastern
589 Europe.

590 Finally, in North Siberia the larger emissions were calculated along the transect
591 between Yekaterinsburg and Chelyabinsk, while flaring in Nenets-Komi oblast is probably
592 overestimated in the a priori emissions. Increased emissions in the borders between Russia
593 and Mongolia are probably due to biomass burning in villages along the Trans-Siberian
594 Railway.

595

596 *Data availability.* All data generated for the present publication are stored on NIRD
597 (<https://www.uio.no/english/services/it/research/storage/nird-sigma.html>) (project NS9419K)
598 and can be obtained from the corresponding author upon request.

599

600 *Competing financial interests.* The authors declare no competing financial interests.

601

602 *Acknowledgements.* We would like to acknowledge the project entitled “Emissions of
603 Short-Lived Climate Forcers near and in the Arctic (SLICFONIA)”, which was funded by the
604 NORRUSS research program (Project ID: 233642) and the project entitled “The Role of
605 Short-Lived Climate Forcers in the Global Climate” funded by the KLIMAFORSK program
606 (Project ID: 235548) of the Research Council of Norway. Also the Research Council of
607 Norway strategic institute initiatives (SIS) project “SOCA-Signals from the Arctic Ocean in
608 the Atmosphere” is acknowledged. We also acknowledge partial support by the AMAP
609 secretariat, as this work shall contribute to the next AMAP assessment on short-lived climate
610 forcers. Work was performed at the Nordic Centre of Excellence eSTICC (eScience Tools for
611 Investigating Climate Change in northern high latitudes), supported by NordForsk grant
612 57001. We thank IIASA (especially Chris Heyes and Zig Klimont) for providing the
613 ECLIPSEv5 emission dataset for BC. Computational and storage resources for the
614 FLEXPART simulations were provided by NOTUR (NN9419K) and NIRD (NS9419K). All
615 results can be accessed upon request to the corresponding author of this manuscript.

616

617 *Author contributions.* NE performed the simulations, analyses and wrote the paper, RLT
618 helped in the adaptation of FLEXINVERT for BC and commented on the paper, SE helped in
619 the implementation of the experiments and AS coordinated, commented and wrote parts of
620 the paper.

900 **Table 3.** Annual prior and posterior emissions of BC for 2013, 2014 and 2015 (inversion using best representative species and best prior
 901 inventory). Four different optimized emission estimates are given corresponding to use of different prior dataset.

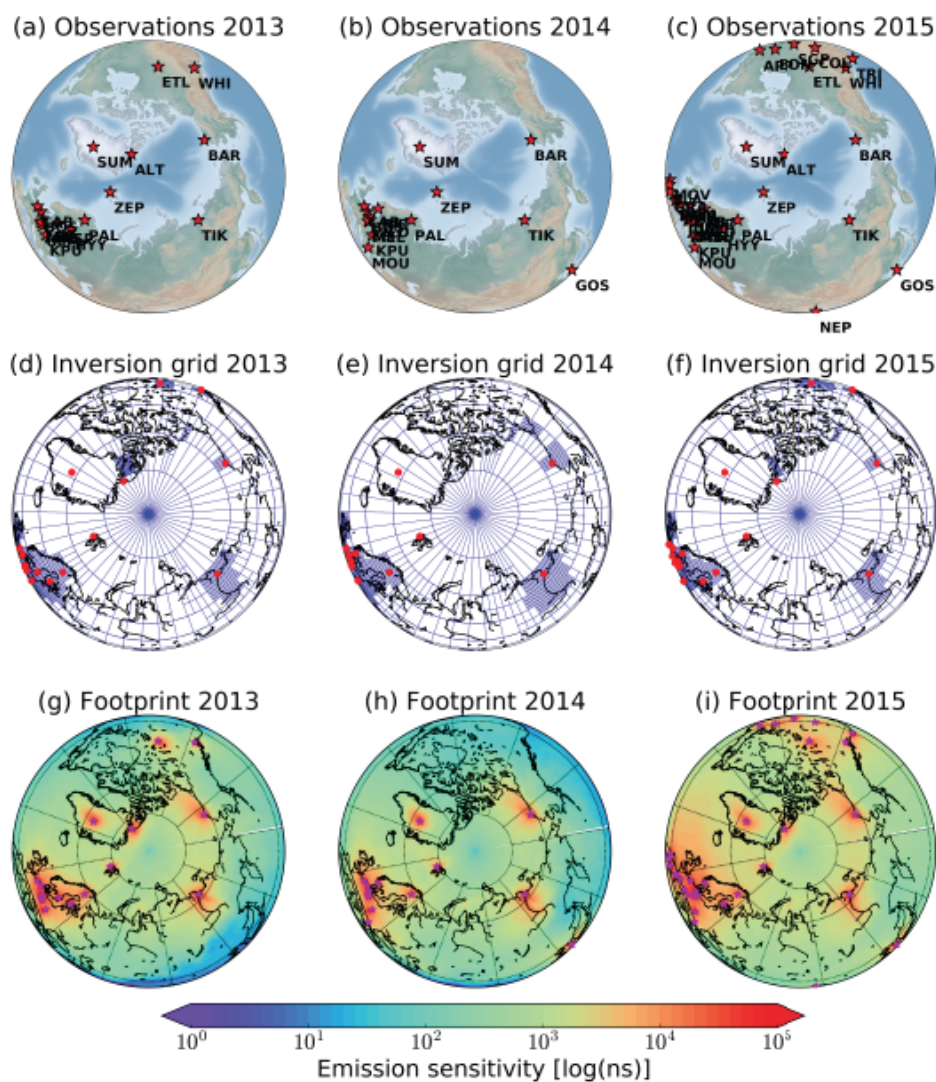

kilotons per year	N. America	N. Europe	N. Siberia	Nenets-Komi	Khanty-Mansiysk
2013					
ACCMIPv5 (prior)	116	241	127	0.6	1.8
EDGAR_HTAPv2.2 (prior)	117	163	108	0.3	0.6
MACCcity (prior)	117	244	129	0.6	1.9
ECLIPSEv5 (prior)	148	352	187	26	25
Posterior (ECLIPSEv5)	149±45	152±46	230±66	17±5	32±8
2014					
ACCMIPv5 (prior)	130	253	178	0.5	1.9
EDGAR_HTAPv2.2 (prior)	131	175	159	0.3	0.7
MACCcity (prior)	131	256	179	0.5	1.8
ECLIPSEv5 (prior)	162	364	238	25	26
Posterior (ECLIPSEv5)	193±61	124±44	291±73	15±5	28±8
2015					
ACCMIPv5 (prior)	149	250	155	0.5	1.8
EDGAR_HTAPv2.2 (prior)	150	172	136	0.3	0.6
MACCcity (prior)	150	252	156	0.6	1.8
ECLIPSEv5 (prior)	182	381	222	25	25
Posterior (ECLIPSEv5)	181±55	238±66	130±52	14±5	37±8
3-year average emissions	174±58	170±59	217±69	15±5	32±8

902

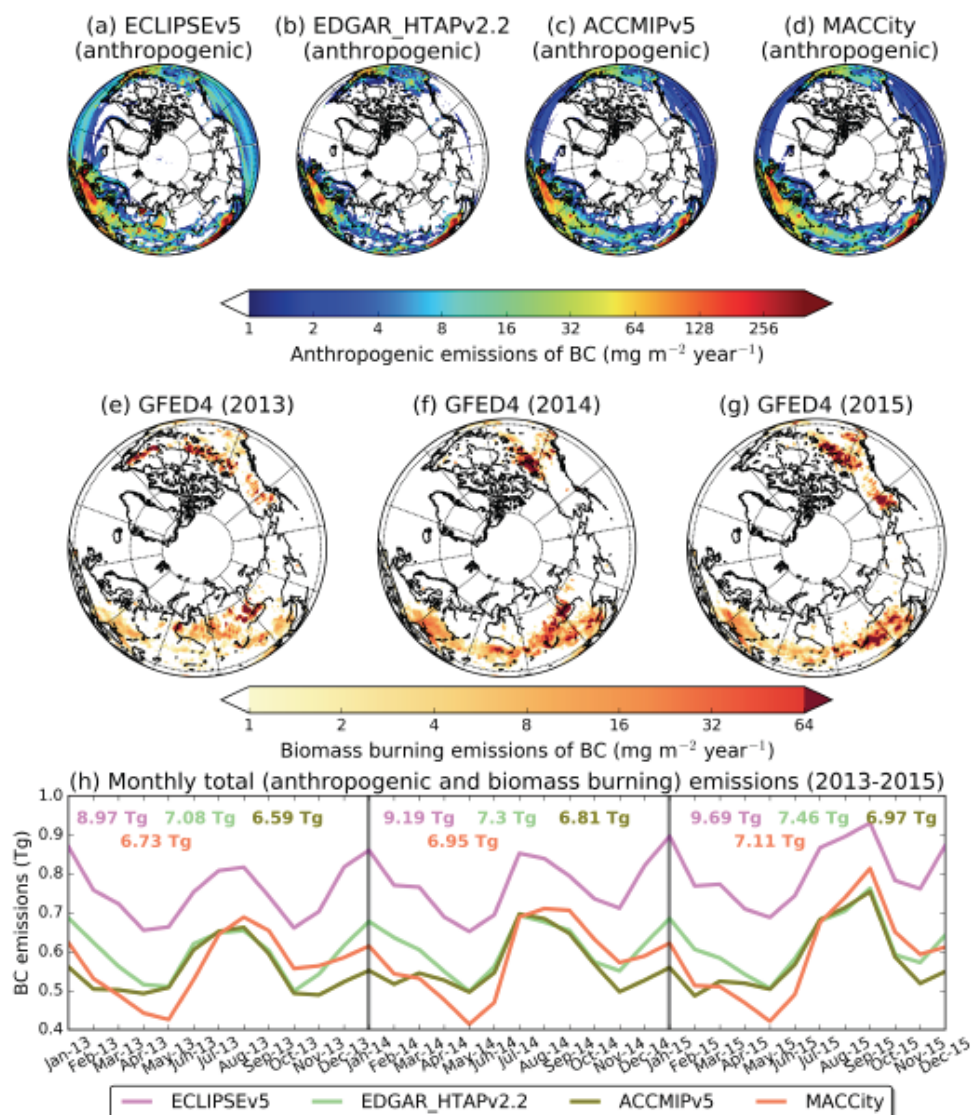

904 FIGURES & LEGENDS

905

906

907 **Figure 1.** Observation network used for the present inversion (a, b and c), and variable-
908 resolution grid used for the inversion (d, e, and f) also showing the location of the observation
909 sites (red stars) for 2013–2015 period. Sensitivity to the surface emissions (i.e., the footprint
910 emission sensitivity or equivalently source-receptor relationship) integrated over all
911 observation sites and all time steps (g, h and i) for the years 2013, 2014 and 2015 (units of
912 $\log(\text{ns})$).

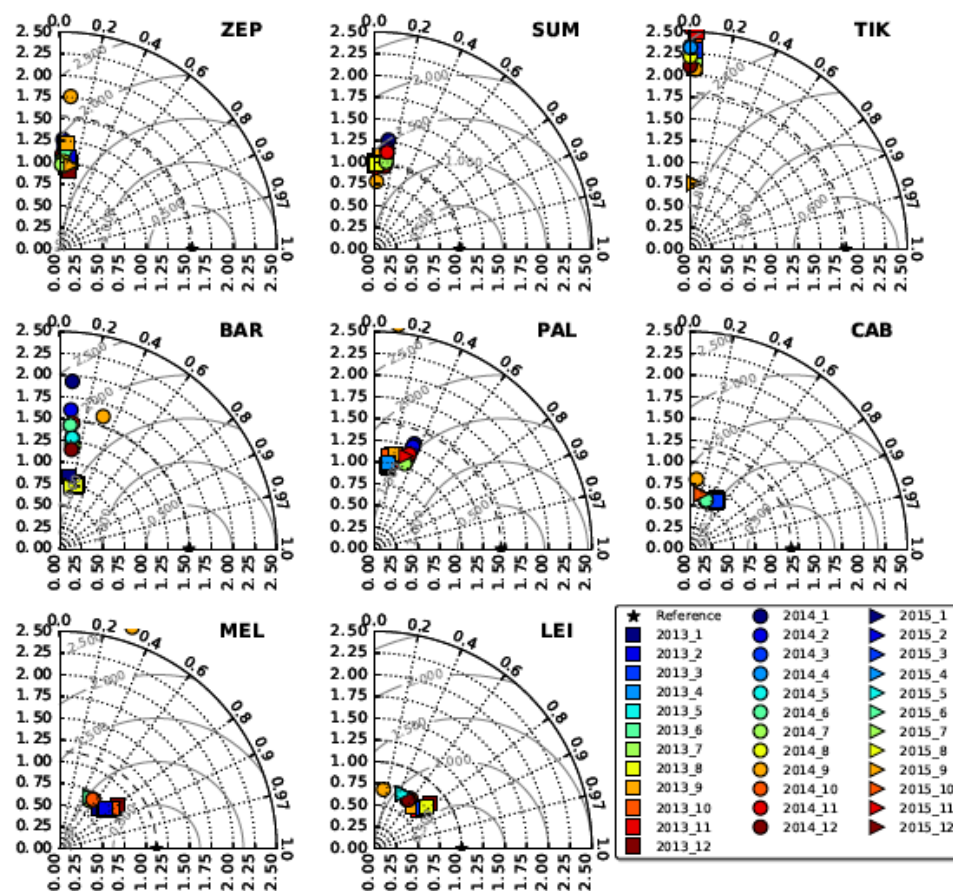

913
 914 **Figure 2.** (a–d) Anthropogenic emissions of BC in the inversion domain ($>50^{\circ}\text{N}$) from
 915 ECLIPSEv5, EDGAR_HTAPv2.2, ACCMIPv5 and MACCity (anthropogenic emissions are
 916 assumed to be constant throughout every year). (e–g) Biomass burning emissions from
 917 GFED4 for 2013, 2014 and 2015 (Giglio et al., 2013). (h) Monthly total (anthropogenic and
 918 biomass burning) emissions of BC north of 50°N from 2013 to 2015 from the four prior
 919 inventories used for the inversion. Coloured numbers correspond to total annual BC from
 920 each emission inventory.

921

COMPARISON OF PRIOR SIMULATED CONCENTRATIONS (ECLIPSEv5) (YEARS 2013-2015)

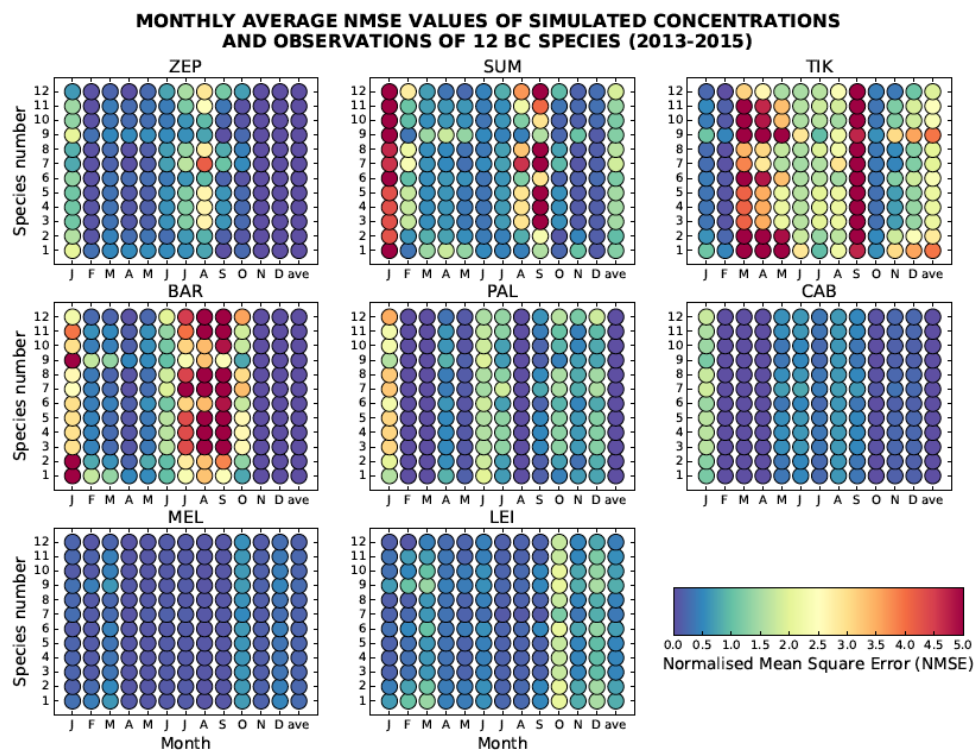

922

923 **Figure 3.** Taylor diagrams for the comparison of the prior (ECLIPSEv5) simulated
924 concentrations with observations for all years (2013 – 2015) for 12 BC species with different
925 scavenging coefficients (**Table 2**). The radius indicates standard deviations normalised
926 against the mean concentration (NSD); the azimuthal angle the Pearson correlation
927 coefficient, while the normalised (against observation) root mean square error (nRMSE) in
928 the simulated concentrations is proportional to the distance from the point on the x-axis
929 identified as “reference” (grey contours).

930

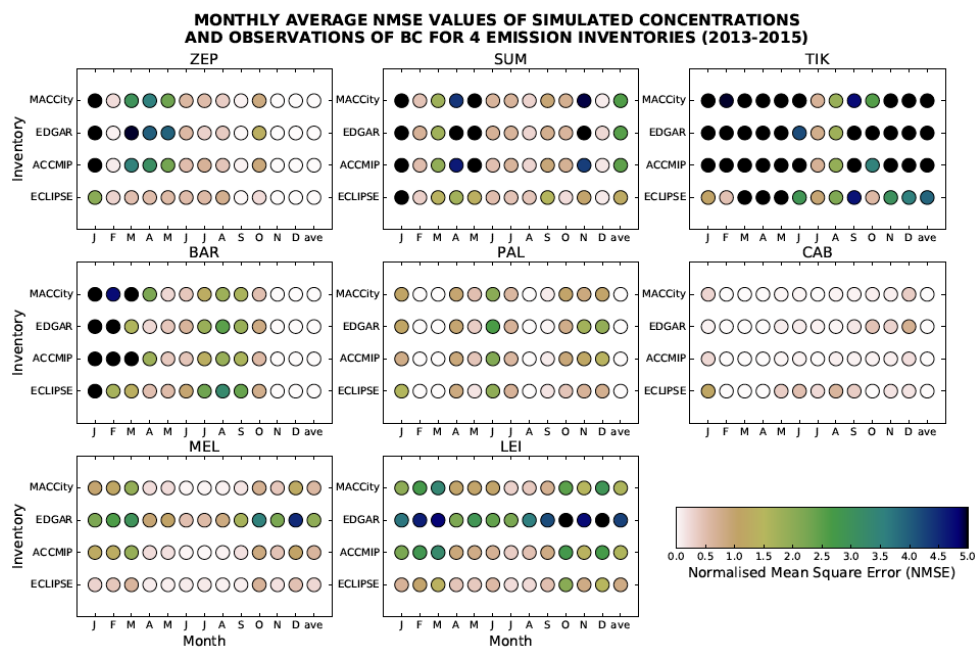

931

932

933 **Figure 4.** Monthly average NMSE values due to use of 12 different BC species defined in
934 **Table 2** for the eight stations with complete data in the period 2013–2015. The annual mean
935 is denoted as “ave”).

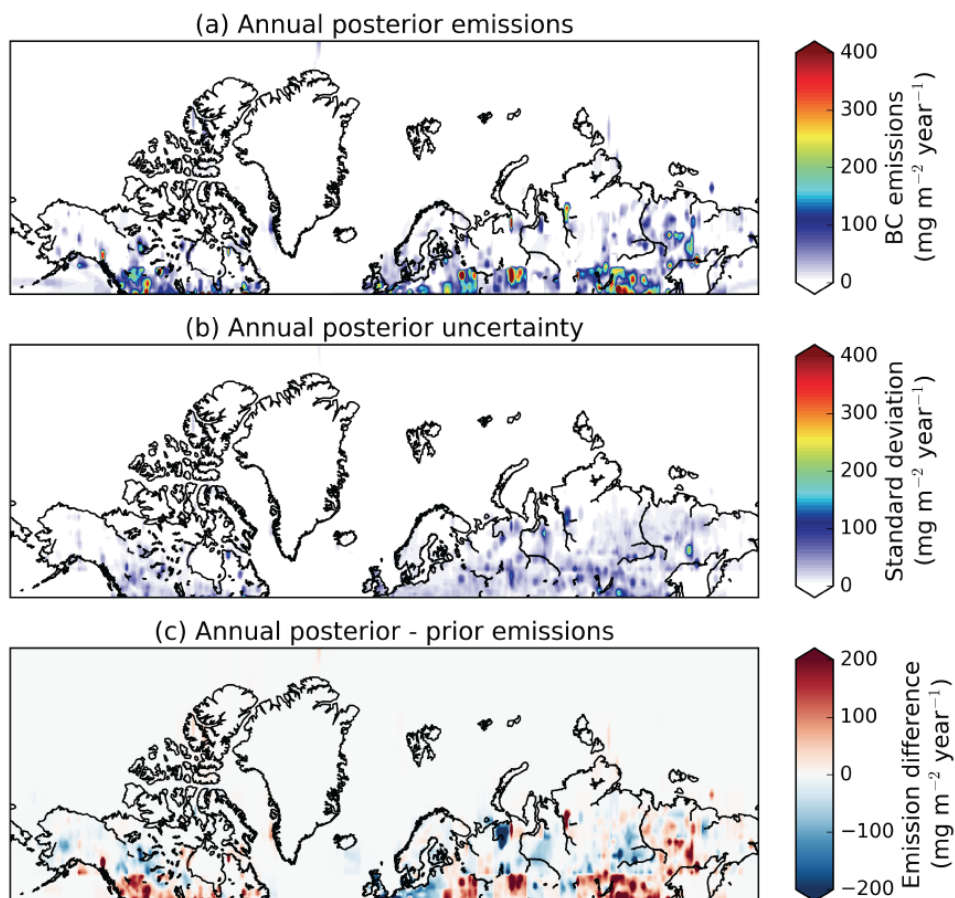

936

937

938 **Figure 5.** Monthly average NMSE values due to use of different emission inventories
 939 (ECLIPSEv5, ACCMIPv5, EDGAR_HTAPv2.2, MACCcity) for the eight stations with
 940 complete data in the period 2013–2015. The annual mean is denoted as “ave”).

941

942

943

Figure 6. (a) Annual posterior emissions of BC in areas >50°N averaged for the period 2013–

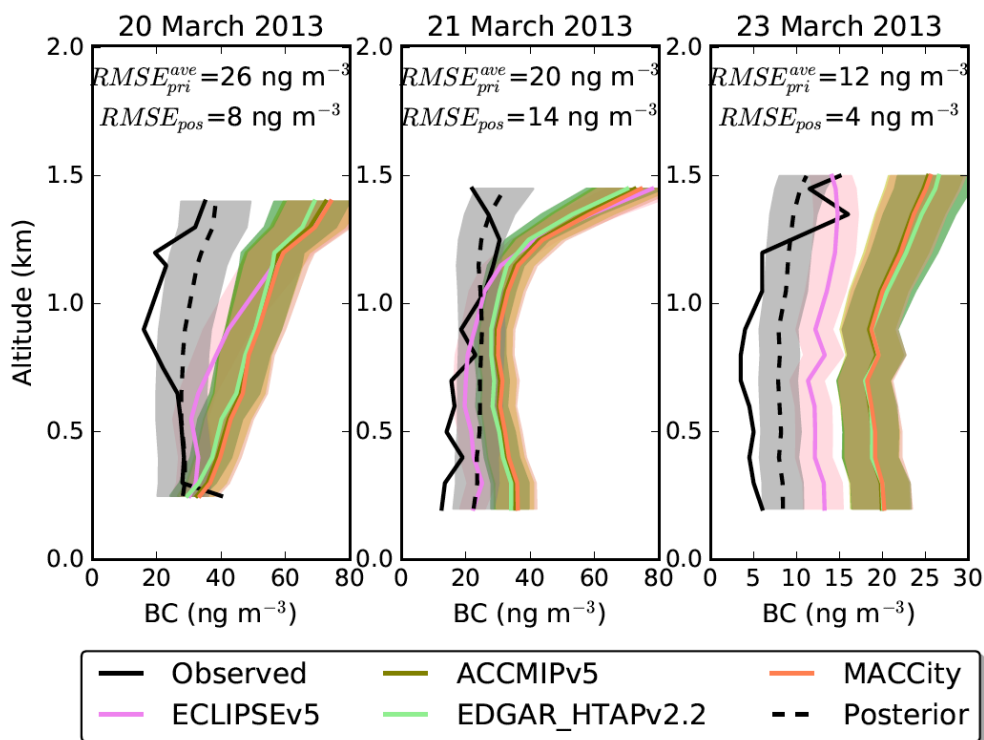

944

2015, (b) average posterior uncertainty due to scavenging and use of different prior emissions

945

for the same period. (c) Difference between posterior and prior emissions for 2013–2015.

946

**VERTICAL PROFILES OF BC (ACCACIA FLIGHT CAMPAIGN)**

947

948 **Figure 7.** Comparison of prior (ECLIPSEv5, ACCMIPv5, EDGAR HTAPv2.2 and
949 MACCity) and posterior simulated concentrations of BC with observations from the
950 ACCACIA flight campaign near Zeppelin station, Ny-Ålesund in 2013 adopted from Sinha et
951 al. (2017). The variability of the prior concentrations (shaded area) was calculated as the
952 standard deviation of BC concentrations from the 12 species with different scavenging
953 coefficients as shown in **Table 2**. Uncertainties of the posterior concentrations are due to
954 scavenging and use of 4 different a priori datasets (section 3.4).

955

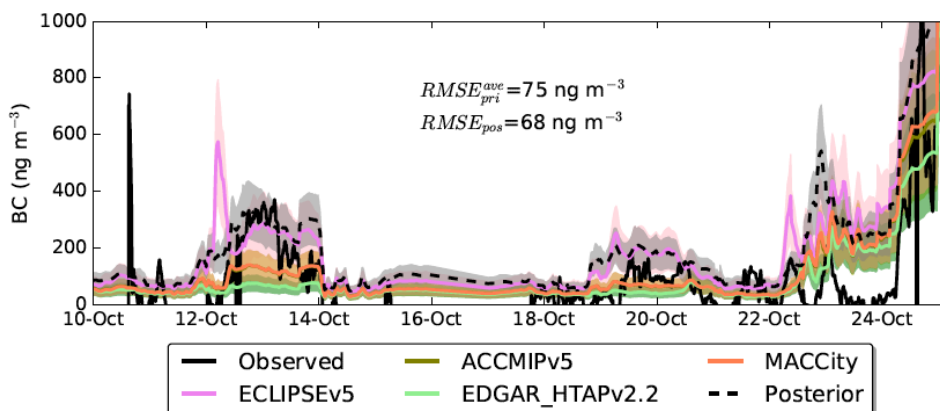

957 **Figure 8.** Comparison of prior (ECLIPSEv5, ACCMIPv5, EDGAR HTAPv2.2 and
958 MACCity) and posterior simulated concentrations of BC with observations from a ship
959 campaign in North Atlantic and Baltic Seas in 2014 adopted from Shevchenko et al. (2016).
960 The variability of the prior concentrations (shaded area) was calculated as the standard
961 deviation of BC concentrations from the 12 species with different scavenging coefficients as
962 shown in **Table 2**. Uncertainties of the posterior concentrations are due to scavenging and use
963 of 4 different a priori datasets (section 3.4).

964

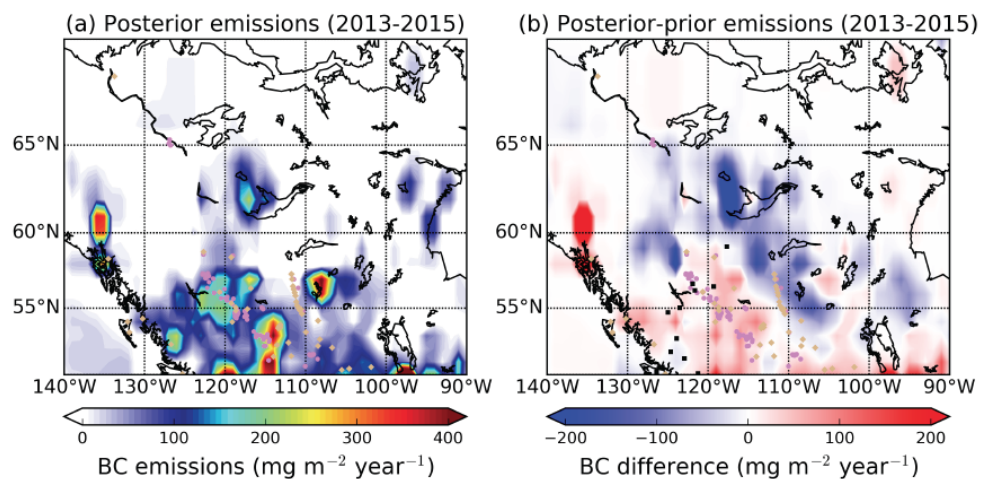

RUSSIAN HIGH ARCTIC SEA CAMPAIGN 2015

965

966 **Figure 9.** Comparison of prior (ECLIPSEv5, ACCMIPv5, EDGAR HTAPv2.2 and
967 MACCity) and posterior simulated concentrations of BC (2015) with observations from a
968 ship campaign in the Russian Arctic in 2015 adopted from Popovicheva et al. (2017). The
969 variability of the prior concentrations (shaded area) was calculated as the standard deviation
970 of BC concentrations from the 12 species with different scavenging coefficients as shown in
971 **Table 2.** Uncertainties of the posterior concentrations are due to scavenging and use of 4
972 different a priori datasets (section 3.4).

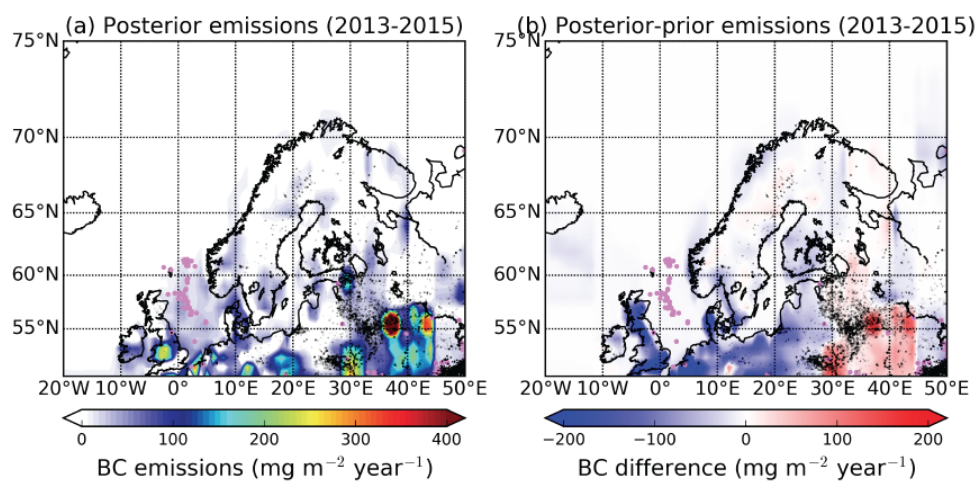

973

974

975 **Figure 10.** (a) Optimised emissions of BC in North America (Western Canada) averaged over
976 the 2013–2015 period. (b) Difference between a posteriori and a priori emissions of BC
977 (ECLIPSEv5 was used as the prior). Magenta points on the map denote the gas flaring
978 industries from the Global Gas Flaring Reduction Partnership (GGFR)
979 (<http://www.worldbank.org/en/programs/gasflaringreduction>), grey points show the power
980 industries that operate using fossil fuels and oil and gas production and oil refining industries
981 adopted from Industry About (<https://www.industryabout.com/canada-industrial-map>), while
982 black rectangles show active fires from MODIS.

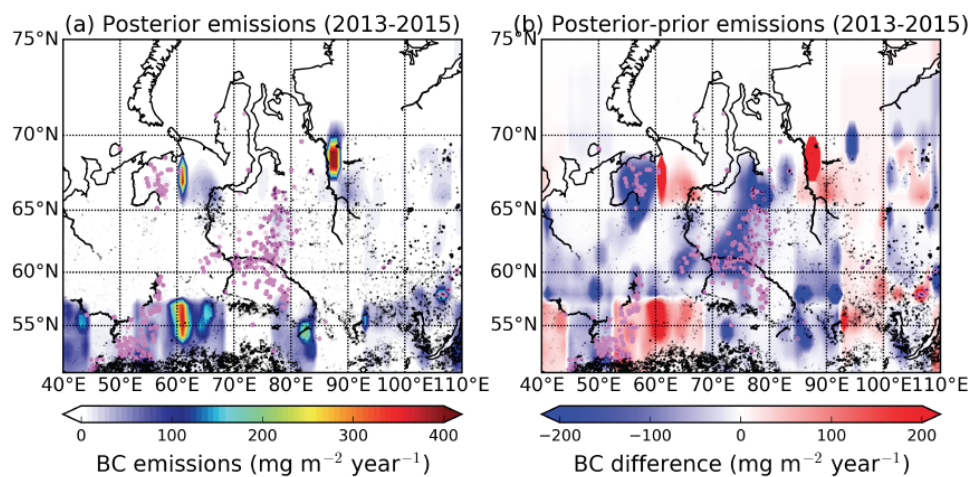

983

984

985 **Figure 11.** (a) Optimised emissions of BC in Northern Europe averaged over the 2013–2015
986 period. (b) Difference between a posteriori and a priori emissions of BC (ECLIPSEv5 was
987 used as the prior). Magenta points on the map indicate the gas flaring industries from the
988 Global Gas Flaring Reduction Partnership (GGFR)
989 (<http://www.worldbank.org/en/programs/gasflaringreduction>), while black rectangles show
990 the vegetation fires adopted from Hao et al. (2016).

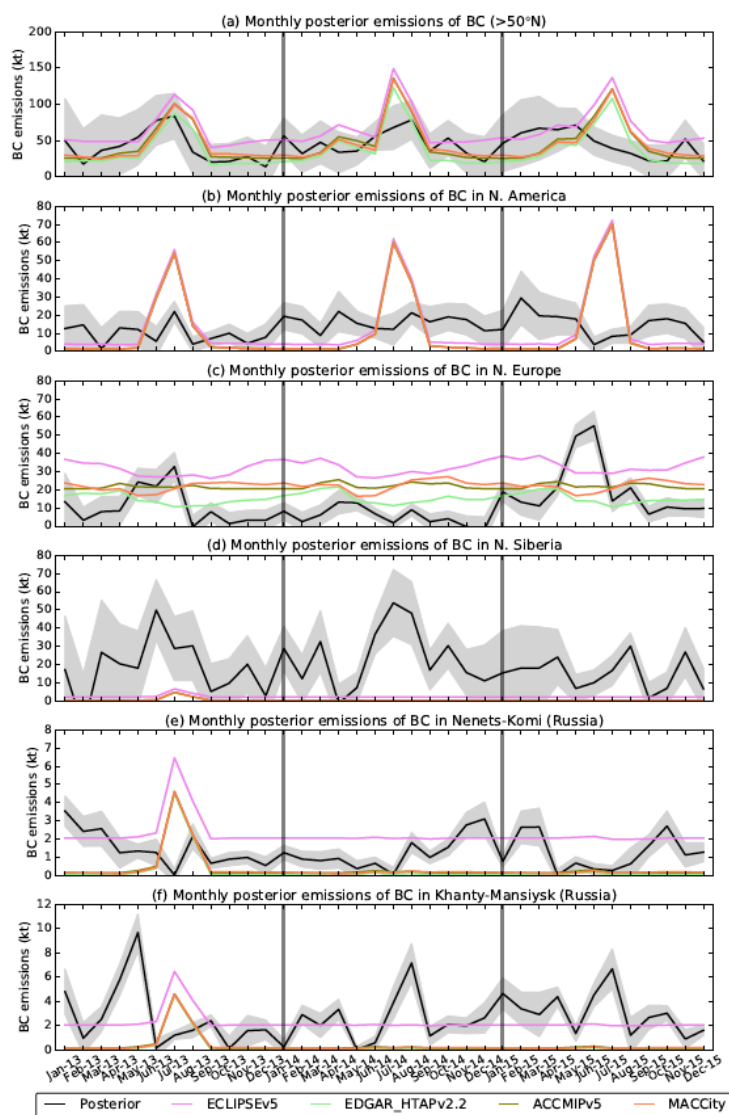

991

992

993 **Figure 12.** (a) Optimised emissions of BC in Western Siberia averaged for the 2013–2015
994 period. (b) Difference between a posteriori and a priori emissions of BC (ECLIPSEv5 was
995 used as the prior). Magenta points on the map indicate the gas flaring industries from the
996 Global Gas Flaring Reduction Partnership (GGFR)
997 (<http://www.worldbank.org/en/programs/gasflaringreduction>), while black rectangles show
998 the vegetation fires adopted from Hao et al. (2016).

999

1000

1001 **Figure 13.** Monthly posterior emissions of BC shown for all regions located (a) $>50^{\circ}\text{N}$, (b) in
 1002 North America ($>50^{\circ}\text{N}$), (c) North Europe ($>50^{\circ}\text{N}$), (d) North Siberia ($>50^{\circ}\text{N}$), (e) Nenets-
 1003 Komi oblast ($>50^{\circ}\text{N}$, Russia) and (f) Khanty-Mansiysk oblast ($>50^{\circ}\text{N}$, Russia) for the 2013–
 1004 2015 period. Monthly prior emissions of BC from ECLIPSEv5, EDGAR-HTAPv2.2,
 1005 ACCMIPv5 and MACCity emissions inventories are also shown for the same regions and
 1006 time period. The uncertainty of the posterior emissions of BC stems from the use of different
 1007 scavenging coefficients and different prior emission datasets (see section 3.3).
