Interactive comment on "Thermal structure of the mesopause region during the WADIS-2 rocket campaign" by Raimund Wörl et al.

Anonymous Referee #1 Received and published: 7 September 2018

A review on the paper "Thermal structure of the mesopause region during the WADIS2 rocket campaign" by Raimund Wörl, Boris Strelnikov, Timo P. Viehl, Josef Höffner, Pierre-Dominique Pautet, Michael J. Taylor, and Franz-Josef Lübken. Although the paper provides no new knowledge about the temperature regime of the mesopause, solar tides and gravity waves, the paper is interesting in terms of a comparison of simultaneous temperature measurements by three independent instruments (the rocket CONE instrument, the IAP Fe lidar and the AMTM mapper).

I recommend the paper for publication after minor revisions.

Minor comments:

P. 6, L.17: "unclear wave structures" It is better to replace it with "random wave structures".

changed

P. 6, L. 18-19: "A linear fit of the phase is used to estimate the phase slope for every component: a vertical wavelength and a phase are calculated using the slope and the position of the fitted lines at 86 km."

This is the most problematic issue. I do not understand this technique of estimating a vertical wavelength, having just a 15 km altitude range of the data profiles shown in Fig. 5. Some strong assumptions are required. This technique should be clarified in more detail. Besides, uncertainties for the estimated vertical wavelengths and phases should be presented in Table 1.

page 7, line 31: a short explanation is added

P. 8, Capture to Fig. 5: "Figure 5. Amplitudes (a), (c) and phases (b), (d) ..." Labels (c) and (d) should be swapped around.

changed

P. 12, L. 27-29: "A vertical wavelength (at about 90 km) in the range of 30–35 km (24 h tide) and 20–30 km (12 h tide) in that analysis is in good agreement with the findings in this study (40 km and 22 km)."

First. In Table 1, a vertical wavelength of 43 km for the 24 h wave is shown (not 40 km). Second. Having vertical wavelength of 30-35 km (from Forbes, 1982a) and the found vertical wavelength of 43 km, one cannot say that "it is in good agreement". This sentence should be corrected/rephrased.

numbers are updated in the table and the text

page 13, line 31 ff. and page 14: text is corrected and rephrased

P. 13, L. 1-2: "Winds from radar measurements and temperatures from airglow measurements at polar latitudes are discussed relating the 8 h and the 6 h tides (Younger et al., 2002; Wu et al., 2005; K. Smith et al., 2004)."

It is worth indicating here that Dalin et al. (2017) have demonstrated significant solar tidal components (24h, 12 and 8h) both in the PMSE strength and wind velocity components in the polar mesopause.

Page 14, line 20: Dalin et al. (2017) is mentioned

P.13,L.4-5: "This is in good agreement with our finding of 30 km."

In Table 1, a vertical wavelength of 23 km for the 8 h wave is shown. This value should be corrected.

numbers are corrected

P. 14, L. 7-9: "...suggest an OH centroid altitude between 84 km and 86 km. However, in context of this paper such statements refer only to the observation in this single night and the assumption of a fixed altitude and layer shape is not justified in all cases (e.g., Zhao et al., 2005; Dunker, 2017)."

It is worth adding other important references of this important topic on the variability of OH layer characteristics in height and time: Perminov et al., 1999; Melo et al., 2000; Liu and Shepherd, 2006; Khomich et al., 2008; Grygalashvyly et al., 2014.

Interactive comment on "Thermal structure of the mesopause region during the WADIS-2 rocket campaign" by Raimund Wörl et al.

Anonymous Referee #2 Received and published: 28 September 2018

The study presents temperature measurements taken by three instruments during a 24 hour period. Thus it can be classified as a case study. The combination of AMTM, lidar, and CONE measurements is unique, but simultaneous observations taken by AMTM and lidar as well as lidar and CONE instruments have been published before. Given that Wörl et al. show that the addition of the CONE data to AMTM and lidar data provides mostly redundant information concerning large scale gravity waves or tides, I think this manuscript does not provide enough new results for an ACP publication. Therefore, I suggest that the authors focus more on quantitative analysis of gravity waves and tides, and in particular small-scale perturbations. I recommend a major revision or re-submission for this manuscript.

### Major comment 1

According to the authors, the IAP Fe lidar has been operating at the ALOMAR observatory since summer 2014 and the AMT since 2010. It is probably reasonable to assume that a large amount of data was collected by both instruments in the following years until the rocket launch. It is surprising to me that the authors did not even try to classify conditions observed during the rocket launch with respect to the climatological mean state or at least typical conditions. Instead, the authors spend significant time speculating about tides, where most of the speculation is based on a comparison with measurements taken in the southern hemisphere at the wrong time of the year. Discussion of gravity waves is limited to the statement "In contrast to other examples (Bossert et al., 2014; Pautet et al. 2014) no clear small structures are visible". The authors make no attempt whatsoever to quantify gravity waves in their observations. Thus, the manuscript is merely a presentation of measurement data without any meaningful analysis. Conclusions drawn by the authors are weak.

According to the Review Criteria [https://www.atmospheric-chemistry-andphysics.net/peer\\_review/review\\_criteria.html](https://www.atmospheric-chemistry-andphysics.net/peer_review/review_criteria.html) reviewers are asked to answer the question "Does the manuscript represent a substantial contribution to scientific progress within the scope of Atmospheric Chemistry and Physics (substantial new concepts, ideas, methods, or data)?" Yes, the data are new in the sense that every observation of the atmosphere is different. However,

temperature measurements in the mesopause region are hardly anything new and numerous case studies were published during the last 30 years. Thus, without thorough analysis, publishing the data is of low scientific significance, and the manuscript in its current state might be seen as an attempt to boost the publication statistics with minimum effort.

I am not arguing that the data should not be published. On the contrary, the observational data presented in this study has potential. But the authors should invest the time and analyze the data, critically review their hypothesis, and draw meaningful conclusions.

The main goal of the paper is giving an overview about the mesopause temperature structure during the WADIS-2 campaign as background information for further studies. Small-scale variations of gravity waves and turbulence are part of a separate paper and out of the scope of this paper. A recent submitted paper deals e.g. with small scale variations gravity waves and turbulence:

Strelnikov, B. et. al.: Simultaneous in situ measurements of small-scale structures in neutral, plasma, and atomic oxygen densities during WADIS sounding rocket project. Atmos. Chem. Phys. Discussion, 2018, submitted.

Gravity waves are often discussed in literature by selecting periods of strong gravity wave activities as mentioned above, focusing on short duration measurements of a few hours, but not covering the required measurement length for identifying tides/long period waves. Because of this selection process the importance of tides/long period waves are ignored and most of the time not even discussed. We note that most measurements in literature (lidar and OH-imager) do not even have the capability of true 24-hour measurements or measurements are too short because of weather or other limitations. The references given (Pautet et al., 2014; Bossert et al., 2014) are examples of this selected view to the mesosphere.

In contrast, we show in this paper for the day of the WADIS-2 campaign that small-scale gravity waves can be absent for most of a day in the field of view of 200x160 km<sup>2</sup>, playing nearly no role (see Fig 8). Fig. 9 shows for three locations of lidar and rocket the agreement of the AMTM-temperature measurements for different locations as an example for all measurements within the field of view of the AMTM. For the whole field of view this is already discussed in the manuscript. We note that a comparison of different instruments at different locations with high accuracy is not possible in the presence of small-scale gravity waves. This is to the best of our knowledge the first data set allowing such a detail comparison in literature and therefore new. The agreement of all instruments in absolute temperatures cannot be expected and is often showing a time dependence over the measurement period. This is clearly not the case here. We note that 3 different methods of temperature observations are compared here.

As an example that this in general is not the case is shown at the lower altitude part in figure 2. The temperatures measured with CONE on the rocket are the same at altitudes above 80 km. In the range 70 km to 80 km the profiles look less smoothed due to small scale gravity waves and there is a temperature

difference of more than 30 K (also mentioned in the text). We note that this measurements are only two minutes and 50 km apart. In this unique case such major differences do not occur throughout the day at the altitude of the AMTM measurement in a field of view of 200x160 km<sup>2</sup> which is an unexpected finding not published elsewhere and in agreement with the lidar observations.

The conditions during the WADIS-2 campaign therefore allow to our knowledge for the first time a detailed comparison of several instruments at different locations with high accuracy

The Fe lidar can provide information on long periodic variations due to the possibility for solar background free daylight measurements. This optimisation reduces the sensitivity for short periodic waves. The short period, small-scale gravity are not observed because of the very small amplitudes of these waves during this particular day.

There are not many measurements during the winter season with the lidar. It is usually not operated for short good weather periods of only a few hours, which is the typical situation during the winter in Andoya. As already mentioned in the text, there are not enough measurements in February or March to give a more detailed overview. As mention below, a fitted temperature climatology is used to compare with the daily mean temperature. A climatology of tides or waves with long periods are hardly possible. A lot of measurements don't cover a full day or more, due to weather conditions and other operation limits.

The AMTM can measure only during night-time and therefore can hardly cover a full day, which is needed to get reliable tidal information. Measurements are only available during and around the winter season.

If it is assumed (reviewer comment to saturated gravity wave amplitudes) the small scale waves have such small amplitudes because of saturation effects it is necessary to include tidal amplitudes (see also comment to saturated gravity waves below) to characterise the small scale waves. Without tidal information for the winter season as background temperature field (not enough measurements in this season with the Fe lidar) a classification in context of a gravity wave climatology can hardly be done.

## Suggestions

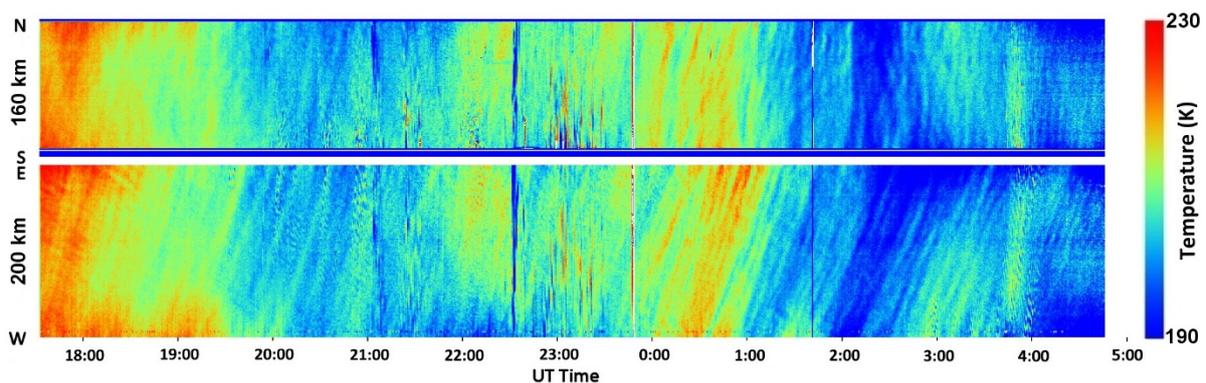

1) The speculation about tides can be resolved with the help of meteor radar data (a meteor radar is located in the vicinity of the launch site). Retrieving tidal components and phases from meteor winds is common practice.

This study is dealing with temperatures. Since there is no simple and direct connection between wind and temperature variations (e.g. different modes for wind and temperature), we don't think it's helpful to add wind information. A tidal analysis of the winds provides different results as for the temperatures. With one single day of measurements it is not possible to understand the differences in wind and temperatures and we think at the end there are more

new questions than answers. The comparison of temperatures and wind should be done with a larger dataset and in a separate study.

2) Keograms created from AMTM data can provide information on the horizontal structure of the larger-scale waves and direction of propagation.

As mentioned in the text, the variations with long periods are practical simultaneous on the whole AMTM temperature maps. The large scale variation (red to blue in the keograms) don't show a clear propagation direction (19:00 maybe from west, 22:00 maybe from east?).

It is correct the Keograms show some small scale wave (mainly 5 min period with small amplitudes). But from time to time there were clouds or fog during this night. There are several time slots which are disturbed by the effects of the clouds or fog, e.g.: around 21:00, 23:00, 03:00, 04:00.

The Keogram is already submitted by Strelnikov et al. as mentioned above

4) Include temperature data taken by the co-located Rayleigh lidar (I assume it was running during the WADIS-2 campaign). Extending the altitude range down to ~70 km may help to distinguish between tides and gravity waves.

It is not possible to extend the altitude range with the RMR lidar in this way. Similar to the lower part of the Fe lidar data set (75 - 80 km) the RMR lidar doesn't provide temperatures during the whole 24-hour in the altitude range 70 - 80 km due to daylight conditions. With only partial coverage no meaningful results can be expected above 70 km altitude in terms of long period waves/tides. For this reason we show e.g. no results from the wave analysis (figure 6) for the altitude range below 80 km. The lower altitude (< 70 km) are out of the scope of this paper and shown by Strelnikov et al.

## Major comment 2

The authors do not meet the data policy ([https://www.atmospheric-chemistry-andphysics.net/about/data\\_policy.html](https://www.atmospheric-chemistry-andphysics.net/about/data_policy.html)) which clearly states the request for depositing the data in reliable (public) data repositories.

page 16, line 20: data is available now, at the mentioned repository.

#### Minor comments

Page 2, line 4: What does "nearly background free measurements" mean?

Page 3, line 8: free of solar background is meant, text is changed

Page 3, line 20: What is the idea behind "connecting vertical data sets"? What does that mean in practice?

page 3, line 21: text is changed to clarify, that the horizontal resolved variations can help to decide if the structures of two, or several vertical profiles belong to the same phenomena or are two independent features.

Page 4, line 15: What is the typical temperature error of these lidar measurements?

page 5, line 5: typical temperature error is mentioned now at the beginning of the paragraph

Caption of Figure 2: "the RMS of all Fe lidar profiles with in a period of +/- 60 min around launch time" – The integration time is 60 min for all profiles, right? Are you saying that you computed the RMS of all profiles which have their centers in the interval 60 min before launch to 60 min after launch? How many profiles did you use?

Caption figure 2: correct, mentioned now in the caption

page 13, line 3: also mentioned in the text

Page 5, line 3: I suggest you move the information concerning resolutions and errors to the beginning of this section, before you discuss the lidar temperature profile in Figure 1.

page 5, line 5: done

Page 5, line 6: "Mean temperatures during the observation period are around 190 K which is typical for the mesopause region..." - Well, that depends on what altitude you are talking about. According to your Figure 3, the mesopause is at the top of your profiles or above.

Page 6, line 3: mean temperature profile of the day is compared with a profile of the climatology, figure 4 added.

Page 5, line 4: "not more than 10 K" – Did you limit the vertical extent of your temperature profiles to altitudes where the error is <10 K?

page 5, line 6: Correct, temperatures with uncertainties larger than 10 K are not shown, written in the text now.

Page 7, line 1: "deviation from the mean in comparison to the deviation of a temperature field reconstructed..." – I assume you computed the mean for each altitude and removed it?

page 8, line 3: correct, sentence changed

Page 10, line 6: "are averaged correspondingly" - What temperatures are averaged? Earlier you stated that the integration time is 60 min. Please clarify.

page 8, line 11: yes, integration time is already 60 min for the lidar profiles. Only the AMTM temperatures are averaged, to get a similar time resolution. Sentence changed

Page 11, lines 15-16: "very similar variations of the 3 profiles suggest a dynamic structure at a larger scale than the measurement distances of about 60 km" – That statement is not well supported by your data. In my opinion, all you can safely say here is that there appears to be no significant variability at horizontal scales below about 60 km.

page 12, line 17: modified, large structures are mentioned as a possibility, not as fact, now.

Page 11, lines 19-20: "Variations on scales shorter than the measurement distance would cause either larger differences or a phase shift between the profiles" – Please clarify. What are you referring to? Are you comparing the three profiles which were taken approximately at the same time, or are you referring to the temporal evolution of the lidar measurements? In any case, a phase shift between the profiles causes larger RMS differences, unless the phase shift is  $2\pi$ .

page 13, line 3: paragraph is rewritten to make it clearer.

Page 12, lines 30-33: I do not think you can say that your value (43 km according to Table 1, or 40 km as written in the text?) is in good agreement with a vertical wavelength of 30-35 km reported by Forbes.

page 14, line 9 ff.: numbers are updated and corrected, the text is changed

Page 13, line 8: According to your Table 1 the vertical wavelength of the 8-hour component is 23 km and not 30 km. Please make the values consistent.

all numbers has been checked and corrected, there was something wrong.

Page 14, lines 15-16: "were dominated by larger waves ... and are nearly undisturbed by gravity waves of smaller scales" – This statement is sort of trivial. It is clear that small-scale waves, in particular waves with small vertical wavelengths, become quickly unstable as amplitudes grow. Therefore, amplitudes of small-scale waves are in general smaller than larger scale waves, and the larger scale waves appear to be undisturbed by the small-scale waves. A more interesting question is whether amplitudes are close to the saturation limit. See for example Smith et al., Evidence for a saturated spectrum of atmospheric gravity waves, 1987.

page 16, line 4: sentences are changed to "play only a minor role", instead of disturbed.

Correct, small scale wave are limited at smaller amplitudes than waves with large scales. Nevertheless, there are situations (usually the cases which are selected for gravity wave analysis in other studies) with larger wave amplitudes (mentioned example in the text). We have a situation without significant waves with periods from 6 h to 5 min and only minor important small scale/period waves (5 min).

The limit of amplitudes is always function of the amplitudes of all waves. As mentioned above we don't have enough common and long lidar and AMTM measurements to classify the conditions in a way of a climatology including tides and gravity waves.

Typos, grammar, wording

Page 2, line 14: "allows us to study" or "allows for studies"

**Correspondence:** Raimund Wörl (woerl@iap-kborn.de)

**Abstract.** This paper presents simultaneous temperature measurements by three independent instruments during the WADIS-2 rocket campaign in northern Norway (69° N, 14° E) on 5 March 2015. Vertical profiles measured in-situ with the CONE instrument ~~and continuous~~. Continuous mobile IAP Fe lidar (Fe lidar) measurements during a period of 24 h, as well as horizontal resolved temperature maps ~~of by~~ the Utah State University (USU) Advanced Mesospheric Temperature Mapper (AMTM) in the mesopause region, are analysed. Vertical and horizontal temperature profiles by all three instruments are in good agreement. An harmonic analysis of the Fe lidar measurements shows the presence of waves with periods of 24 h, 12 h, 8 h, and 6 h. Strong waves with amplitudes of up to 10 K at 8 h and 6 h are found. The 24 h and 12 h components play only a minor role during these observations. In contrast only few short periodic gravity waves are found. Horizontally resolved temperatures measured with the AMTM in the OH layer are used to connect the vertical temperature profiles. In the field of view of 200 x 160 km<sup>2</sup> only small deviations from the horizontal mean of the order of 5 K are found. Therefore only weak gravity wave signatures occurred. This suggests horizontal structures of more than 200 km. A comparison of Fe lidar, rocket-borne measurements, and AMTM temperatures indicate an OH centroid altitude of about 85 km.

## 1 Introduction

The MLT (mesosphere and lower thermosphere) region is one of the key regions for the interaction of planetary waves, tides, and gravity waves. Thermal tides are typically excited by solar heating of water vapor in the troposphere, ozone in the stratosphere and mesopause region, and oxygen above 90 km altitude. They can also be excited in the troposphere by latent-heat release due to deep convection (e.g., Chapman and Lindzen, 1970; Forbes, 1984; Hagan and Forbes, 2002). Due to the excitation processes, tides have periods of the solar day (24 h) and its harmonics (12 h, 8 h, ...). Gravity waves are mostly generated in the troposphere and lower stratosphere by the flow above orographic structures, convective instabilities, wind shears, jet streams, or wave-wave interactions (e.g., Fritts and Alexander, 2003). Their propagation depends on the background wind field and its modulation by tides and planetary waves (e.g., Eckermann and Marks, 1996; Senf and Achatz, 2011). The different atmospheric layers are coupled by the transport of momentum and energy on a wide range of scales due to the propagation

and interaction of these waves. Gravity waves and tides are therefore a key driving mechanism for atmospheric processes and play an important role in their understanding.

Our knowledge of properties of the MLT region is still very limited. The main reason for this lack of knowledge is the difficulty of experimental research at this altitude. Detailed and continuous measurements are still rare (e.g., Smith, 2012).

5 In recent decades different techniques have been developed to investigate the MLT region. While satellites provide a global overview of the atmosphere, ~~they do not allow it's no possible~~ to investigate variability on short time scales since they typically need several weeks to cover 24 h of local time. In-situ observations with sounding rockets ~~allow are~~ local measurements with high resolution and precision but can be realised sporadically only. Remote sensing methods typically rely on specific phenomena which appear in the mesopause region, e.g., meteors evaporating at these altitudes. This creates layers of metallic  
10 atoms such as iron (Fe) which can be probed by resonance lidars to derive temperatures. Furthermore, the specific chemistry of the mesopause region creates a persistent hydroxyl (OH) layer. The airglow resulting from excited OH molecules can be detected from ground based imagers to derive temperatures and horizontal resolved wave informations.

This paper shows results from experimental investigation of temperatures in the mesopause region in the frame of the WADIS-2 sounding rocket campaign, which ~~allows make it possible~~ to study the MLT region with high temporal and spatial  
15 resolution. The name WADIS stands for 'Wave propagation and dissipation in the middle atmosphere: Energy budget and distribution of trace constituents'. The main goal of the campaign led by the Leibniz Institute of Atmospheric Physics (IAP), was to study propagation of gravity waves from their sources in the troposphere to their level of dissipation in the MLT and quantification of their contribution to the energy budget of the upper atmosphere. For an overview of the WADIS project and its main mission the reader is referred to Strelnikov et al. (2017). In section 2 three instruments providing MLT temperature  
20 observations with some important parameters are described. The observations and their analysis are described in section 3. Finally, the results are discussed in section 4, and a short summary is given in section 5.

## 2 Instruments

Three instruments provided direct and indirect temperature observations in the MLT region during the WADIS-2 campaign ~~are analysed in this study: the~~. The CONE instrument on-board the WADIS-2 rocket, the mobile IAP Fe lidar, and the Utah State  
25 University Advanced Mesospheric Temperature Mapper (AMTM are analysed in this study). These instruments are briefly introduced in the following.

The WADIS-2 payload was equipped with two identical CONE instruments (COMbined sensor for Neutrals and Electrons) on the front and rear deck of the payload. They measure turbulence, neutral air temperature and density, and electron density with very high spatial resolution of the order of centimetres (Giebeler et al., 1993; Strelnikov et al., 2013). Data acquisition is  
30 performed independently for each sensor. As the rocket probes the upper atmosphere, the centre of mass of the payload follows a ballistic curve but the orientation remains roughly upright. This means that the same ends of the payload are always facing upwards and downwards. The data of the respective CONE sensors pointing in the direction of the flight (front bay for the

upleg, rear bay for the downleg) are analysed in this study. More details on the CONE instrument and the complete payload instrumentation can be found in Giebler et al. (1993) and in Strelnikov et al. (2013, 2017).

Two further instruments providing ground-based observations of temperatures in the mesopause region are located at the ALOMAR observatory (Arctic Lidar Observatory for Middle Atmosphere Research), at a distance of approximately 2 km to the South of the WADIS-2 rocket launch site at the Andøya Space Center.

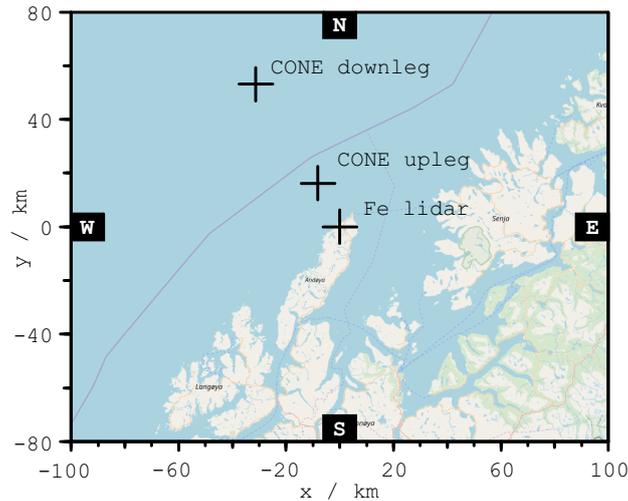

The mobile IAP Fe lidar (Fe lidar) has been operating at the ALOMAR observatory since summer 2014. It determines mesospheric temperatures and Fe densities by probing the Doppler-broadened Fe resonance line at 386 nm with a frequency-doubled alexandrite ring laser. The system ~~is capable of observations ca measure during night and day. Observations~~ in full daylight ~~and allows nearly background free measurements during night and day~~ are nearly free of solar background. The receiving telescope is pointed vertically. The altitude range of accurate resonance lidar temperature measurements is limited to about 75 km to 100 km due to the extent of the meteoric Fe layer (e.g., Lautenbach and Höffner, 2004; Viehl et al., 2016). Further information about the instrument has been published by e.g., Lautenbach and Höffner (2004) and Höffner and Lautenbach (2009).

The Utah State University (USU) Advanced Mesospheric Temperature Mapper (AMTM) (Pautet et al., 2014) was installed at the ALOMAR observatory in 2010 and measures OH (3,1) rotational temperatures at the altitude of the OH layer. An altitude range of 82 km to 90 km ~~was found~~ is typical for the OH centroid height (e.g., von Zahn et al., 1987; Baker and Stair, 1988). The AMTM ~~allows temperature observations can observe temperatures~~ with high temporal and spatial (horizontal) resolution during the night even in presence of auroras. During the day, the solar background rises above the OH emission which prevents further observations. An OH intensity and temperature map with a resolution of 320 x 256 pixels (0.6 x 0.6 km<sup>2</sup> per pixel) is taken from the OH layer every 30 s. This corresponds to an overall area of 200 x 160 km<sup>2</sup> centred at the observation site (ALOMAR). In Pautet et al. (2014) more information on the instrument and its development are given.

The horizontal arrangement of the measurement volumes at the OH layer altitude is shown in Fig. 1. The ~~horizontally resolved features in the vertical profiles can be connected by the horizontally resolved structures in the~~ AMTM temperature maps ~~allow to connect the vertical datasets, which are point measurements in the horizontal domain and identify them as the same or different phenomena~~. As illustrated in Fig. 1, the WADIS-2 rocket was launched ~~roughly~~ approximately in north-western direction. The marks labelled 'rocket upleg' and 'rocket downleg' indicate the positions at which the rocket passed through the OH layer during the up- and the downward flight paths, respectively. The 'Fe lidar' mark defines the location of Fe lidar measurements at the ALOMAR observatory, where the AMTM is also located. The crosses on the map mark only the location, not the size of the CONE and the lidar measurement volumes. Their horizontal extent is of the order of several cm for the CONE sensors and several 10 m for the Fe lidar.

### 30 3 Observations

The WADIS-2 rocket was launched from the Andøya Space Center in northern Norway (69° N, 14° E) on 5 March 2015 at 01:44 UT. Good weather conditions with clear sky in the period from 4 March 2015, 10:00 UT to 5 March 2015, 12:00 UT ~~allowed~~ enabled for simultaneous and nearly continuous Fe lidar and AMTM measurements with high data quality. No relevant

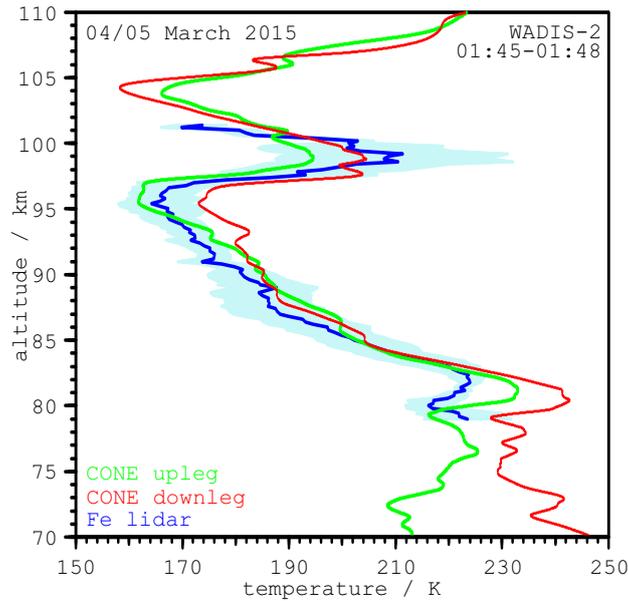

**Figure 1.** Map showing the area covered by the AMTM at the centroid altitude of the OH layer at about 86 km. The points of measurement at that altitude are marked for each instrument (see text for further details).

ground based optical measurements were obtained during the days before or after the launch due to poor weather conditions. In the following we focus on the discussion of data obtained within a 24 h period around the launch night, i.e. from 4 March 2014 12:00 UT to 5 March 2015 12:00 UT.

### 3.1 WADIS-2 rocket (CONE)

- 5 Figure 2 shows the vertical temperature profiles obtained from the CONE measurements on the rocket payload. The horizontal distance of the up- and downleg measurements is around 50 km at an altitude of 86 km (see Fig. 1). The duration of the flight through the mesopause altitude range between 70 km and 110 km is about 50 s both for the up- and downleg. In between the two profiles, the rocket spent about 2 min in the apogee range above 110 km. An effective altitude resolution of the temperature measurements with the CONE sensor is about 200 m (Rapp et al., 2003). The shapes of both profiles are very similar above 80
- 10 km and differ only in small details. The uncertainty is about 2 K at 70 km and increases with altitude (up to about 5 K at 110 km) (Strelnikov et al., 2013). For the most part the differences are within the uncertainty. The temperature shows two maxima at about 80 km and 100 km. Such features are often referred to as "mesospheric inversion layer" (e.g., Hauchecorne et al., 1987; Hauchecorne and Maillard, 1992; Meriwether and Gerrard, 2004). The most prominent deviations between the profiles are of the order of 10 K and occur at around 95 km and below 80 km.

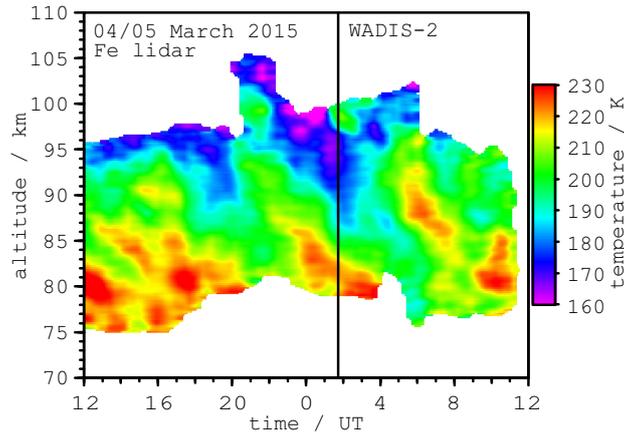

**Figure 2.** Vertical temperature profiles at the launch time of the WADIS-2 rocket. The red and green curves show the in-situ measurements with the rocket payload (CONE). The upleg (green) and the downleg (red) profiles are measured with two independent instruments at the ends of the payload. The Fe lidar (blue) profile is integrated over 60 min and centred at 01:45. ~~In addition, The blue shaded area shows the RMS of all Fe lidar profiles which have their centre within a period of  $\pm 60$  min around launch time (blue shaded area) show the variability in time.~~

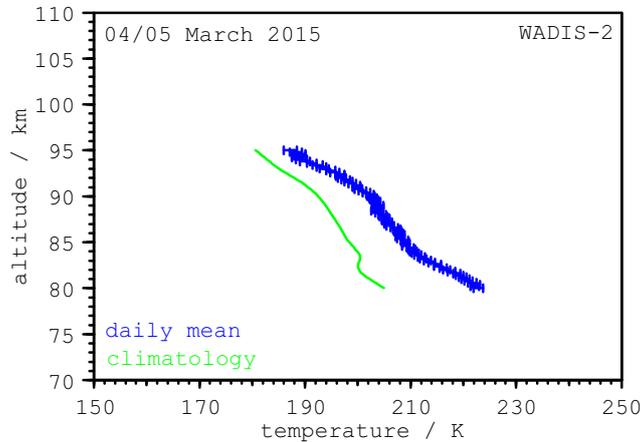

### 3.2 Fe lidar

For direct comparison with the CONE data, the temperature profile obtained by the Fe lidar at the time of the rocket launch is shown in Fig. 2. In contrast, to the in situ measurements, the Fe lidar data ~~is~~ are integrated over 60 min and 1 km in altitude (with 0.2 km intervals) to derive a temperature profile. The centre of the averaging window is 01:45 UT.

- 5 Typical uncertainties are of the order of 2 K. At the edge of the layer where metal densities are lower than in the centre and the backscatter signal therefore is weaker the uncertainties are larger. Only temperatures with uncertainties not more than 10 K are shown. As shown in Fig. 1 for an altitude of 86 km, the distance of the Fe lidar profile to the upleg of the rocket is about 10 km. Therefore, the maximum distance between all three profiles is around 60 km. The temperature profile measured with the Fe lidar is in good agreement with the profiles measured with the CONE sensors on the rocket.
- 10 Figure 3 shows the temporal evolution of the temperatures in the mesopause region. Temperatures are calculated in 15 min and 0.2 km intervals using running means of 60 min and 1 km width, respectively. ~~Typical uncertainties are of the order of 2. At the edge of the layer where metal densities are the lowest and the backscatter signal therefore the weakest the uncertainties are not more than 10.~~ The observable altitude range as well as measurement uncertainties vary over time as absolute Fe

**Figure 3.** Temperatures measured with the Fe lidar in the 24 h period around the WADIS-2 launch at 01:44 UT (vertical line). Measurement uncertainties are smaller than 10 K throughout the altitude range and decrease to around 2 K towards altitude with highest Fe density.

**Figure 4.** Daily mean temperature profile (WADIS-2 day) compared to the profile from the climatology for the same day of the year. Only altitudes with 24 h observation time is shown.

densities and the vertical extent of the metal layer changes throughout the day (e.g., Höffner and Fricke-Begemann, 2005; Viehl et al., 2016).

Fig. 4 shows the mean temperature profile of the shown 24 h Lidar measurement (see Fig. 3) compared to a profile calculated from the temperature climatology for the same day of the year. The climatology is calculated as described in Gerding et al. (2008) with a fit and includes about 2000 h of measurements since 2008 at Andøya. Mean temperatures during the observation period are around 190 which is typical for the polar mesopause region in the late winter state. and the differences between the profiles are in the order of the day to day variability.

Strong wave like modulations with amplitudes of more than 30 K are clearly present. Lübken et al. (2011) observed similar wave-like modulations with the same instrument at the conjugate latitude in Antarctica. That study found surprisingly strong tidal signatures in temperature and Fe density observations with an harmonic analysis (24 h and 12 h components) in summer. We perform a similar harmonic analysis to further investigate the apparent wave-like temperature structure in Fig. 3. The data shown in Fig. 3 is averaged in intervals of 60 min and 1 km vertical resolution. A non-linear function of sinusoidal components with fixed periods  $P_i$  is then fitted to the observations according to the relation

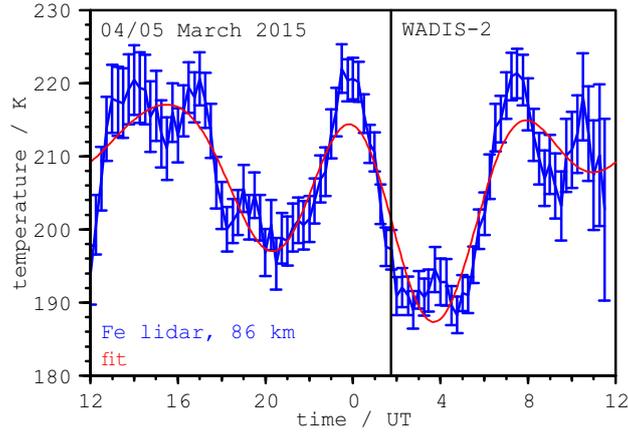

~~Temperatures measured with the Fe lidar in the 24 period around the WADIS-2 launch at 01:44 (vertical line). Measurement uncertainties are smaller than 10 throughout the altitude range and decrease to around 2 towards altitude with highest Fe density.~~

$$10 \quad T(t, z) = A_0(z) + \sum_i A_i(z) \cdot \cos\left(\frac{2\pi \cdot (t - \Phi_i(z))}{P_i}\right) \quad (1)$$

where  $A_i(z)$  are the amplitudes,  $\Phi_i(z)$  the phases (at the time of the maximum amplitude), and  $z$  the altitude. In addition to the periods of 24 h and 12 h investigated by Lübken et al. (2011), we also consider the higher harmonic 8 h and 6 h components. All four components are optimised simultaneously but independently for each altitude using a least square fit routine. The seasonal variation in this analysis of 24 consecutive hours can be neglected contrary to the method presented by Lübken et al. (2011).

Figure 4-5 shows the result for the exemplary altitude of 86 km over time compared with the measurement. The main variation with large amplitudes is nearly fully described by the model using 4 components. The remaining variations are small compared to overall modulation which is of the order of 30 K. The mean square-squared error of the deviation is 4.6 K. The amplitudes for the 24 h and the 12 h components are 4.8 K and 2.8 K, respectively. The higher 8 h and 6 h components show amplitudes of 6.5 K and 1.4 K.

Figure 5-6 shows the amplitudes and phases derived for all altitudes. Not all available temperature measurements shown in Fig. 3 are included here, as altitudes below 80 km and above 95 km are not fully covered throughout the 24 h observation period. Noteworthy is the large amplitude of the 8 h component at all altitudes which partly exceeds 10 K as well as the strong 6 h component (above 87 km). Neither the 24 h nor the 12 h components reach comparable amplitudes. Altitudes at which the amplitudes of the harmonic fit is smaller than their uncertainty are removed in the phase plots. All 4 components show a clear phase response-progression in altitude without large phase jumps. This suggests clear waves in the data with periods near the chosen fit periods (24 h and higher harmonics). Since every altitude is fitted independently, unelear-random wave structures would lead to a more incoherent phase response and amplitude-amplitude. A linear fit of the phase is used to estimate the phase slope for every component: a. A vertical wavelength and a phase are calculated using the slope and the position of the fitted lines at 86 km. Table 1 summarises the derived vertical wavelengths ( $\lambda_{\text{vertical}}$ ) and the phases at 86 km. Phases are given in local solar time (LST) which was UT + 51 min at the launch site on 5 March 2015. These values are calculated with a simple assumption of a linear phase progression with altitude. Due to the short available altitude range of only 15 km and the variability of the phase values with altitude (see Fig. 6) this can only be a rough estimation (without uncertainty). Generally

**Figure 5.** Comparison of the temperature variations measured with the Fe lidar (blue) at an altitude of 86 km with the reconstruction (magenta) using the results of the harmonic wave analysis. The amplitudes of the 24 h, 12 h, 8 h and 6 h components are 4.8 K, 2.8 K, 6.5 K and 1.4 K.

periode	24 h	12 h	8 h	6 h
$\lambda_{\text{vertical}}$	43 km	22 km	23 km	30 km
phase	<del>+6-14</del> LST	<del>+4-11</del> LST	<del>+8-17</del> LST	<del>+5-13</del> LST

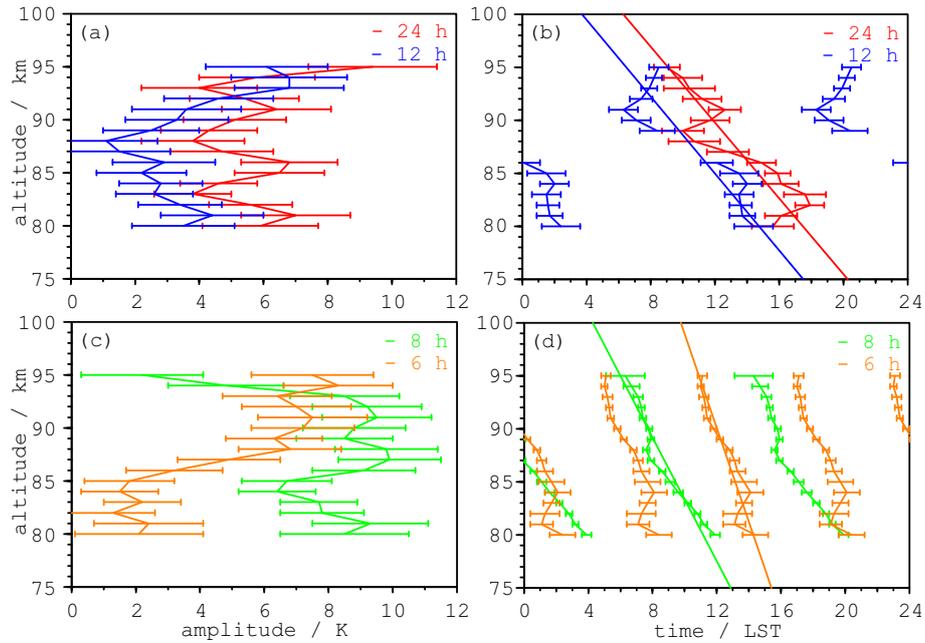

**Table 1.** Vertical wavelengths ( $\lambda_{\text{vertical}}$ ) and phases (at 86 km) derived from the harmonic fit of Fe lidar temperatures.

the shape of the phase progression is no straight-line and the exact wavelength has to be identified from the distance between to extrema, which is not possible with our dataset.

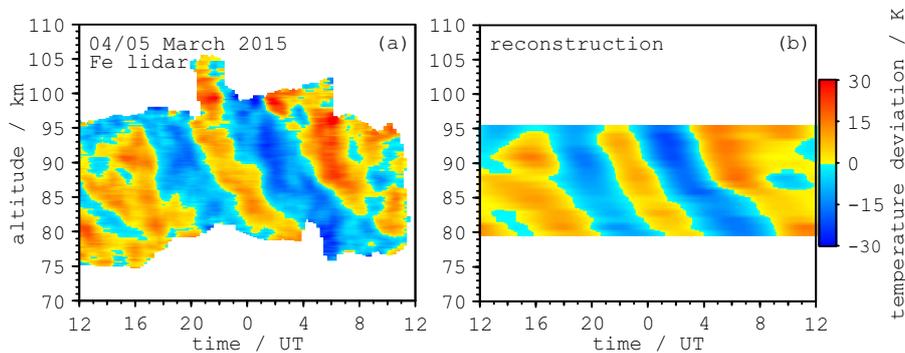

Figure ~~6~~ shows the ~~observed temperature~~ 7 shows the deviation from the mean temperature at each altitude in comparison to the deviation of a temperature field reconstructed using only the components derived in the harmonic analysis. This reconstruction is in good agreement with the observations. The residuals do not exhibit any systematic deviations (not shown). Differences between measured and reconstructed temperatures mainly consist of small variations with periods smaller than 6 h which are not considered in the fit.

### 3.3 Advanced Mesospheric Temperature Mapper (AMTM)

The ~~Advanced Mesospheric Temperature Mapper (AMTM)~~ AMTM provides horizontally resolved temperature maps during night-time conditions (sun more than  $9^\circ$  ~~under~~ below the horizon). In early March, first temperature maps are available at around 17:30 UT and observations end at around 05:00 UT. On the ~~particular~~ day of the WADIS-2 campaign, the data quality was somewhat affected by passing clouds between 22:00 UT and 24:00 UT as well as after 04:00 UT.

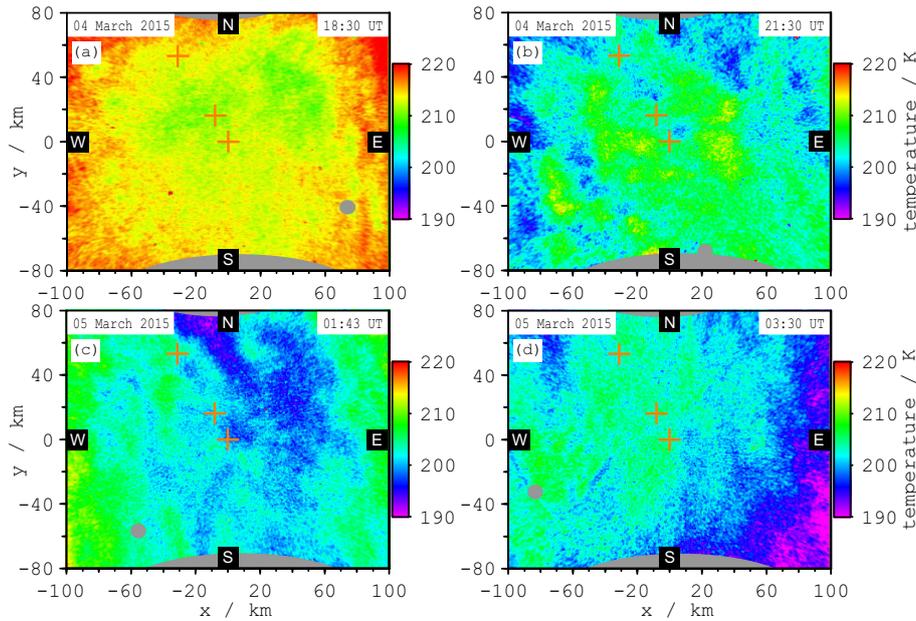

**Figure 6.** Amplitudes (a), (c) and phases (b), (d) of the 24 h (red), 12 h (blue), 8 h (green), and 6 h (orange) wave components during the 24 h period around the WADIS-2 launch. The phase shift with altitude is approximated with straight lines and used to calculate vertical wavelengths. The approximation corresponds to vertical wavelength of 43 km for the 24 h, 22 km for the 12 h, 23 km for the 8 h and 30 km for the 6 h component.

**Figure 7.** Temperature observations with the Fe lidar (a) and the reconstruction using the 4 harmonic components (b) derived in the analysis.

### 3.3.1 Horizontal temperature structure

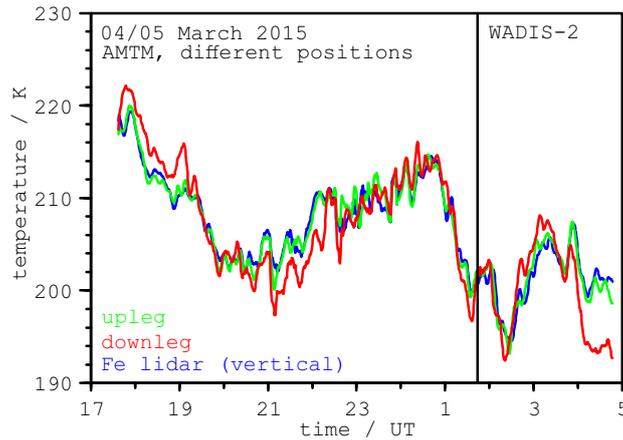

Four representative examples of horizontal temperature maps are shown in Fig. 78. All panels show absolute temperatures (same scale with 30 K range). The boundary areas of the maps are partly shaded by other equipment on the roof or dust (the grey areas in the upper and lower part of the figures). Panels (a) and (b) are taken at 18:30 UT and 21:30 UT, that is, 7.2 h

**Figure 8.** Temperature maps measured with the AMTM. In (a), (b) and (d) the typical situation during the observation time is shown. (c) shows the situation at the rocket launch time. Very little-low gravity wave activity is apparent, which was the typical condition during this night.

and 4.2 h before the rocket launch. Panel (c) shows the temperature structure at the time of the rocket launch at 01:44 UT. This observation was taken one minute before the launch, since the camera was overexposed due to the brightness of the rocket engine one minute later. Panel (d) shows the situation at the end of the AMTM observations at 03:30 UT (1.8 h after rocket launch). Due to higher temperatures at the beginning of the observations (see Fig. 8-9 or Fig. 9-10) the temperature map in panel (a) (18:30 UT) differ-is different from the other panels (more red and yellow instead of green and blue). These examples show only a slight increase or decrease at the edges and otherwise exhibit no systematic variations throughout the horizontal extent of the observations. In particular, the regions with vertical observations by CONE and Fe Lidar (indicated by orange crosses, compare to Fig. 1) show only very small temperature variations. Observations with more gravity wave activity visible in AMTM maps are also available. Examples of common AMTM and lidar measurements with more gravity wave activity at the ALOMAR observatory can be found in e.g., Bossert et al. (2014).

Figure 8-9 shows the temporal evolution of the temperatures at different locations. The selected positions are the marked observation volumes of the other instruments (sub-array of  $9 \times 9$  pixels which corresponds to about  $5 \times 5$  km<sup>2</sup>) and show the time-dependent OH temperature evolution measured with-by the AMTM. The time series is averaged by a 5 min running mean window shifted in 30 s intervals. The temperature differences between the selected locations does not vary significantly beyond the 2-3-2 K measurement uncertainty of the AMTM at-for most of the time. Temperature variations in time are dominated by long term variations of several hours. There are also waves with periods around 5 min, but with small amplitudes of only a few

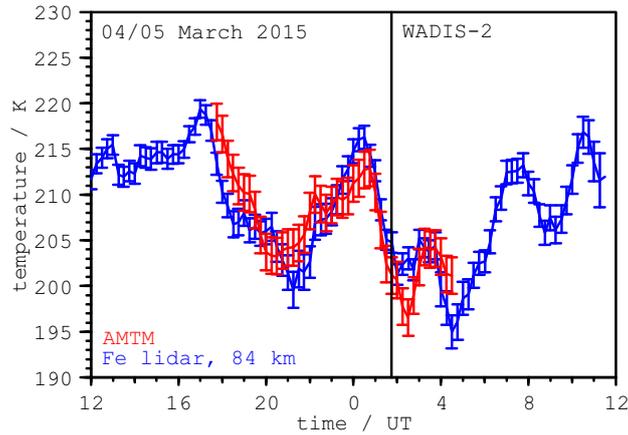

**Figure 9.** Temporal evolution of AMTM temperature observations derived from sub-arrays of  $9 \times 9$  pixels (about  $5 \times 5 \text{ km}^2$ ) at the centre (blue), the rocket upleg (green), and the rocket downleg (red), respectively. The time series is smoothed with a Hanning filter of 5 min width.

K (not shown). But they are disturbed from time to time by passing clouds. At the exact time of the launch, no temperature differences are discernible. The variations are nearly synchronous at all locations. The choice of the sub-array size (here  $9 \times 9$  pixels) used to calculate a representative temperature for every position has nearly no effect on the results. A single pixel as well as an area larger than  $9 \times 9$  pixels yield to nearly the same temperatures (not significant different, not shown). This implies structures larger than the field of view ( $200 \times 160 \text{ km}^2$ ) in horizontal direction, since neither the average area size (sub-array) nor the position on the map have significant influence on the temperature results on this night.

### 3.3.2 Comparison of horizontal and vertical temperature observations

In Fig. 9, temperatures from AMTM observations are compared to vertical Fe lidar observations. An area of  $9 \times 9$  pixels around the centre of the AMTM temperature map is taken and smoothed using a 60 min running mean window. The That is the same time resolution as the Fe lidar temperatures ~~shown here are averaged correspondingly (integration time of 60 min).~~ Furthermore, a vertical averaging needs to be applied to the Fe lidar data to take the ~~altitude distribution vertical profile~~ of the OH layer and the subsequent altitude weighing of AMTM temperature measurements into account. However, the actual vertical extent of the OH layer during this observation is unknown. A Gaussian distribution with a constant FWHM of about 9 km is frequently assumed (e.g., Pautet et al., 2014)(e.g., Pautet et al., 2014; Zhao et al., 2005). This distribution is applied to the Fe lidar data as a weighting function, simulating the AMTM's vertical averaging throughout the OH layer. The centroid altitude of the weighting function is then shifted in altitude to find the best agreement between absolute AMTM and Fe lidar temperatures. The best agreement is found at a centroid altitude of for the centroid altitude  $84 \pm 1 \text{ km}$ , where both instruments show the same temperatures within the error bars throughout the full observation period. This is a plausible altitude of the OH layer and hereafter assumed to be the peak-mean altitude during the night. The best temperature agreement is found at a slightly higher centroid altitude of  $85 \pm 1 \text{ km}$  if relative temperature variations and not absolute temperatures are considered.

**Figure 10.** Time series of OH temperatures (red) in comparison with the Fe lidar temperatures (blue). Lidar temperatures are averaged in altitude with a Gaussian weighting of 9 km FWHM and peak altitude of  $84 \pm 1$  km. Temperatures of the AMTM are taken from a sub-array of  $9 \times 9$  pixels at the ~~locations~~location of the Fe lidar and smoothed by a 60 min running mean.

However, this difference of 1 km (within the altitude uncertainty) is not significant for the following discussion as the weighing function smooths the values from different altitudes at a comparatively broad FWHM of 9 km. The exact knowledge of the OH layer altitude is not important ~~to study for studies of~~horizontal structures, since relative ~~instead of absolute temperatures can~~temperatures are be used .

## 5 4 Discussion

The temperature profiles obtained by the CONE instrument during the up- and downleg (50 km distance) show a remarkably good agreement. ~~Temperatures~~The profiles are comparatively smooth above 80 km and only a few small structures disturb the dominating large structure. Small differences of about 5 K are observed at around 87 km or at 104 km and 106 km. The uncertainty is about 2 K at 70 km, 5 K at 100 km and 25 K at 110 km (Strelnikov et al., 2013). The CONE sensors measure the whole profile during the short flight time of about 50 s for the altitude range from 70 km to 110 km. Waves with short periods are therefore not averaged out of the temperature profiles derived from the CONE instrument. While the up- and downleg temperature profiles are in good overall agreement above 80 km, they deviate from each other at lower altitudes. Small-scale structures with vertical sizes of several km are largely absent at higher altitudes, but noticeable in the ~~lowest range~~lower part. A possible explanation for the observed behaviour is an enhanced gravity wave activity at altitudes below 80 km. A more detailed analysis of the wave activity at lower altitudes is not possible with the given observations. Above 80 km altitude, the two profiles are also in very good agreement with the Fe lidar measurements. This is noteworthy since all three profiles were measured at different locations and are separated by a distance of up to 60 km. While the CONE sensors have a high time resolution, the Fe Lidar profile is averaged over a 60 min period. The Fe lidar's measurement uncertainty is about 3 K in that

altitude range. ~~The~~ Due to the good agreement (within the uncertainties) and very similar variations of the 3 profiles ~~suggest~~ ~~a dynamic structure at a larger scale than not variability at scales of~~ the measurement distances ~~of about~~ can be identified. Dynamic structures larger than 60 km might be the reason.

Figure 2 ~~shows the vertical profiles at launch time and additionally the RMS of all temperature profiles~~ additionally shows the  
5 RMS of Fe lidar temperature profiles (blue shaded area). The RMS is calculated from all profiles of the Fe lidar (in 15 intervals)  
which have their centres within  $\pm 60$  min around the launch (~~blue shaded area~~ 7 profiles integrated over 1 h, respectively). The  
~~variability of temporal variability of the Fe lidar measurements is~~ up to 20 K within only one hour. This is significantly larger  
than the observed differences between the three profiles (or two instruments) at different horizontal locations. This means  
the phases of these three profiles are the same or deviate from each other by  $2\pi$  or a multiple of it. The latter would mean  
10 wavelength in the order of 60 km (or shorter) and should be visible on AMTM temperature maps. Since the temperature maps  
show no such structures with the same large amplitudes than the temporal variations, they must have wavelengths significant  
larger than 60 km. Variations on scales shorter than the measurement distance would cause either larger differences or a phase  
~~shift between the profiles.~~

The temporal evolution of the thermal structure ~~of the mesopause altitudes in the mesopause region~~ is obtained by analysing  
15 the full dataset of the Fe lidar. As noted above, the temperature structure is dominated by waves with comparatively long periods  
of 8 h and 6 h. This occasionally causes vertical temperatures profiles not following the simple model of a mesopause region  
with a negative temperature gradient below and a positive temperature gradient above. Such inverted temperature profiles are  
sometimes referred to as 'mesospheric inversion layers' and occur quite regularly in the presence of strong ~~long-periodic waves~~  
waves with long periods (e.g., Meriwether and Gardner, 2000). An harmonic analysis demonstrates that the main variability  
20 is given by only 4 harmonic components (24 h, 12 h, 8 h and 6 h), adding up to more than 30 ~~K~~-K temperature difference.  
In addition to these 4 components, only waves with periods smaller than 6 h remain. We note that the dataset the harmonic  
analysis is performed on, is not sensitive to waves with periods smaller than about 2 h due to the 60 min integration time of  
the Fe lidar temperatures.

Fe lidar measurements with the same instrument at the opposite latitude in the southern hemisphere at Davis, Antarctica  
25 (69° S) had revealed clear and regular 24 h (diurnal) and 12 h (semi-diurnal) tides with large amplitudes (Lübken et al., 2011).  
During the WADIS-2 campaign we find a dominating 8 h wave structure. An additional strong 6 h component may also be  
present above 87 km. In contrast to the observations in the southern hemisphere, 24 h and 12 h variations were comparatively  
weak. We note that this current analysis is limited to a single day (24 h) and not a composite of 180 h of measurements during  
a period of 12 days as in Lübken et al. (2011). Due to the high variability in tidal phases and amplitudes (e.g., Murphy et al.,  
30 2006; Baumgarten et al., 2018) the results of a single day (our dataset) are to be expected to deviate to some extent in phase  
(several hours) and amplitude from an average (Lübken et al., 2011).

The presence of clear 24 h and 12 h tides as reported in Lübken et al. (2011) for Davis suggests that tides could be an  
explanation for the measured 24 h and 12 h waves. Nevertheless, gravity waves have to be taken into account, in particular for  
the higher frequency components. It is not possible to exclude them but there are some arguments for tides we discuss below.  
35 ~~The~~ With the analysis of the phase ~~response progression~~ (see Fig. 5) ~~allows~~ 6 an estimation of the vertical wavelength and

the phase are possible. A vertical wavelength of 43 km for the 24 h wave and 22 km for the 12 h wave is found in this study. The phase of the 24 h component at 86 km derived in this study has a maximum at about ~~+6~~14:00 LST, the 12 h component at about ~~14~~11:00 LST. The data used in Lübken et al. (2011) was obtained at different location (southern instead of northern hemisphere) and also during a different season (summer instead of spring). Therefore, a more detailed comparison does not necessarily result in a good agreement due to the seasonal variability. Lübken et al. (2011), however, report only a slightly different vertical wavelength of 30 km for observations of 24 h temperature tides and 40 km for tides in Fe densities, as well as a phase maximum at 86 km at 13:00 LST. Model calculations for thermal tides were done for temperatures, e.g., for 24 h by Forbes (1982a) and for 12 h by Forbes (1982b) at 60° latitude during equinox conditions. The phase ~~response~~-progression reported in Forbes (1982a, b) ~~allows are used~~ to estimate the phase and vertical wavelength for the 24 h and 12 h tide in the same way. ~~A vertical~~Vertical wavelength (at about 90 km) in the range of 30–35 km (~~for the~~ 24 h tide ~~) and is similar to the findings of 43 km in this study, while the range of 20–30 km (for the~~ 12 h tide ~~) in that analysis~~ is in good agreement with the findings of 22 km in this study (~~40 and 22~~). A comparison of the phase does not add up to a clear result. ~~While the~~The phase maximum of the 24 h tide (08:00 LST) calculated by Forbes (1982a) differs significantly from our finding (1614:00 LST), the phase maximum of the 12 h tide (14:00 LST, Forbes (1982b)) ~~is in good agreement with~~differs slightly from our result (~~also~~1411:00 LST). The model calculations in Forbes (1982a, b) do not include short term variability in tides ~~which and also the difference in latitude (Forbes 60°, this study 69°)~~ might be the reason for the differences. The short available dataset in this study (24 h) can also explain the differences, especially for the 24 h tide, since the dataset covers only one period to fit. Nevertheless, the ~~good~~rough agreement of the model calculations, the results in Lübken et al. (2011) and the WADIS-2 dataset in this study is a presumption that at least the 24 h and the 12 h waves are of tidal origin.

Winds from radar measurements and temperatures from airglow measurements at polar latitudes are discussed relating the 8 h and the 6 h tides (~~Younger et al., 2002; Wu et al., 2005; Smith et al., 2004~~)(Younger et al., 2002; Wu et al., 2005; Smith et al., 2004; Dalin). In contrast to our results the higher harmonic components (8 h and 6 h) were found to be significantly smaller than the 24 h and 12 h tides. Vertical wavelength in the range of 25 km to 45 km (spring) are reported for the 8 h tide (Younger et al., 2002; Wu et al., 2005). This is in good agreement with our finding of 30-23 km. 30 to 50 km for the 6 h tide as reported in Smith et al. (2004) is also in good agreement with our result of 30 km and might suggest that the strong 8 h and 6 h components found in this paper are tides. In contrast to the good agreement in vertical wavelength the large amplitudes of the 8 h and 6 h waves are unexpected. Higher harmonic tides, in particular the 8 h component, are discussed in several, also theoretical papers (e.g., Thayaparan, 1997; Taylor et al., 1999; States and Gardner, 2000; Akmaev, 2001; Younger et al., 2002; Batista et al., 2004; Smith et al., 2004; Wu et al., 2005; Beldon et al., 2006; Jacobi and Fyterer, 2012; Lilienthal et al., 2018). Generally the amplitude of the 8 h component and higher harmonics are assumed to be significantly smaller than the 24 h and 12 h components. A small number of publications report 8 h tides with large amplitudes (e.g., Taylor et al., 1999; Thayaparan, 1997), but at mid latitudes. They also report a 8 h tidal component with amplitudes smaller compared to the 24 h and the 12 h component in averaged datasets. However, single events (days) with 8 h tides and amplitudes larger than the 24 h and the 12 h tides are described, too.

Some good reasons can be found that not only the 24 h and the 12 h waves, but also the strong 8 h and the 6 h waves are tides, as described above. However, a larger dataset with global coverage is necessary to determine the temporal and the spatial structure, and to separate the tidal and the gravity wave components unambiguously.

In addition to the vertical information provided by the CONE and Fe lidar instruments, horizontal information can be extracted from the AMTM temperature maps. The AMTM measurements are limited to the OH layer altitude. While this is only a single altitude or rather an altitude range of about 9 km (FWHM) due to the thickness of the OH layer, the analysis reveals interesting horizontal structures. A peak altitude of the OH layer at about 85 km and a FWHM of 9 km are **plausible typical** values and seem to be good estimates since both absolute temperatures and also the structures in the time series show a good agreement with the Fe lidar. Without the presence of small structures (with large amplitudes), like gravity waves, the large structures should dominate the horizontal AMTM temperature maps. In Bossert et al. (2014) and Pautet et al. (2014) some examples of typical AMTM observations with gravity wave activity are described. Figure 7-8 shows the typical situation during the night of the WADIS-2 launch. In contrast to other examples (Bossert et al., 2014; Pautet et al., 2014) **no-clear only random like** small structures are visible. The whole map shows temperature differences of no more than 10 K. This does not exclude the presence of smaller perturbations. Because temperatures are derived from the OH layer with a thickness of about 9 km, vertical structures of a similar size or smaller than the layer width cannot be resolved. A simple way to estimate the relation between datasets measured at different locations in a time series is to pick the temperatures at the locations of interest in the AMTM maps and compare them. Figure 8-9 shows an impressive synchronous evolution at all locations at a resolution of 5 min. Taking the measurement uncertainty of the AMTM of about **2-3-2** K into account there are only a few short periods where the deviations are significant. **At** From time to time, e.g. at around 22:00 UT and at **the end at** about 04:00 UT, the deviations **come from disturbances by** are due to clouds. Comparing the different locations in the horizontal resolved AMTM temperature maps shows that the large structures found in all vertical profiles are not only long periodic, but have also large horizontal scales since no systematic deviation or change in temperature was observed in horizontal direction. Clearly, a dynamic variation with a horizontal extent larger than the field of view of the AMTM, which corresponds to an area of about 200 x 160 km<sup>2</sup>, was present around the time of the WADIS-2 launch. Large structures in horizontal direction are in principle an indication of tidal structures. However, the field of view is limited to 200 x 160 km<sup>2</sup> and it is not possible to exclude gravity waves with horizontal wavelengths of the same order.

Temperatures derived from the Doppler-broadening of metal atoms with the Fe lidar and from excited rotational OH (3,1) transitions with the AMTM are in very good agreement to each other. Both the absolute temperatures and the deviation during the observation period suggest an OH centroid altitude between 84 km and 86 km. However, in context of this paper such statements refer only to the observation in this single night and the assumption of a fixed altitude and layer shape is not justified in all cases (e.g., Zhao et al., 2005; Dunker, 2017)(e.g., Perminov et al., 1999; Melo et al., 2000; Zhao et al., 2005; Liu and Shepherd, 2006; Gry

## 5 Summary

We have analysed the temperature structure in the mesopause region during the WADIS-2 rocket campaign in March 2015. Temperatures in the night of the rocket launch were dominated by larger waves at 8 h and 6 h periods and ~~are nearly undisturbed by gravity~~ waves of smaller scales play only a minor role. The lidar measurements show waves with typical periods for ~~24-24~~ 5 h and ~~12-12~~ h tides. A strong 8 h wave (and at higher altitudes also a 6 h wave) is dominating the variations in temperatures and might be also tides. Amplitudes of up to 10 K for this single harmonic component exceed the corresponding amplitudes of the longer 24 h and 12 h components of 6 K. Disturbances by waves or other structures with smaller periods ~~play only a minor~~ have only small amplitudes and play a minor role.

~~We found only unclear wave pattern with comparable~~ On this night the small-scale gravity wave activity was limited to 10 comparatively small amplitudes of only a few K in the horizontal AMTM measurements. The long periodic tidal-like variations in time domain show no structures in the observable area of 160 x 200 km<sup>2</sup>. The structure size of the dynamic variation dominating this night has to be larger than 200 km, as temperatures change quasi-synchronously at all locations. As result of this situation, the rocket borne measurements show two vertical temperature profiles with very similar structures, although they were measured at a horizontal distance of 50 km.

15 The Fe lidar, which was located 10 km away from the WADIS-2 measurements, provides further vertical temperature profiles which show the same features as the profiles measured with CONE during the rocket flight. Especially the altitude range around the OH layer at about 85 km show the same structures and absolute temperatures.

In this case the OH temperatures show a remarkably good agreement with the lidar temperatures during the whole night, if we assuming an OH density centroid altitude of 85 km. Below 80 km stronger temperature deviation and also small variations 20 are the result of increasing influence of small scale gravity waves.

*Data availability.* Data are available at <ftp://ftp.iap-kborn.de/incom/woerl/WoerlACP2018/>.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* This work was supported by the German Space Agency (DLR) under grant 50OE1001 (project WADIS). The design and initial development of the AMTM was supported under the AFOSR DURIP grant F49620-02-1-0258. Its installation and operations 25 at ALOMAR were supported under the NSF collaborative grant AGS-1042227. This project was also partly supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under project LU1174/8-1 (PACOG), FOR1898 (MS-GWaves). The work was also partly supported by the Bundesministerium für Bildung und Forschung (BMBF, Federal Ministry of Education and Research) under project D/553/67210010 (ROMIC-GWLcycle).
