**Abstract.** Past studies have suggested that ozone in the troposphere has increased globally throughout much of the 20th century due to increases in anthropogenic emissions and transport. We show by combining satellite measurements with a chemical transport model that during the last four decades tropospheric ozone does indeed indicate increases that are global in nature, yet still highly regional. Satellite ozone measurements from Nimbus-7 and Earth Probe Total Ozone Mapping Spectrometer (TOMS) are merged with ozone measurements from Aura Ozone Monitoring Instrument/Microwave Limb Sounder (OMI/MLS) to determine trends in tropospheric ozone for 1979-2016. Both TOMS (1979-2005) and OMI/MLS (2005-2016) depict large increases in tropospheric ozone from the Near East to India/East Asia and further eastward over the Pacific Ocean. The 38-year merged satellite record shows total net change over this region of about +6 to +7 Dobson Units (DU) (i.e., ~15-20% of average background ozone), with the largest increase (~4 DU) occurring during the 2005-2016 Aura period. The Global Modeling Initiative (GMI) chemical transport model with time-varying emissions is **used to aid in the interpretation of** tropospheric ozone trends for 1980-2016. The GMI simulation for the

30 combined record also depicts greatest increases of +6 to +7 DU over India/east Asia, **very similar**  
31 to the satellite measurements. In regions of significant increases in **tropospheric column ozone**  
32 **(TCO)** the trends are a factor of 2-2.5 larger for the Aura record when compared to the earlier  
33 TOMS record; for India/east Asia the trends in TCO for both GMI and satellite measurements  
34 are  $\sim+3$  DU-decade<sup>-1</sup> or greater during 2005-2016 compared to about +1.2 to +1.4 DU-decade<sup>-1</sup>  
35 for 1979-2016. The GMI simulation and satellite data also reveal a tropospheric ozone increase  
36 of  $\sim+4$  to +5 DU for the 38-year record over central Africa and the tropical Atlantic Ocean. Both  
37 the GMI simulation and satellite-measured tropospheric ozone during the latter Aura time period  
38 show increases of  $\sim+3$  DU-decade<sup>-1</sup> over the N Atlantic and NE Pacific.

39

## 40 **1. Introduction**

41

42 Over the last several decades there have been substantial regional changes in **emissions and**  
43 **concentrations of global pollutants** including precursors of tropospheric ozone as documented by  
44 many studies (e.g., Granier et al., 2011; Parrish et al., 2013; Young et al., 2013; Cooper et al.,  
45 2014; Lee et al., 2014; Zhang et al., 2016; Heue et al., 2016; Lin et al., 2017). The largest  
46 increases in global pollutants over the last four decades occurred broadly over a region extending  
47 from the Near East to India and east/SE Asia. Lin et al. (2017) used a global chemistry-climate  
48 model (CCM) for 1980-2014 to study the effects of global changes in emissions on surface  
49 ozone. They show that rising increases in emissions, including a tripling of Asian NO<sub>x</sub> (NO +  
50 NO<sub>2</sub>) since just 1990, lead to large increases in surface ozone over India/East Asia and to a lesser  
51 extent over the western US due to long-range transport. **Young et al. (2013) combined 15 global**  
52 **chemistry climate models projected to year 2100 and found significant inter-model differences;**  
53 **relative to year 2000, global tropospheric ozone from the models indicated both increases and**  
54 **decreases up to year 2030, and largely decreases by 2100. One conclusion from Young et al.**  
55 **(2013) is that the models are sensitive to emission and climate changes in different ways; they**  
56 **mention that this requires a unified approach to ozone budget specifications and rigorous**  
57 **investigation of the factors driving tropospheric ozone to attribute changes in tropospheric ozone**  
58 **and inter-model differences more clearly.**

59

60 The changes in global emissions since 1980 are described by Zhang et al. (2016) as an  
61 equatorward redistribution over time into developing countries of India and those of SE Asia.  
62 Zhang et al. (2016) used a global chemical-transport model (CTM) for 1980-2010 to quantify the  
63 effects of these changes in emissions on tropospheric ozone. The model simulations and  
64 OMI/MLS satellite measurements employed by Zhang et al. (2016) indicated largest increases in  
65 tropospheric ozone extending from the Near East to India and SE Asia and further eastward over  
66 the Pacific Ocean. Zhang et al. (2016) included IAGOS aircraft ozone profiles that also showed  
67 large increases (i.e., double-digit percent increases) for India, SE Asia, and East Asia between  
68 the 1994-2004 and 2005-2014 time records. The model used by Zhang et al. (2016) also  
69 simulated a net increase in global tropospheric ozone of about 28 Tg (~8.9%) over the 30-year  
70 record. The results by Zhang et al. (2016) appear consistent with the Bulletin of the American  
71 Meteorological Society BAMS State of the Climate Report for year 2016 that indicates about  
72 21.8 Tg increase in OMI/MLS tropospheric ozone when averaged over 60°S-60°N between  
73 October 2004 and December 2016, with largest contribution to global trends (about +3 to +4  
74 DU-decade<sup>-1</sup> for OMI/MLS) originating from the same India and east/SE Asia region. The  
75 increases in tropospheric ozone for OMI/MLS are from a shorter record than the 30-year record  
76 of Zhang et al. (2016) and not global. (We discuss trends for a 38-year merged record from  
77 combined TOMS and OMI/MLS satellite measurements later in section 3.3.) The first evidence  
78 of increases in tropospheric ozone over SE Asia from satellite data was shown by Beig and Singh  
79 (2007). Beig and Singh used a version of Convective-Cloud Differential (CCD) gridded  
80 tropospheric ozone for 1979-2005 that was a predecessor to the current CCD data used for our  
81 study (discussed in Section 2). The CCD algorithm is described by Ziemke et al. (1998). The  
82 largest increases in tropospheric ozone reported by Beig and Singh (2007) were up to 7-9%  
83 decade<sup>-1</sup> and were located in SE Asia.

84

85 The Tropospheric Ozone Assessment Report (TOAR) provides analyses of trends in tropospheric  
86 ozone calculated from a large array of data sources including satellite, aircraft, balloon  
87 ozonesondes and surface measurements (Gaudel et al., 2018). Figure 24 of Gaudel et al., (2018)  
88 shows calculated linear trends/decadal changes during the Aura time record for six global data  
89 products, five from satellite and one from trajectory-mapped ozonesondes. The six products  
90 show large divergence in estimated trends, in part due to their short and differing time records; it

91 was noted that one should be careful about placing precise numbers on estimated trends in TCO  
92 from the results. Figure 25 of Gaudel et al. (2018) combined all six TCO products together  
93 statistically and showed that the largest and most consistent (and positive) trends between the six  
94 products were centered over SE Asia.

95  
96 Heue et al. (2016) derived a merged 1995-2015 tropical tropospheric ozone dataset from multiple  
97 satellite instruments using a variant of the CCD approach for latitude range  $\pm 20^\circ$ . Their dataset  
98 was **constructed** by concatenating measurements from several instruments including  
99 SCIAMACHY and GOME (but not including either TOMS or OMI/MLS). Their main findings  
100 included evidence for increases in tropospheric ozone over both India/SE Asia and the tropical  
101 Africa/Atlantic region; however, their largest detected positive trends were across tropical  
102 Africa/Atlantic rather than India/SE Asia. Heue et al. (2016) estimated a mean trend in TCO of  
103 about  $+0.7 \text{ DU-decade}^{-1}$  in the tropics ( $15^\circ\text{S}-15^\circ\text{N}$ ). **Heue et al. (2016) indicated that significant**  
104 **positive trends occurred over central and southern Africa that maximized during June-August**  
105 **which represents the peak burning season for this region; they suggested that the trends in**  
106 **central/southern Africa are associated with an increase in biomass burning.** Leventidou et al.  
107 (2018) using similar (but processed differently) SCIAMACHY/GOME CCD TCO measurements  
108 for 1995-2015 found  $\sim +3 \text{ DU-decade}^{-1}$  trend over southern Africa, but no statistical change in  
109 the tropics ( $15^\circ\text{S}-15^\circ\text{N}$ ).

110  
111 The purpose of our study is to derive trends in tropospheric ozone for 1979-2016 by combining  
112 TOMS (1979-2005) and OMI/MLS (2005-2016) measurements. A main incentive is to evaluate  
113 TCO trends for a longer satellite record than previous investigations including TOAR, and to  
114 identify and possibly explain the regional trend patterns that emerge from the data. Areal  
115 coverage for calculated trends is all longitudes and latitudes  $30^\circ\text{S} - 30^\circ\text{N}$  for TOMS and  $60^\circ\text{S}-$   
116  $60^\circ\text{N}$  for OMI/MLS. **The Global Modeling Initiative (GMI) CTM replay simulation is included**  
117 **to assess ozone trends during both the TOMS and OMI/MLS time periods.** All satellite ozone  
118 products were re-processed from previous versions to improve data quality for trend calculations.  
119 We also provide a preliminary evaluation of tropospheric column ozone (TCO) measured from  
120 the Ozone Mapping Profiler Suite (OMPS) nadir-mapper and limb-profiler instruments  
121 beginning in 2012 as possible future continuation of the OMI/MLS TCO record. Section 2

122 discusses the satellite measurements, GMI model, ozonesonde data, and trend calculations.  
123 Section 3 discusses derived trends in tropospheric ozone including net changes for the combined  
124 38-year record. Results are summarized in Section 4. We also include Supporting Material  
125 (Sections A-D) that discusses validation of OMI/MLS, TOMS, and OMPS TCO, and  
126 comparisons of decadal changes/trends between ozonesonde and OMI/MLS TCO.

127

## 128 **2. Satellite Measurements, MERRA-2 GMI Model, Ozonesondes, and Trend Calculations.**

129

### 130 2.1. Satellite Measurements.

131

132 All satellite measurements of TCO used for our study are developed at NASA Goddard Space  
133 Flight Center (Code 614) and updated and upgraded periodically for the science community.  
134 TCO measurements and their validation from Nimbus-7 (N7) and Earth Probe (EP) TOMS  
135 instruments are discussed by Ziemke et al. (2005, and references therein). TOMS TCO for 1979-  
136 2005 is derived using the Convective-Cloud Differential (CCD) algorithm (Ziemke et al., 1998)  
137 which differences clear versus thick cloud measurements of column ozone. Useful CCD gridded  
138 TCO is limited mostly to tropical latitudes due to having both a large number of deep convective  
139 clouds and small zonal variability of SCO. Our TOMS CCD dataset originates from a  
140 preliminary TOMS CCD gridded dataset that Beig and Singh (2007) used for evaluating TCO  
141 trends, but now includes a re-processing with extensive flagging of outliers out to latitudes  $\pm 30^\circ$ .  
142 The N7 and EP TOMS instruments have similar spectral/spatial/temporal resolution with TCO  
143 obtained from both using the same version 8 algorithm. TOMS TCO is determined by  
144 subtracting thick cloud column ozone measurements (to estimate stratospheric column ozone,  
145 SCO) from near clear-sky total column ozone. By differencing SCO and total ozone from the  
146 same instrument, derived TCO is largely self-calibrating over time and should not be affected by  
147 instrument/inter-instrument drifts or offsets. Standard precision error (i.e.,  $1\sigma$  standard  
148 deviation) of TOMS gridded TCO is estimated to be about 1.7 DU (e.g., Ziemke et al., 1998).  
149 Validation of TOMS TCO is discussed in Section C of the Supporting Material. The validation  
150 of TOMS TCO involves comparisons with ozonesondes beginning in 1979.

151

152 We also include OMI/MLS TCO (Ziemke et al., 2006) for January 2005-December 2016 and  
153 latitude range 60°S-60°N. TCO is determined by subtracting MLS SCO from OMI total column  
154 ozone each day at each grid point. Tropopause pressure used to determine SCO invoked the  
155 WMO 2K-km<sup>-1</sup> lapse-rate definition from NCEP re-analyses. For consistency these same lapse-  
156 rate tropopause pressure fields were used to derive TCO for ozonesondes, OMPS, and the GMI  
157 model (discussed below). OMI total column ozone is retrieved using the OMT03 v8.5 algorithm  
158 that includes **co-located** UV cloud pressures from OMI (Vasilkov et al., 2008) and several other  
159 improvements from version 8. The OMI total ozone and cloud data including discussion of data  
160 quality are available from <https://ozoneaq.gsfc.nasa.gov/>. The MLS data used to obtain SCO  
161 were derived from their v4.2 ozone profiles (<https://mls.jpl.nasa.gov/data/datadocs.php/>). We  
162 estimate 1σ precision for the OMI/MLS monthly-mean gridded TCO product to be about 1.3  
163 DU. The additional Supporting Material discusses both validation and adjustments made to  
164 OMI/MLS TCO. It can be shown that OMI/MLS TCO derived from this residual technique is  
165 nearly identical to the TCO from OMI CCD measurements for the same time period, albeit with  
166 the CCD data limited mostly to tropical/subtropical latitudes (e.g., Ziemke et al., 2012).

167  
168 Tropospheric ozone for January 2012 through 2016 is also determined from the OMPS nadir-  
169 mapper and limb-profiler instruments onboard the National Polar-orbiting Operational  
170 Environmental Satellite System (NPP) spacecraft. The OMPS tropospheric ozone is evaluated  
171 for possibly continuing the OMI/MLS data record. TCO is determined by subtracting OMPS  
172 v2.5 limb-profiler SCO from OMPS v2.3 nadir-mapper total column ozone. SCO is determined  
173 from the limb-profiler measurements using the same tropopause pressure fields as for MLS SCO.  
174 With both OMPS instruments onboard the same NPP satellite, the time difference between the  
175 limb and nadir measurements is about 7 minutes (similar to Aura MLS and OMI instruments).  
176 The OMPS data including evaluation of data quality are available from  
177 <https://ozoneaq.gsfc.nasa.gov/data/omps/>. **Section B of the Supporting Material discusses the**  
178 **derived OMPS TCO. A main conclusion regarding this preliminary version of OMPS TCO is**  
179 **that these measurements will be useful for extending the OMI/MLS record of TCO.**

180  
181 All satellite-derived TCO represents monthly-means under mostly clear-sky conditions with  
182 radiative cloud fractions < 40%. This cloud threshold reduces the number of total column ozone

183 pixels by ~20%. The cloud filtering was applied to reduce precision error in satellite-measured  
184 TCO due to errors in assumed climatological below-cloud ozone for thick cloud scenes. These  
185 errors in tropospheric ozone are largely random in nature on a pixel-by-pixel basis and do not  
186 affect calculated trend magnitudes whether or not such measurements are removed from the  
187 analyses. Satellite-derived TCO was gridded to  $5^\circ \times 5^\circ$  bins centered on longitudes  $-177.5^\circ$ ,  $-$   
188  $172.5^\circ$ , ...,  $177.5^\circ$ , and latitudes  $-27.5^\circ$ ,  $-22.5^\circ$ , ...,  $27.5^\circ$  for TOMS and latitudes  $-57.5^\circ$ ,  $-52.5^\circ$ ,  
189 ...,  $57.5^\circ$  for OMI/MLS (and also OMPS). This bin size for all measurements was chosen for  
190 consistency because the original bin size for the CCD measurements for 1979-2005 is  $5^\circ \times 5^\circ$ .

191

## 192 2.2. MERRA-2 GMI Model.

193 The Modern-Era Retrospective analysis for Research and Applications (MERRA-2) GMI  
194 simulation is produced with the Goddard Earth Observing System (GEOS) modeling framework  
195 (*Molod et al.*, 2015), using winds, temperature, and pressure from the MERRA-2 reanalysis  
196 (*Gelaro et al.*, 2017). The configuration for this study is a dynamically constrained replay (*Orbe*  
197 *et al.*, 2017) coupled to the Global Modeling Initiative's (GMI) stratospheric and tropospheric  
198 chemical mechanism (*Duncan et al.*, 2007; *Oman et al.*, 2013; *Nielsen et al.*, 2017). The GMI  
199 mechanism includes a detailed description of ozone-NO<sub>x</sub>-hydrocarbon chemistry and has over  
200 100 species and approximately 400 chemical reactions. The simulation was run at  $\sim 0.5^\circ$   
201 horizontal resolution, c180 on the cubed sphere, and output on the same  $0.625^\circ$  longitude x  $0.5^\circ$   
202 latitude grid as MERRA-2 from 1980-2016.

203

204 The MERRA-2 GMI simulation includes emissions of NO, CO, and other non-methane  
205 hydrocarbons from fossil fuel and biofuel sources, biomass burning, and biogenic sources. There  
206 are also NO emissions from lightning and soil. Fossil fuel and biofuel sources are prescribed  
207 from the MACCity Measuring Atmospheric Composition and Climate megaCity – zoom for the  
208 environment (MACCity) inventory (*Granier et al.*, 2011), which interpolates to each year from  
209 the decadal Atmospheric Chemistry and Climate - Model Inter-comparison Project (ACCMIP)  
210 emissions (*Lamarque et al.*, 2010) and applies a seasonal scaling factor. The MACCity inventory  
211 ends in 2010, so for later years we use fossil fuel and biofuel emissions from the Representative  
212 Concentration Pathways 8.5 (RCP8.5) scenario. Time-dependent biomass burning emissions for  
213 1997 onwards come from the Global Fire Emissions Dataset (GFED) version 4s (*Giglio et al.*,

214 2013). Biomass burning emissions for prior years have interannual variability from regional  
215 scaling factors based on the TOMS aerosol index (*Duncan et al., 2003*) imposed on a climatology  
216 derived from GFED-4s, similar to the approach used in *Strode et al. [2015]*. Emissions of  
217 isoprene and other biogenic compounds are calculated online using the Model of Emissions of  
218 Gases and Aerosols from Nature (MEGAN) model [*Guenther et al., 1999, 2000*], and thus  
219 respond to MERRA-2 GMI meteorology. NO emissions from soil, parameterized based on  
220 *Yienger and Levy [1995]*, also responds to the MERRA-2 meteorology. **Lightning NO**  
221 **production is prescribed monthly based on the scheme of *Allen et al. (2010)* using a de-trended**  
222 **cumulative mass flux in the mid-troposphere from MERRA-2, constrained seasonally with the**  
223 **OTDLIS v2.3 lightning climatology (*Cecil et al., 2014*). A global mean scaling factor is applied**  
224 **to the de-trended cumulative mass flux so that the annual average global mean lightning NO<sub>x</sub>**  
225 **production is 6.5 Tg N yr<sup>-1</sup> for each year of simulation. Methane is specified as a latitude and**  
226 **time-dependent surface boundary condition. In addition to chemical loss, dry deposition**  
227 **provides a major sink for tropospheric ozone. GMI uses a resistance-in-series method [*Wang et***  
228 ***al., 1998; Wesely and Hicks, 1977*] for dry deposition and thus depends on factors including land**  
229 **surface type and leaf area index. Ozone depleting substances are specified using the A12014**  
230 **scenario from WMO [2014].**

231  
232 TCO is derived from the GMI simulation by integrating the generated ozone profiles from the  
233 surface up to tropopause pressure. GMI TCO (discussed below) was also averaged monthly and  
234 re-gridded from original 0.5° latitude × 0.625° longitude resolution to this same 5° × 5° gridding.  
235 Where we refer to GMI in this paper it is equivalent to MERRA-2 GMI.

236

### 237 2.3. Ozonesondes.

238

239 We include balloon-launched ozonesonde measurements for comparisons and validation of the  
240 OMI/MLS TCO. The ozonesonde database extends from 2004-2016 and includes measurements  
241 from Southern Hemisphere ADditional OZonesondes (SHADOZ) (*Thompson et al., 2017; Witte*  
242 *et al., 2017*), World Ozone and Ultraviolet Data Center (WOUDC) (<https://woudc.org/>), and  
243 Network for the Detection of Atmospheric Composition Change (NDACC).  
244 (<http://www.ndsc.ncep.noaa.gov/>). The ozonesondes provide daily ozone profile concentrations

245 as a function of altitude from several dozen global station sites. The ozone profiles are  
246 integrated vertically each day to derive tropospheric column measurements. Most of the sonde  
247 ozone profile measurements during the Aura record that we used are derived from  
248 Electrochemical Concentration Cell (ECC) instruments. Non-ECC instruments include Brewer-  
249 Mast (for the entire Aura record at Hohenpeisenberg) and Carbon-Iodide (up through November  
250 2009 at Sapporo and Tateno, up through October 2008 at Naha, and through March 2005 at  
251 Kagoshima). Section A of the Supporting Material discusses the ozonesonde analyses and  
252 includes evaluation of potential offset and/or drift in OMI/MLS data. The ensuing corrections  
253 made to the OMI/MLS TCO were small. The corrections included a +2 DU offset adjustment  
254 (via ozonesonde comparisons) and a  $-1.0 \text{ DU-decade}^{-1}$  drift adjustment (via OMI row anomaly  
255 analysis).

256

#### 257 2.4. Trend Calculations.

258

259 For the short 15-month overlapping time period of October 2004 – December 2005 between  
260 TOMS and OMI/MLS, mean offset differences in TCO were found to be regionally varying with  
261 values up to 5 DU or greater which hampers any useful effort for deriving trends from their  
262 concatenated datasets. Offsets of several DU between TOMS and OMI total ozone have been  
263 well documented (e.g., Witte et al., 2018, and references therein). Therefore, we have calculated  
264 trends independently for the TOMS (1979-2005) and OMI/MLS (2005-2016) datasets. Total net  
265 change in TCO (in DU) at each grid point for the 38-year record was determined by adding  
266 together the net changes (i.e. trend in  $\text{DU-month}^{-1} \times \text{number of months}$ ) for the TOMS and  
267 OMI/MLS records. Year 2017 and later months were not included in our analyses because the  
268 MERRA-2 GMI simulation ended December 2016 and also that the global ozonesonde  
269 measurements used for validating the OMI/MLS TCO extended only into mid-2016.

270

271 Multivariate linear regression (MLR) (Ziemke et al., 1997, and references therein) was applied to  
272 estimate trends in TCO. The regression includes components for the seasonal cycle, linear trend,  
273 and ENSO (e.g., Nino 3.4 index) from  $TCO(x,t) = A(x,t) + B(x,t) \cdot t + C(x,t) \cdot Nino3.4(t) + \varepsilon(x,t)$ ,  
274 where  $x$  is the grid point and  $t$  is month. The term  $\varepsilon(x,t)$  represents residual error. We applied  
275 two approaches regarding  $Nino3.4(t)$  in the MLR model. One approach was to de-trend

276 *Nino3.4(t)* prior to the regression analysis and the other was not to de-trend this proxy. A main  
277 reason for possibly wanting to de-trend *Nino3.4(t)* is that TCO variability is not truly linear with  
278 *Nino3.4(t)* variability over any timescale including decadal which may potentially influence  
279 linear trend calculations in the MLR method. We opted not to include de-trending of *Nino3.4(t)*  
280 after finding little or no difference between either approach for both OMI/MLS and TOMS  
281 records. The seasonal coefficient *A* in the MLR equation above includes a constant plus annual  
282 and semi-annual harmonics while coefficients *B* and *C* each include a constant. Since our study  
283 does not evaluate seasonality of trends, we constrained the number of regression constants for  
284 trend *B* to only one which tends to improve overall trend statistical uncertainties when compared  
285 to using several regression seasonal constants for *B*. Trend magnitudes exceeding the calculated  
286  $2\sigma$  value uncertainty for *B* are deemed statistically significant. Calculated  $2\sigma$  uncertainties for  
287 trends included an autoregressive-1 adjustment as presented in Weatherhead et al. (1998).  
288 Trends were calculated similarly for GMI TCO and NO emissions using this MLR approach.

289

### 290 **3. Trends in Tropospheric Ozone.**

291

#### 292 3.1. The Aura Record (2005-2016).

293

294 OMI/MLS TCO trends for 60°S - 60°N are shown in Figure 1a with asterisks denoting regions  
295 that are statistically significant at  $2\sigma$  level. Positive trends lie in the tropics and extra-tropics in  
296 both hemispheres with the largest trends (shown in red) of  $\sim +3$  DU-decade<sup>-1</sup> or greater extending  
297 from India to East/SE Asia and further eastward over the Pacific Ocean. There are also  
298 statistically significant increases in ozone in the north Atlantic **extending eastward over central**  
299 **Africa.**

300

301 Trends for GMI TCO (Figure 1b) have features similar to trends for OMI/MLS TCO. Large  
302 positive trends for GMI also extend from Saudi Arabia and India to SE/East Asia and further  
303 eastward over the Pacific Ocean. Changes for both OMI/MLS and GMI TCO over this region  
304 are  $\sim +3$  DU-decade<sup>-1</sup>. **GMI TCO also indicates evidence of positive trends over Africa and in**  
305 **the north Atlantic, although these trends are generally weak compared to India/east Asia. For the**  
306 **north Atlantic region the positive trends for GMI are also not in the same location as the positive**

307 trends for OMI/MLS. There are other differences between GMI and OMI/MLS trends in Figure  
308 1 such as in the SH where GMI does not indicate statistically significant positive trends as the  
309 satellite observations do. Anet et al. (2017) examined surface ozone data from El Tololo, Chile  
310 (30°S, 71°W) and found a small positive trend of  $\sim+0.7$  ppbv-decade<sup>-1</sup> for the period 1995-2010.  
311 Their analyses indicated that the positive increase at the site was driven mainly by stratospheric  
312 intrusions and not photochemical production from anthropogenic and biogenic precursors. The  
313 results from Anet et al. (2017) suggest that the positive trends in SH OMI/MLS TCO in Figure  
314 1a (primarily over ocean) may be real; however, one cannot make any conclusion based on only  
315 ground-level measurements and from only one station. Lu et al. (2019) detected positive trends  
316 in ozone throughout the Southern Hemisphere (SH) since 1990 from a large number of surface,  
317 ozonesonde, and satellite measurements; they also included the GEOS-Chem CTM that showed  
318 similar increases throughout the SH. Lu et al. (2019) suggested that the increases in tropospheric  
319 ozone in the SH are linked to a broadening of the Hadley association. Their analyses indicate  
320 that broadening of the Hadley circulation is associated with changes in meridional transport  
321 which coincides with greater influx of ozone from the stratosphere and larger tropospheric ozone  
322 production due to stronger uplifting of tropical ozone precursors into the upper troposphere. We  
323 have calculated ozonesonde column ozone trends for the 2005-2016 Aura record to compare  
324 with the GMI and OMI/MLS TCO trends in Figure 1. (Section D of the Supporting Material  
325 discusses these trend comparisons.) Figure S10 in Section D indicates that it is not possible from  
326 the ozonesondes to conclude anything definitive regarding trends, particularly in the SH extra-  
327 tropics where the ozonesondes are relatively scarce over the short Aura time record.

328  
329 Trends for NO emissions for 2005-2016 from the GMI simulation are shown in Figure 2, again  
330 with positive (negative) trends as red (blue). Largest increases in tropospheric NO emissions in  
331 Figure 2 are located over India and east/SE Asia while greatest decreases originate over the  
332 eastern US, Europe, and Japan. We note that although there are large increases in NO emissions  
333 over eastern China for 2005-2016 depicted in Figure 2, observations show NO<sub>2</sub> concentrations  
334 decreased over this region after year 2012 (e.g., Krotkov et al., 2016). This recent downturn is  
335 not included in the GMI emissions, likely contributing to the overestimate of the ozone trend  
336 over eastern China in the GMI simulation. Overall, however, the ability of the GMI simulation

337 to capture the positive trends above and downwind of regions with large NO<sub>x</sub> emission increases  
338 suggests that the NO<sub>x</sub> emission trends are driving the trends in TCO over India and east Asia.

339  
340 Figure 1 shows that the regions of large decrease in NO emissions such as the eastern US and  
341 Europe in Figure 2 do not coincide with similar decrease in TCO for either GMI or OMI/MLS.  
342 Both GMI and OMI/MLS TCO instead show essentially zero or slightly positive trends for these  
343 regions, despite the fact that the GMI simulation indicates significant negative trends in  
344 tropospheric column NO<sub>2</sub> over the eastern U.S. and Europe. This contrasts with the situation at  
345 the surface, in which simulations with GMI chemistry indicate decreases in surface ozone over  
346 the eastern U.S. in response to NO<sub>x</sub> reductions (Strode et al., 2015).

347  
348 Figure 3 shows comparisons between OMI/MLS and GMI deseasonalized TCO time series and  
349 their calculated linear trends for (a) SE Asia, (b) equatorial Africa, (c) NE Pacific, and (d) north  
350 Atlantic. Included in each panel are MLR regression fits for linear trends and their calculated 2σ  
351 uncertainties (both in DU-decade<sup>-1</sup>). Not only are trends for GMI and OMI/MLS comparable and  
352 statistically significant in Figure 3 in each panel, but their month-to-month variations in their de-  
353 trended time series have relatively large cross-correlations varying from +0.64 to +0.70. Several  
354 inter-annual features are common with both MERRA-2 GMI and OMI/MLS TCO time series in  
355 Figure 3 such as large reductions (exceeding -5 DU) during spring 2008 over the NE Pacific and  
356 spring 2010 in the north Atlantic.

357

### 358 3.2. The TOMS Record (1979-2005).

359

360 Trends for TOMS (1979-2005) and GMI (1980-2005) TCO are shown in Figure 4. As with both  
361 OMI/MLS and GMI TCO for the Aura period 2005-2016 in Figure 1, largest positive trends in  
362 Figure 4 are also located over the Near East to East Asia and extending further eastward over the  
363 Pacific Ocean. Calculated trends for this region are ~+1.2 to +1.4 DU-decade<sup>-1</sup> for both TOMS  
364 and GMI which are considerably smaller than during the Aura record. An important conclusion  
365 is that both the model and measurements in Figures 1 and 4 suggest that the trends in  
366 tropospheric ozone over this region are markedly larger during the Aura period compared to the  
367 earlier TOMS period, by a factor of about 2-2.5.

368

369 As with OMI/MLS and GMI TCO trends in Figure 1 there are discrepancies between the TOMS  
370 and model TCO trends in Figure 4. For TOMS TCO in Figure 4 there are regions of negative  
371 trends (in blue) as much as  $-0.6 \text{ DU-decade}^{-1}$  over ocean in both hemispheres that are not  
372 explainable. Trends for GMI in Figure 4 are instead largely positive within these regions and  
373 actually positive throughout much of the SH when compared with TOMS. This suggests that the  
374 TOMS trends may be biased slightly low overall, provided that the simulation is closer to truth.

375

376 The trends for GMI TCO are positive over Brazil whereas OMI/MLS TCO shows only a hint of  
377 positive trends. It is likely that there will be smaller trends for TOMS because most ozone  
378 produced from biomass burning over Brazil lies in the **lower** troposphere, and also that TOMS  
379 has reduced ability to detect ozone in the **lower** troposphere. The GMI simulation shows that of  
380 the  $\sim +1.4 \text{ DU-decade}^{-1}$  TCO trend over Brazil in Figure 4, about  $+0.9 \text{ DU-decade}^{-1}$  of this trend  
381 comes from ozone in the **lower** troposphere below 500 hPa. With a known retrieval efficiency of  
382 50-60% below 500 hPa (and essentially 100% above 500 hPa) for TOMS over Brazil, the model  
383 suggests that TOMS should detect a trend of about  $+0.5 \text{ DU-decade}^{-1}$  below 500 hPa. Therefore  
384 TOMS would then have a trend in TCO of about  $+0.9 \text{ DU-decade}^{-1}$  which is comparable to the  
385  $\sim +0.8 \text{ DU-decade}^{-1}$  measured for TOMS in Figure 4.

386

387 Trends in NO emissions during 1980-2005 for the GMI simulation are shown in Figure 5.  
388 Figure 5 is similar to Figure 2 except for an earlier time period coinciding with the TOMS  
389 record. The largest increases in tropospheric NO emissions in Figure 5 are located over India  
390 and east/SE Asia, as noted earlier for Figure 2. Negative trends over the eastern US are much  
391 less pronounced (nearly non-existent) in Figure 5 during the TOMS record compared to the  
392 negative trends for the region in Figure 2.

393

394 In Figure 6 we show some examples of time series of TCO for TOMS and MERRA-2 GMI in  
395 regions where both records exhibit statistically significant positive trends. The positive  
396 correlations between TOMS and model TCO in Figure 6 are generally small compared to the  
397 correlations between OMI/MLS and model TCO in Figure 3. The only large correlation in  
398 Figure 6 is over Indonesia and is due to the intense El Nino of 1997-1998 that caused record

399 increases in TCO in October 1997 in the region due to record levels of biomass burning (e.g.,  
400 Chandra et al., 2003). The cross-correlations in the other panels in Figure 6 are small; these  
401 smaller correlations indicate the noisy nature of TOMS measurements compared to OMI/MLS  
402 and also possibly larger uncertainties present in meteorological winds, temperatures, and  
403 emissions during these earlier TOMS years for the GMI simulation. Changes in the observing  
404 system increases transport uncertainties for MERRA-2; these transport uncertainties increase the  
405 further back we go in time with MERRA-2, in particular the TOMS record. The recent Aura  
406 period for MERRA-2 has both more observations and higher vertical resolution than during the  
407 TOMS record. Stauffer et al. (2019) suggests that there is less impact of the changing observing  
408 system using the “Replay” technique compared to traditional CTMs. Wargan et al. (2018)  
409 discusses changes in the observing system for MERRA-2 for 1998-2016, including changes in  
410 the input assimilated radiances.

411  
412 A main result from Figures 4 and 6 is that the positive trends for both TOMS and MERRA-2  
413 GMI TCO are substantially larger, by a factor of about 2 or more, during the OMI/MLS record  
414 compared to the TOMS record. The GMI simulation suggests that larger trends during the Aura  
415 record are the manifestation of an escalation of anthropogenic emissions and transport.

416

### 417 3.3. The Merged Record (1979-2016).

418

419 The net increases in tropospheric ozone over India and east/SE Asia for the merged 38-year  
420 record are sizable. Total changes in GMI and satellite-measured TCO for the merged record are  
421 shown in Figure 7 where contour values were determined by adding changes from the individual  
422 TOMS and OMI/MLS records together. There are two regions of greatest increase of TCO in  
423 Figure 7 for both GMI and the satellite measurements, one coinciding with the Near East to East  
424 Asia (increases of  $\sim+6$  to  $+7$  DU, or about 15-20% average background ozone) and the other  
425 being tropical Africa/Atlantic (increases of  $\sim+4$  to  $+5$  DU, of about 10-15% average background  
426 ozone). There is also an area of negative net change in the SH lying between Australia and the  
427 maritime continent in Figure 7 for both GMI and measurements (shown in blue); these negative  
428 variations over the SH Indian Ocean appear small and are not statistically significant.

429

430 The color bar in Figure 7 also provides conversion from DU to tropospheric ozone mass surface  
431 density in units of metric tons per km<sup>2</sup>. This conversion was included primarily to compare our  
432 results with the model simulation of Zhang et al. (2016). The large TCO trends over India and  
433 east/SE Asia in Figure 7 are about +0.13 to +0.15 metric tons per km<sup>2</sup> for both GMI and the  
434 satellite data. These numbers are comparable to increases of ~+0.11 metric tons per km<sup>2</sup> for this  
435 region as modeled by Zhang et al. (2016) for years 1980-2010.

436

437 Using the 38-year net changes from the two independent regression analyses of  
438 TOMS+OMI/MLS TCO we can estimate the mass of ozone in the bands 0°-30°N and 0°-30°S for  
439 the years 1979 and 2016 that model simulations can compare with. Based on 2016 OMI/MLS  
440 TCO fields and extrapolated backwards linearly in time, mean area-weighted 0-30°N ozone  
441 masses are about 75.1 Tg for year 1979 and 83.1 Tg for year 2016, yielding about  $8.0 \pm 4.6$  ( $2\sigma$ )  
442 Tg net increase. For 0°-30°S, the mean numbers are 73.7 Tg for 1979 and 78.2 Tg for 2016,  
443 yielding about  $4.4 \pm 4.2$  ( $2\sigma$ ) Tg net increase. As percentage change, tropospheric ozone mass in  
444 the 0-30°N band increased by about 10.1%, and about 5.8% for 0-30°S from 1979 to 2016 from  
445 the satellite measurements.

446

447 Figure 8 shows TCO time series from the merged satellite measurements for 1979-2016 centered  
448 over the two regions of largest increase in Figure 7 (i.e., eastern Asia and equatorial Africa). In  
449 both panels TOMS is the solid red curve and OMI/MLS is the dotted blue curve. For plotting  
450 purposes, offsets were applied to the TOMS data in both panels using 2005 overlap  
451 measurements (see figure and caption). The last five years in both panels in Figure 8 shows that  
452 current OMPS TCO (solid black curves) with several years of overlap with OMI/MLS TCO will  
453 be useful to continue the OMI/MLS record which has already extended past 13 years.

454

455 Studies suggest that ozone in the lower stratosphere in both hemispheres has been decreasing  
456 over the last 1-2 decades despite the decrease in global CFC concentrations following the 1987  
457 Montreal Protocol. Ball et al. (2018) evaluated global ozone trends for 1985-2016 by combining  
458 models with measurements from several satellite instruments. A conjecture as stated by Ball et  
459 al. (2018) is that while ozone in the upper stratosphere above ~10 hPa appears to be recovering,  
460 ozone in the lower stratosphere appears to be decreasing which models do not seem to replicate

461 despite the decrease in CFCs. A main point of Ball et al. (2018) is that total ozone has not  
462 changed because the ongoing stratospheric ozone decrease is opposed by tropospheric ozone  
463 increase. A global decrease in lower stratospheric ozone of about 2 DU below 32 hPa was  
464 detected by Ball et al. (2018) and it appeared to be compensated largely by opposite increases in  
465 tropospheric ozone. In their study they included OMI/MLS TCO for 2005-2016 (i.e., their  
466 Figure 4 and Figure S13) and measured a trend in 60°S-60°N TCO of about +1.7 DU-decade<sup>-1</sup>  
467 which mostly cancels out the negative trend in stratospheric ozone. Wargan et al. (2018) in a  
468 related paper evaluated MERRA-2 assimilated ozone for 1998-2016 using an idealized  
469 atmospheric tracer also driven from MERRA-2 meteorological fields. Similar to Ball et al.  
470 (2018), Wargan et al. (2018) also found net decrease in ozone in the lower stratosphere (i.e.,  
471 within a 10 km layer above the tropopause) in both hemispheres; their trend values were about -  
472 1.2 DU-decade<sup>-1</sup> in the SH and about -1.7 DU-decade<sup>-1</sup> in the NH. Wargan et al. (2018) found  
473 evidence that these negative trends over the last two decades have been driven by enhanced  
474 isentropic transport of ozone between the tropical and extratropical lower stratosphere.

475  
476 The increases in measured TCO from TOMS and OMI/MLS as indicated in Figures 1, 3, 4 and  
477 in Figures 6-8 can have implications for evaluating global ozone trends, particularly for trends in  
478 total column ozone and assessment of the recovery of stratospheric ozone. One should be careful  
479 using total ozone to infer stratosphere ozone recovery if trends in TCO are not accounted for.  
480 The increases in TCO of +6 to +7 DU in Figures 7-8 for India-eastern Asia represent a sizeable  
481 change even for total column ozone.

482  
483 **4. Summary.**

484  
485 Studies suggest that ozone in the troposphere has increased globally throughout much of the 20th  
486 century due largely to increases in anthropogenic emissions. We provide evidence from  
487 combined satellite measurements and a chemical transport model that tropospheric ozone over  
488 the last four decades does indeed indicate increases that are global in nature, yet highly regional  
489 due to combined effects of regional pollution and transport.

490

491 We have obtained tropospheric ozone trends for 1979-2016 by merging TOMS (1979-2005) and  
492 Aura OMI/MLS (2005-2016) satellite measurements. We included the MERRA-2 GMI CTM  
493 simulation to evaluate and possibly explain the global trend patterns found for both TOMS and  
494 OMI/MLS TCO. Trends were calculated independently for TOMS and OMI/MLS records using  
495 a linear regression model. Net changes in both measured and modeled TCO for the entire  
496 merged record were estimated by adding net changes for the TOMS and OMI/MLS time periods  
497 together.

498  
499 A persistent trend pattern emerges with TCO for the GMI simulation and satellite measurements  
500 for both the TOMS and OMI/MLS records. The GMI model, and also measurements from  
501 TOMS and OMI/MLS all independently show large (positive) trends in TCO in the NH  
502 extending from the Near East to India and east/SE Asia, and further eastward over the Pacific  
503 Ocean. An important finding is that the trends in TCO for both the GMI model and satellite  
504 measurements for this region are smaller during the earlier part of the merged record; that is, the  
505 trends for both GMI and satellite measurements increase from about +1.2 to +1.4 DU-decade<sup>-1</sup>  
506 (1979-2005) to about +3 DU-decade<sup>-1</sup> or greater (2005-2016). Analysis of the NO emissions  
507 input to the GMI simulation indicates that the measured trends in tropospheric ozone in this  
508 region including the escalation of increased trends during the latter Aura period are consistent  
509 with increases in pollution in the region.

510  
511 For the long merged record there are again strong similarities between the GMI simulation and  
512 satellite measurements of TCO. Net changes in tropospheric ozone for India and east/SE Asia  
513 for 1979-2016 are about +6 to +7 DU, or about 0.13-0.15 metric tons per km<sup>2</sup> for both the GMI  
514 and satellite TCO. These are pronounced increases in TCO representing ~15-20% average TCO  
515 background amounts. Both the GMI simulation and satellite measurements show that of these  
516 +6 to +7 DU increases over this broad area, about half or slightly most of the change (i.e., ~+4  
517 DU) occurs during the Aura time record of 2005-2016. The GMI simulation and satellite  
518 measurements also depict a secondary maximum of TCO increase for 1979-2016 over the  
519 tropical Atlantic/Africa region of about +4 to +5 DU (~10-15% average background ozone).

520

521

522 **Author Contributions.** J. R. Ziemke contributed as lead author to the production of the satellite  
523 tropospheric ozone measurements and analysis. L. D. Oman, S. A. Strode, A. R. Douglass, M.  
524 A. Olsen were responsible for the production and analyses involving the MERRA-2 GMI  
525 simulation. R. D. McPeters, P. K. Bhartia, G. J. Labow, D. P. Haffner, N. A. Kramarova, S. M.  
526 Frith, L.-K. Huang, G. R. Jaross, C. J. Seftor, M. T. Deland and S. L. Taylor all contributed to  
527 the paper by their involvement in the development of the satellite total ozone products including  
528 their long-term calibration necessary for ozone trend evaluation. L. Froidevaux contributed by  
529 his involvement in the MLS product development and use in this study. J. C. Witte and A. M.  
530 Thompson provided key contributions to the paper regarding ozonesonde data and analysis.

531

532

533 **Acknowledgments.** We thank the NASA Goddard Space Flight Center Ozone Processing Team  
534 for the TOMS and OMI total ozone measurements and the Jet Propulsion Laboratory MLS team  
535 for MLS v4.2 ozone. OMI is a Dutch-Finnish contribution to the Aura mission. We thank  
536 WOUDC and the NDACC for providing extensive ozonesonde measurements that we used for  
537 the comparisons/validation of satellite tropospheric ozone. We also thank the NASA MAP  
538 program for supporting the MERRA-2 GMI simulation and the NASA Center for Climate  
539 Simulation (NCCS) for providing high-performance computing resources. **Special thanks go to**  
540 **Ryan Stauffer for important discussions regarding the ozonesonde measurements and the**  
541 **MERRA-2 GMI simulation.** More information on the MERRA-2 GMI simulation and access is  
542 available at <https://acd-ext.gsfc.nasa.gov/Projects/GEOSCCM/MERRA2GMI/>. Tropospheric  
543 ozone data used in this study are available from NASA Goddard Space Flight Center at  
544 [http://acdb-ext.gsfc.nasa.gov/Data\\_services/cloud\\_slice/](http://acdb-ext.gsfc.nasa.gov/Data_services/cloud_slice/) and links from the Aura Validation Data  
545 Center (<https://avdc.gsfc.nasa.gov/>). Funding for this research was provided in part by NASA  
546 NNH14ZDA001N-DSCOVOR.

799

800 **FIGURES AND FIGURE CAPTIONS**

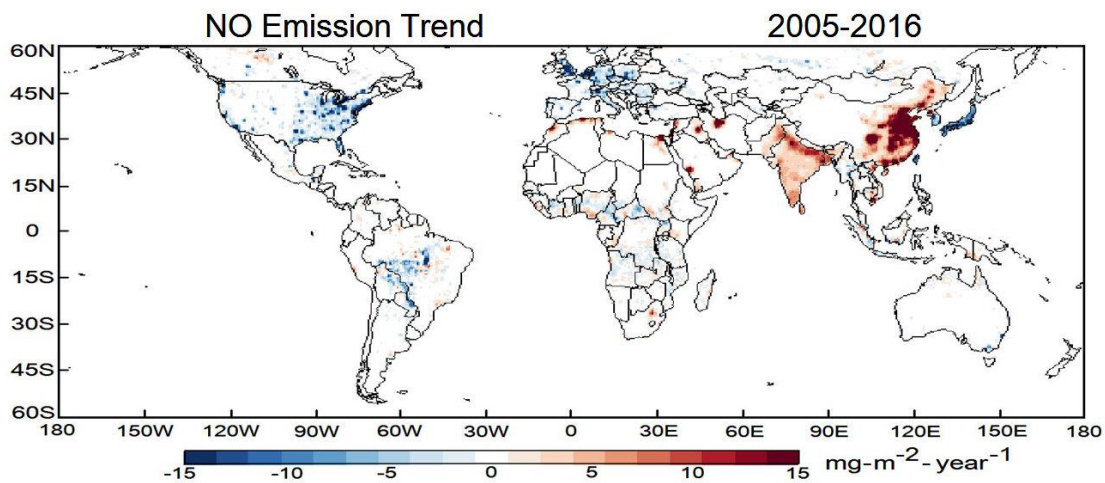

801

802

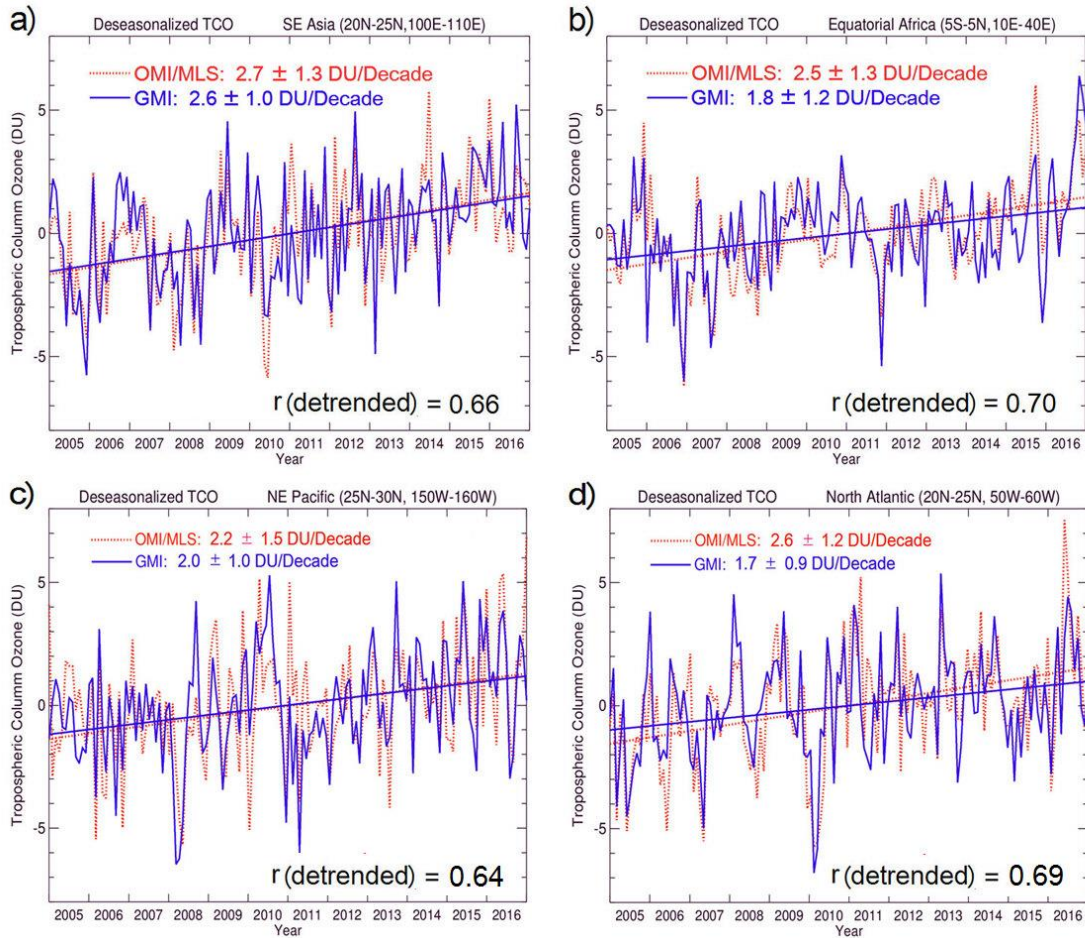

803 **Figure 1.** (a) Trends in OMI/MLS TCO (in DU-decade<sup>-1</sup>) for 2005-2016. Asterisks denote grid  
804 points where trends are statistically significant at the 2 $\sigma$  level. (b) Same as (a) except for  
805 MERRA-2 GMI TCO.

806  
807

808  
809 **Figure 2.** Trends in MERRA-2 GMI NO emissions (units mg-m<sup>-2</sup>-y<sup>-1</sup>) for 2005-2016.

810  
811

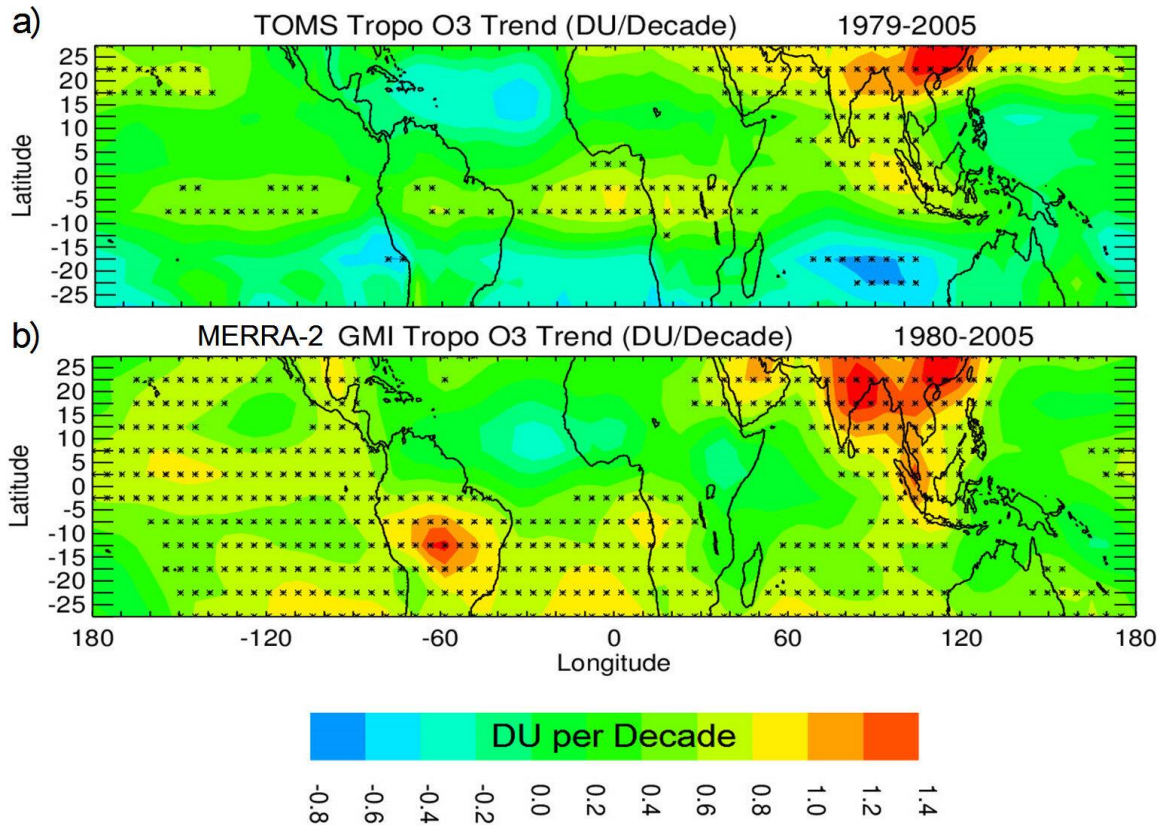

812

813

814 **Figure 3.** (a) Deseasonalized TCO for OMI/MLS (red, dashed curve) and the MERRA-2 GMI  
 815 model (blue, solid curve) for SE Asia. Included are MLR regression fits for linear trends and  
 816 calculated  $2\sigma$  values (both in DU-decade<sup>-1</sup>). Shown at the bottom is the correlation  $r$  between the  
 817 two time series after removing their linear trends. (b) Same as (a), but for equatorial Africa. (c)  
 818 Same, but for NE Pacific. (d) Same, but for north Atlantic.

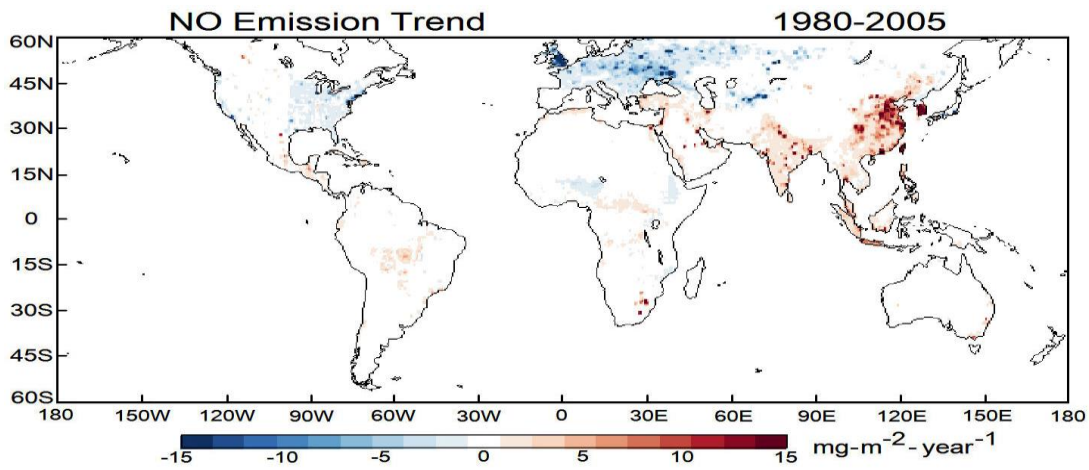

819

820

821  
 822 **Figure 4.** (top) Trends ( $\text{DU-decade}^{-1}$ ) calculated for TOMS CCD TCO measurements for years  
 823 1979-2005. Asterisks denote grid points where trends are statistically significant at the  $2\sigma$  level.  
 824 (bottom) Similar to (top), but for MERRA-2 GMI TCO and for 1980-2005.

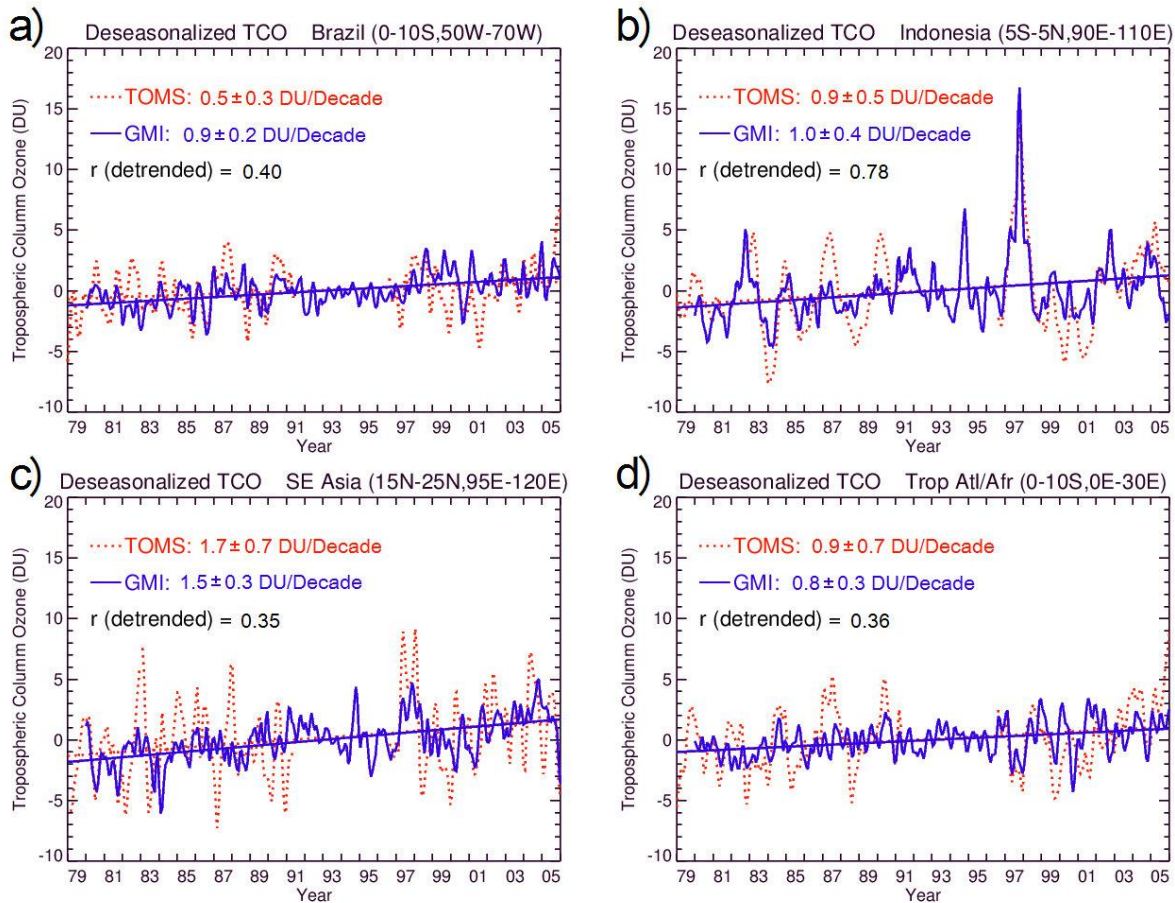

825  
 826

827

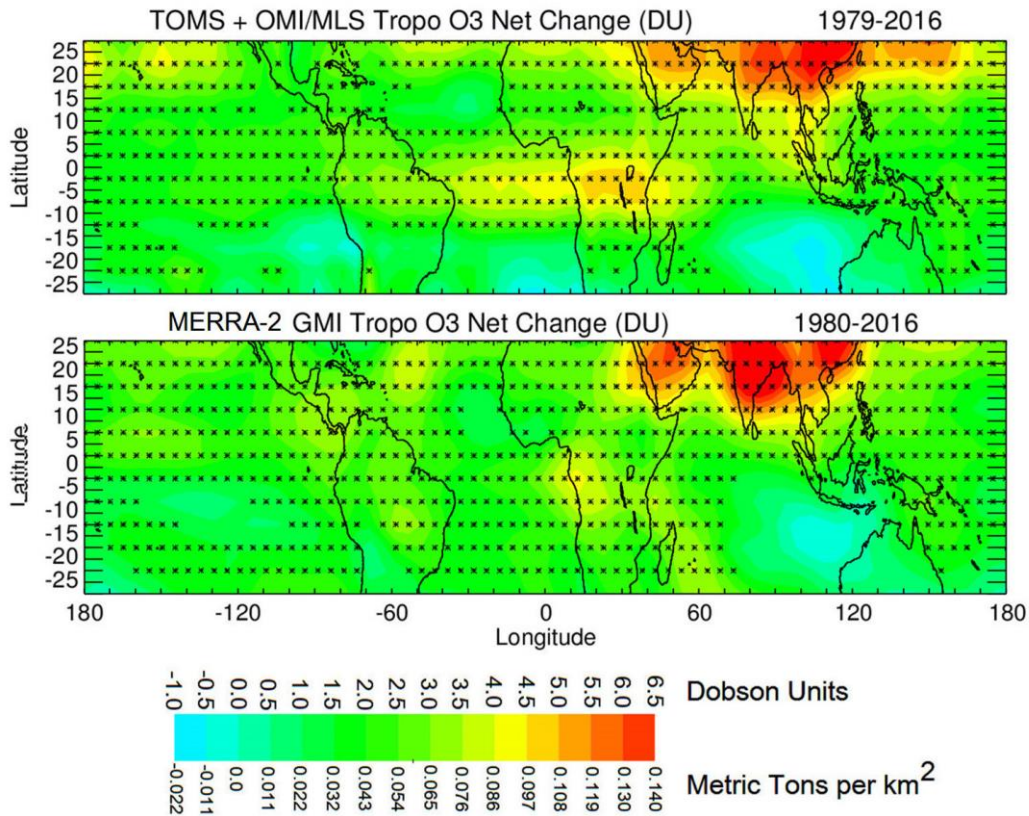

828 **Figure 5.** Trends in MERRA-2 GMI NO emissions (units  $\text{mg}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ ) for 1980-2005. This  
 829 figure is similar to Figure 2, except for having an earlier 1980-2005 time record.

830  
 831

832  
 833 **Figure 6.** (a) Deseasonalized TCO for TOMS (red, dashed curve) and the MERRA-2 GMI  
 834 model (blue, solid curve) for Brazil. Included are their MLR linear trends and calculated  $2\sigma$   
 835 values (both in  $\text{DU}\cdot\text{decade}^{-1}$ ) averaged over the specified region. Shown also is the cross-  
 836 correlation  $r$  between the two time series after removing their linear trends. (b) Same as (a), but  
 837 for Indonesia. (c) Same as (a) but for SE Asia. (d) Same as (a) but for tropical Atlantic/Africa.

838  
 839

840

841

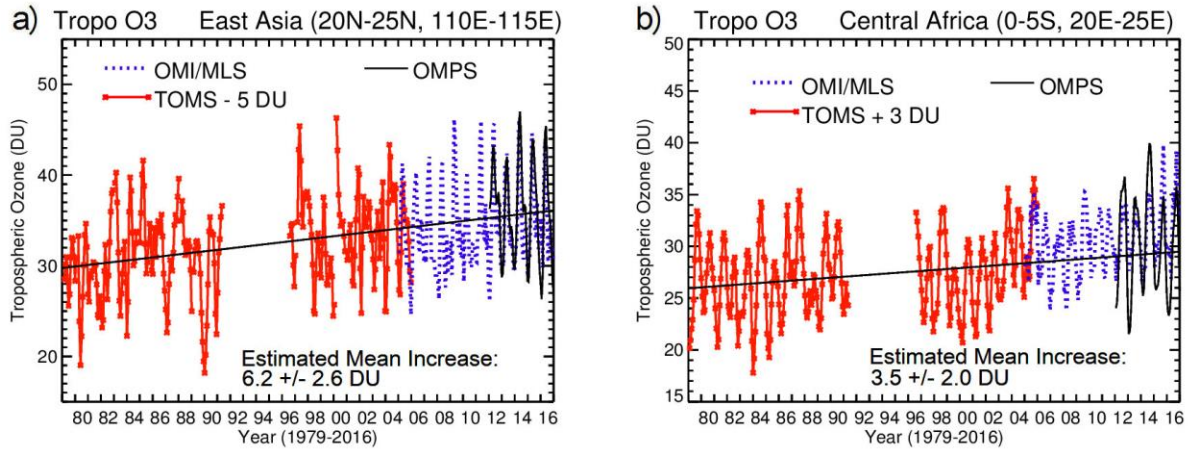

842 **Figure 7.** (top) Net changes in TOMS and OMI/MLS TCO calculated for their combined time  
 843 records (1979-2016). The net changes for TCO are shown in the color bar in both DU and  
 844 metric tons of ozone per km<sup>2</sup> (1 DU  $\equiv$  0.0214 metric tons per km<sup>2</sup> for ozone). Asterisks denote  
 845 grid points where net changes are statistically significant at the  $2\sigma$  noise level. (bottom) Similar  
 846 to (top), but for GMI TCO and years 1980-2016. Net change for GMI TCO is determined  
 847 similar to the satellite measurements by adding together the net changes for the two records (i.e.,  
 848 for GMI, the 1980-2005 and 2005-2016 periods).

853

854 **Figure 8.** (a) Merged time series of TOMS/OMI/MLS/OMPS TCO for 1979-2016 over east  
 855 Asia centered at 22.5° N and 112.5° E (5° × 5° region). The solid red curve is TOMS TCO and  
 856 dashed blue curve is OMI/MLS. OMPS TCO (solid black curve) is also over-plotted with  
 857 OMI/MLS TCO starting 2012 for comparison. A constant adjustment of about -5 DU (using  
 858 year 2005 coincident overlap data) was applied to the TOMS measurements for plotting with  
 859 OMI/MLS. Both OMI/MLS and OMPS TCO also included offsets of +2 DU and -2 DU  
 860 following comparisons with ozonesonde measurements (see Supplementary Material). The  
 861 indicated total increase of 6.2 DU was estimated using a regression best-fit line (black line  
 862 shown) to the TOMS/OMI/MLS merged time series and agrees well with the 6-7 DU net  
 863 increase for this region in Figure 7. (b) Similar to (a) except for central Africa centered at 2.5° S,  
 864 22.5° E and a TOMS offset of +3 DU. The line-fit increase is slightly smaller than the 4-5 DU in  
 865 Figure 7. The estimated mean increases in both panels include calculated 2σ uncertainties.
